Abstract

We report a transport, thermodynamic, and spectroscopic study of the recently identified topological semiconductor ZrTe_5 with a focus on elucidating the connections between its band structure and unusual thermoelectric properties. Using time and angle resolved photoemission spectroscopy (tr-ARPES) we observe a small electronic band gap and temperature dependent Fermi level which traverses from a single valence to conduction band with lowering temperature, consistent with previous reports. This low temperature Fermi surface closely matches that derived from quantum oscillations, suggesting it is reflective of the bulk electronic structure. The Seebeck and low field Nernst response is characterized by an unusually large and non-monotonic temperature evolution. We find this can be quantitatively explained using a semiclassical model based on the observed band character and a linear temperature shifting of the Fermi level. Additionally, we observe a large, non-saturating enhancement of both thermoelectric coefficients in magnetic field. We show this can be captured by the Zeeman energy associated with a large effective g -factor of 25.8 consistent with that derived from Lifshitz-Kosevich analysis of the quantum oscillations. Together these observations provide a comprehensive picture of ZrTe_5 as a model high mobility semiconductor and potential platform for significant magnetic field driven thermoelectricity.

I. INTRODUCTION

The layered material ZrTe_5 has seen a renewed interest in recent years following the prediction that it could harbor topologically non-trivial ground states¹. Originally investigated as a potential charge density wave host^{2,3}, the system shows a large, sign-changing Seebeck response long interpreted as evidence for a change of dominant carrier type⁴. The nature of this crossover has become of heightened interest, as different theoretical models^{1,5} and experiments including Angle-Resolved Photoemission Spectroscopy (ARPES)⁶⁻¹², Scanning Tunneling Spectroscopy (STS)^{8,9,13}, infrared spectroscopy¹⁴⁻¹⁷ and quantum oscillations¹⁸⁻²¹ suggest the system could be a strong topological insulator (TI), weak TI, or Dirac semimetal. At the same time, transport studies have reported a remarkable set of exotic but seemingly disparate phenomena including a chiral magnetic effect²², anomalous Hall effect²³, discrete scale invariance²⁴ three-dimensional quantum Hall effect²⁵, and quantized thermoelectric response²⁶. The understanding of the underlying electronic structure that drive these observations is of significant interest.

It has been pointed out that the electronic structure including the ground state topology are highly sensitive to the lattice constant of ZrTe_5 ^{1,5} which in turn can be affected by the growth method^{24,27}, consistent with experimental results showing the high sensitivity of the system to strain²⁸. This calls for comprehensive studies of ZrTe_5 single crystals to connect observations of transport exotica with the electronic band structure. Here, we report an investigation of single crystals grown by chemical vapor transport (CVT) which are characterized by anomalously large and non-monotonic Seebeck and Nernst effects. We have further performed measurements of electronic transport, magnetic torque, and time and angle resolved photoemission spectroscopy (tr-ARPES) as well as electronic structure calculations. We show that we can quantitatively describe the thermoelectric, quantum oscillation, and spectroscopic results with a model of a small gap ($\Delta_{gap} = 27 \pm 5$ meV) weak TI with a temperature dependent Fermi level (shifting with rate $k_b \cdot \gamma = 0.48 \pm 0.06$ meV/K). This establishes a concrete description of ZrTe_5 grown in this manner that will further enable band engineering for topology and high thermoelectric performance.

II. RESULTS AND DISCUSSION

ZrTe₅ crystallizes in the orthorhombic structure of space group $Cmcm$ (D_{2h}^{17} , No.63), shown in Fig. 1(a,b). The structure is composed of ZrTe₃ prismatic chains oriented along the a -axis with additional Te atoms forming zig-zag between them. A weak inter-chain coupling exists such that two-dimensional layers are formed in the ac plane (denoted by black dashed lines). The coupling between the layers is van der Waals in nature and is much weaker than the inter-chain coupling; the crystal structure is highly anisotropic in all three directions. The crystals presented here were grown by chemical vapor transport²⁷ (CVT) and have a morphology characterized by a long ribbon-like shape with a typical dimension of 3 mm \times 0.05 mm \times 0.5 mm along the a , b , and c -axes.

A. Temperature dependence of Fermi level

We measured the electric and thermoelectric transport response in isothermal and open circuit conditions, respectively. A photo of the thermoelectric measurement setup is shown in Fig. 1(c). As shown in Fig. 1(d), the zero field longitudinal resistivity ρ_{xx} exhibits a hump structure upon cooling peaking near $T_p = 133$ K, as is often reported in CVT grown single crystals^{18,19,21,27,29,30}. Concomitant with this feature, the Seebeck coefficient S_{xx} passes through zero. The sign change of S_{xx} , as well as the low field Hall coefficient³¹ suggest that transport is dominated by hole type carriers for temperature $T > T_p$ and electron type below. For temperatures near T_p the zero field limit of slope of the Nernst effect $dS_{yx}/dB|_{B=0}$ shows a sign reversal. For $T < 80$ K, the system appears to cross over from semiconducting to Fermi liquid behavior suggestive of an electron-like metal. More quantitatively, a linear $S_{xx}(T)$ behavior typical for a normal metal is observed, following the Mott formula $S = \frac{\pi^2}{3} \frac{k_B^2 T}{e} \left(\frac{\partial \ln \sigma}{\partial \epsilon} \right)_{\epsilon_F}$, where ϵ_F is the Fermi level with respect to the band bottom and σ is electron conductivity. A linear fit yields $\frac{dS_{xx}}{dT} = -1.59 \mu\text{V}/\text{K}^2$. In addition, the electrical response is well described by parabolic law³¹ $\rho_{xx} = \rho_0 + A \cdot T^2$, where $A = 0.05 \pm 0.02 \mu\Omega \cdot \text{cm}/\text{K}^2$. Qualitatively, this can be explained by a simple semiconducting band structure and T -dependent Fermi level as sketched Fig. 1(e).

We have performed angle-resolved photoemission spectroscopy (ARPES) on crystals from this same batch. Shown in Fig. 1(f) are energy-momentum cuts across the Γ point taken at

$T = 35$ K and $T = 94$ K, as well as their difference. While the band shape remains largely unchanged, a clear downwards energy shifting at lower T is observed. Such a shift has been observed in a number of recent reports on CVT grown crystals^{11,12}. This is qualitatively consistent with the rigid band shift depicted in Fig. 1(e).

Significant attention has been aimed at understanding the nature of the band gap in ZrTe_5 including if it is gapped or gapless^{11,12}. We show here that the experimental observations above can be quantitatively captured by a gapped scenario depicted in Fig. 1(e). Starting with the assumption of a symmetric semiconducting band structure with a gap Δ_{gap} and Fermi level at ϵ_F , from the Drude model the low field Seebeck and Nernst coefficients are

$$S_{xx} = \frac{k_B}{e} \cdot \frac{pA^h - nA^e}{p+n}, \quad S_{yx} = \frac{k_B}{e} \cdot \frac{-2pn(A^h + A^e)}{p+n} \cdot \omega_c \tau_m \quad (1)$$

where k_B is Boltzmann constant, e is free electron charge, ω_c is the cyclotron frequency, τ_m is the momentum relaxation time, and $\frac{k_B}{e} A^{e(h)} = \frac{k_B}{e} \left(\frac{|\Delta\epsilon|}{k_B T} + 1 \right)$ corresponds to the single carrier type Seebeck coefficient. Given the semiconducting structure, the electron (hole) density n (p) are proportional to $\exp \frac{-|\Delta\epsilon|}{k_B T}$, with $|\Delta\epsilon|$ the energy difference between band top (bottom) and the Fermi level.

Previous ARPES observations suggest that the Fermi level shifting is approximately linear in energy in the intermediate T range of the resistivity anomaly¹¹. We approximate $\epsilon_F - \epsilon_m \approx -\gamma k_B (T - T_m)$, where ϵ_m denotes the mid point of band gap, T_m denotes the temperature when Fermi level is degenerate with the midpoint, and γ is defined as a dimensionless shifting rate. Applying this to the model above, we arrive at expressions for the low field thermoelectric coefficients

$$S_{xx} = \frac{k_B}{e} \cdot \left(\frac{\Delta_{gap}}{2k_B T} + \frac{5}{2} - \beta \right) \cdot \tanh \left(\gamma \frac{T - T_m}{T} \right) - \frac{k_B}{e} \cdot \frac{\gamma(T - T_m)}{T}, \quad (2)$$

$$S_{yx} = \frac{-k_B}{e} \cdot \left(\frac{\Delta_{gap}}{2k_B T} + \frac{5}{2} - \beta \right) \cdot \cosh^{-2} \left(\gamma \frac{T - T_m}{T} \right) \cdot \omega_c \tau_m \quad (3)$$

Whereas a single-band semiconductor with a static Fermi level the thermoelectric coefficients will be monotonic and retain the same sign at different T , the shifting of ϵ_F allows for a dynamic response. The corresponding electrical response³¹ is

$$\rho_{xx} = \frac{m^*}{(p+n)e^2 \tau_m} \propto \frac{m^*}{e^2 \tau_m} \cdot \exp \left(\frac{\Delta_{gap}}{2k_B T} \right) \cdot \cosh^{-1} \left(\gamma \frac{T - T_m}{T} \right) \quad (4)$$

$$\rho_{yx} = \frac{B(p-n)}{e(p+n)^2} \propto \frac{B}{e} \cdot \exp \left(\frac{\Delta_{gap}}{2k_B T} \right) \cdot \tanh \left(\gamma \frac{T - T_m}{T} \right) \cdot \cosh^{-1} \left(\gamma \frac{T - T_m}{T} \right) \quad (5)$$

Similar to the case of the thermoelectric response, the additional degree of freedom associated with shifting ϵ_F makes an important modification to the electrical transport response as a function of T .

We compare the expectations for Eq. (2)-(5) to the experimental results in Fig. 1(d). We directly fit $\rho_{xx}(T)$ and $S_{xx}(T)$ and for the Nernst and Hall response we fit the low field slope $\left. \frac{dS_{yx}}{dB} \right|_{B \rightarrow 0}$ and $\left. \frac{d\rho_{yx}}{dB} \right|_{B \rightarrow 0}$. The fit captures the intermediate and high T response with fit parameters and error bars listed in Table I. The obtained $k_b \cdot \gamma = 0.48 \pm 0.06$ meV/K is consistent with recent ARPES reports¹¹, where the band shifting rate is approximately 0.43 meV/K. The obtained $\Delta_{gap} = 27 \pm 5$ meV is also consistent with our time-resolved ARPES, which we discuss below. The error bar above is defined as the standard deviation among the results in Table I.

TABLE I. Comparison of fitting parameters for the Fermi level shifting rate γ , zero-field energy gap Δ_{gap} , mid-point temperature T_m , and power law of inverse scattering time τ for three samples s0, s1, and s2. Fitting to the zero field resistivity ρ_{xx} , low field slope of the Nernst response dS_{yx}/dB , zero field Seebeck coefficient S_{xx} , and low field Hall slope $d\rho_{yx}/dB$ are shown.

sample	s0	s1	s1	s2	s2
Fitting	$\rho_{xx}(B=0)$	$(dS_{yx}/dB)_{B \rightarrow 0}$	$S_{xx}(B=0)$	$\rho_{xx}(B=0)$	$(d\rho_{yx}/dB)_{B \rightarrow 0}$
Fit regime	110-190 K	100-300 K	80-300 K	110-190 K	100-180 K
$k_b \cdot \gamma$ (meV/K)	0.42 ± 0.01	0.55 ± 0.02	0.53 ± 0.02	0.417 ± 0.004	0.46 ± 0.03
Δ_{gap} (meV)	25 ± 27	-	24 ± 2	33 ± 8	-
T_m (K)	136.6 ± 0.9	130 ± 2	137.0 ± 0.4	142.1 ± 0.2	127 ± 1
β ($\tau \propto T^{-\beta}$)	1.8 ± 1.0	0.2 ± 1.1	1.00 ± 0.08	1.7 ± 0.3	-

For $T < 80$ K, this semiconducting model fails to capture the transport response, as would be expected upon entering the metallic regime. Moreover, as noted above $\rho_{xx}(T)$ and $S_{xx}(T)$ are captured by that expected from a simple metal, suggesting a drop in the magnitude of γ . We hypothesize that this may be due to the increase in the density of states in the conduction band at the Γ point, or that the shifting itself is driven by lattice contraction which would be expected to saturate at low T when the thermal expansion coefficient vanishes³².

B. Fermiology of conduction band

We further verify the above description of CVT grown ZrTe₅ by studying the Fermiology of the low temperature band structure with quantum oscillations and tr-ARPES. For the former we examine the low temperature magnetoresistance $\Delta\rho_{xx}(H, T) \equiv \rho_{xx}(H, T) - \rho_{xx}(H, T = 15 \text{ K})$, *i.e.* using the $T = 15 \text{ K}$ trace as a background. This is shown plotted against $1/H$ in Fig. 2(a) for field applied along the b axis. Clear Shubnikov-de Haas (SdH) oscillations are observed, onsetting near $\mu H_0 \sim 0.25 \text{ T}$, indicating a quantum mobility exceeding $\mu = 1/\mu_0 H_0 \sim 4 \times 10^4 \text{ cm}^2/\text{Vs}$. The oscillation frequency B_f^i is $5.070 \pm 0.005 \text{ T}$ which corresponds to a Fermi surface cross section $A_F^{ac} = 4.84 \pm 0.01 \times 10^{-4} \text{ \AA}^{-2}$.

We have measured the detailed angular dependence of the SdH effect as well as de Haas-van Alphen oscillations in magnetic torque³¹; the variation of oscillation frequency B_f^i as the field rotates away from b axis are plotted in Fig. 2(e), where red squares (blue triangles) denotes rotating in ab (bc plane) and θ (ζ) denotes the angle between b axis and field direction. The angular variation is consistent with an ellipsoidal (3D) rather than cylindrical (quasi-2D) Fermi surface (dashed lines). This is also emphasized by the corresponding Landau fan diagrams (Fig. 2(e) inset) in which a saturating slope for $H\parallel b$ is observed. Assuming an ellipsoid Fermi surface, the corresponding Fermi wave vectors are $k_F^a = 9.46 \times 10^{-3} \text{ \AA}^{-1}$, $k_F^c = 1.63 \times 10^{-2} \text{ \AA}^{-1}$ and $k_F^b = 9.32 \times 10^{-2} \text{ \AA}^{-1}$ (depicted in Fig. 2(d)). This ellipsoid Fermi pocket corresponds to a carrier density of $n = \frac{2}{(2\pi)^3} V_{FS} = 4.85 \times 10^{17} \text{ cm}^{-3}$, in good agreement with that obtained from the Hall coefficient $n = 4.71 \times 10^{17} \text{ cm}^{-3}$ ³¹. Together, these provide a consistent picture of the low T Fermi surface being composed of a single electron pocket.

We can provide a further quantitative comparison with analysis of cyclotron effective mass m^* , carrier lifetime τ , and effective g factor from the Lifshitz-Kosevich formula³³:

$$\Delta\rho_{xx} \propto R_T R_D R_S \cdot \cos\left(2\pi\left(\frac{B_f^i}{B} + \phi\right)\right) \quad (6)$$

The oscillation amplitude is modulated by three factors: the thermal factor $R_T = \frac{\alpha T}{B} / \sinh(\frac{\alpha T}{B})$ due to thermal broadening, the Dingle factor $R_D = \exp\left(\frac{-\alpha T_D}{B}\right)$ due to scattering, and the spin factor $R_S = \cos\left(\frac{\pi g m^*}{2m_e}\right)$ due to Zeeman splitting, where $\alpha = \frac{2\pi^2 k_B m^*}{eh}$. The oscillation amplitude $\Delta\rho_{xx}(T)$ at fixed field ($H\parallel b$) is plotted in Fig. 2(b), with a fit to R_T yielding an average ac -plane $m_{ac}^* = 0.028m_e$ (the result of each field is shown inset) and Fermi

velocity $v_F^{ac} = \hbar \langle k_F^{ac} \rangle / m_{ac}^* = 4.1 \times 10^5$ m/s. As shown in Fig. 2(c), an average Dingle temperature $T_D = 1.65$ K is found from a linear fit to $\ln(\Delta\rho_{xx}/R_T)/\alpha \propto \ln(R_D)/\alpha = \frac{-T_D}{B}$. From $T_D = \frac{\hbar}{2\pi k_B \tau}$ this corresponds to a lifetime $\tau = 0.75$ ps, comparable to $\tau_m = 1.17$ ps calculated from the Hall mobility and m_{ac}^* .

We note that the analysis of above is restricted to $\mu_0 H < 1.3$ T, as in larger field a pronounced Zeeman splitting becomes evident, as shown in Fig. 2(a) and its inset. The modulation effect due R_S can be rewritten as

$$R_S \cos\left(2\pi\left(\frac{B_f}{B} + \phi\right)\right) = \frac{1}{2} \sum_{\uparrow, \downarrow} \cos\left(2\pi\left(\frac{B_f^{\uparrow(\downarrow)}}{B} + \phi \pm \frac{gm^*}{4m_e}\right)\right) \quad (7)$$

where the summation is over two spins (+(-) for spin up \uparrow (down \downarrow)). Therefore, the spin split Landau level indices correspond to the lines with $n_{\uparrow(\downarrow)} = \frac{B_f^{\uparrow(\downarrow)}}{B} + \phi \pm \frac{gm^*}{4m_e}$, as shown in the inset of Fig. 2(a) for $H \parallel b$. Linear fitting gives $B_f^\uparrow = 4.85 \pm 0.04$ T (intercept = 0.29 ± 0.02) and $B_f^\downarrow = 5.31 \pm 0.07$ T (intercept = -0.16 ± 0.04), corresponding to $g \approx 25.8$.

Turning to spectroscopy of the conduction band, results of tr-ARPES performed at $T = 35$ K are shown in Fig. 3(a,b). Here, the conduction band at ϵ_F and the band gap Δ_{gap} are clearly resolved. The horizontal red bar and dashed red lines in Fig. 3(a) indicate the magnitude of Fermi wave vector k_F^a and Fermi velocity v_F^{ac} obtained from quantum oscillations, which are in approximate agreement. Δ_{gap} derived from the transport data in Fig. 1(d) is also drawn in Fig. 3(a). In Fig. 3(b) the Fermi surface cross section is again compared with an in-plane spectrum, showing good agreement at ϵ_F .

Using the Brillion zone defined in Fig. 3(c), in Fig. 3(d) we show the band structure at Γ point of the three possible phases for ZrTe₅, namely strong TI (left panel), Dirac semimetal (middle), and weak TI (right), calculated by density functional theory (DFT). The electronic topology of ZrTe₅ is known to be extremely sensitive to the values of its lattice constants⁵; here, the three panels in Fig. 3(d) are obtained in series thru expanding unit cell volume by $8 \times 10^{-7}\%$, from left to right (the direct gap for the strong TI and weak TI phase nominally agree with experimental observations). In each, the Fermi level is shown for which the Fermi surface volume matches that of the quantum oscillation analysis (dashed line). The corresponding Fermi pockets are plotted in the insets. The band inversion of the strong TI leads to a weaker dispersion; comparing the flatness of these ellipsoids, the strong TI case is closer to that from quantum oscillation results depicted in Fig.2(d). However, surface states were not seen in the tr-ARPES measurements (nor *e.g.* previous static ARPES reports

with high energy resolution^{11,12}). One possible scenario for this within a strong TI system is leakage of surface state into the bulk due to small band gap. The expected inelastic mean free path of excited electrons here is 2-7 nm compared to the penetration depth of surface states estimated to be 45 nm from $\Delta_{gap} = \frac{(\hbar k)^2}{2m^*}$. Additional experiments to probe the potential surface states are of significant interest.

C. Field Enhancement of S_{xx} and S_{yx}

At $100 \text{ K} < T < 150 \text{ K}$ where the thermoelectric response changes most rapidly, we observe a strong enhancement of both S_{xx} and S_{yx} with increasing $H \parallel b$. As shown in Fig. 4(a,b), peak magnitude of $S_{xx}(T)$ is enhanced more than 3 fold at 14 T, reaching $500 \mu\text{V/K}$, while that of S_{yx} approaches $700 \mu\text{V/K}$. The maximum values at fixed H for both quantities appear to be monotonically increasing with H without saturation at our largest applied fields (see Fig. 4(d)). The Seebeck coefficient of a simple metal is not typically strongly enhanced in field; this suggests a significant modification to the electronic band structure. Given the acute sensitivity of ϵ_F to T , one natural origin for this response would be a magnetic field dependence to ϵ_F . To connect these, we plot the H dependence of the T at which the thermoelectric coefficients peaked and the zero crossing for $S_{xx}(T)$ occur. They show similar behavior with features shifting towards higher temperature for stronger magnetic fields, consistent with a spin down valence band being raised by the Zeeman energy at high temperature. Upon cooling, this would lead to the Fermi level traversing the gap at higher T , which can be tracked by a vanishing $S_{xx}(T)$ and maximal $S_{yx}(T)$. From zero field to $H = 14 \text{ T}$, the observed shift is approximately 40 K, which corresponds to a Fermi level shift of $\approx 20 \text{ meV}$ given the fitted shift rate γ from Table I. This is comparable to the size of the Zeeman splitting $\approx 20 \text{ meV}$ given the large g factor. We note also this is approaching the size of the zero-field energy gap, suggesting a potentially complex evolution at high field. Thus despite their unusually large magnitude, these effects are consistent with the band structure described above. It is of significant interest to pursue these and related materials to higher magnetic fields to test recent predictions for extremely large field-induced figure of merit ZT in systems with highly dispersive bands³⁴.

III. CONCLUSION

We have synthesized single crystals of ZrTe_5 by chemical vapor transport and probed the band properties via electric and thermoelectric transport, magnetic torque, and tr-ARPES. Both transport and photoemission results indicate a temperature dependent Fermi level shifting across a small semiconducting gap. A semiclassical calculation of the transport coefficients based on such a model describes the observations, yielding $k_b \cdot \gamma = 0.48 \pm 0.06$ meV/K and $\Delta_{gap} = 27 \pm 5$ meV. For T below this range, the system behaves as a simple metal. Quantum oscillations and ARPES reveal a consistent picture of an a light-mass ($0.028m_e$), small ellipsoidal electron pocket with large $v_F \approx 4 \times 10^5$ m/s. The lack of surface states in ARPES is consistent with weak TI regime, supported by our first principles calculations. Finally, a significant enhancement of both the Seebeck and Nernst effect with magnetic field indicates that the band structure is strongly affected in H , consistent with the relatively large $g = 25.8$. Together this study demonstrates that comprehensive experiments and analysis of single crystals of ZrTe_5 grown in the same manner can produce a clear picture of the underlying physical mechanisms for unusual transport effects. Extending these studies to the recent exotica reported²²⁻²⁶ in ZrTe_5 grown by other methods may elucidate the origin of the rich electronic physics in this system.

IV. METHODS

A. Crystal Growth

Polycrystalline ZrTe_5 was obtained by sintering high purity zirconium (99.9999%) and tellurium (99.9999%) at 500 °C . Single crystals were grown by a CVT method with the prepared polycrystalline powder and I_2 as the transport agent. The temperature of source zone and growth zone are 520 °C and 475 °C, respectively. The obtained crystal were confirmed as structurally single phase by powder X-ray diffraction.

B. Measurement

Electrical and thermoelectric transport measurements were performed in commercial cryostats equipped with superconducting magnets. Electrical transport is measured with

a standard Hall bar configuration of six gold wire contacts. Thermoelectric transport is measured with a static temperature gradient along the a axis driven a heater directly attached to one end of the crystal. Temperature gradient is detected by a pair of thermocouple and electrical voltage drops are detected by two pairs of electrical contacts along a and c axis which gives Seebeck and Nernst signal respectively. Torque measurements are done with a home-made cantilever magnetometer.

Photoemission measurement was done at 6 eV photon energy. The sample was cleaved *in situ* under a pressure of 1×10^{-10} torr and a temperature of 35 K. In time-resolved measurements the system was optically pumped with 1.6 eV laser pulses before subsequent probe pulses.

C. Density Functional Theory Calculations

We performed the density functional theory (DFT) calculations implemented in Vienna Ab initio Simulation Package (VASP) code^{35,36}, with the Projector augmented wave method (PAW)³⁷ for the pseudo potential formalism. The ground state for the ZrTe_5 primitive unit cell is converged with exchange-correlation energies parametrized by Perdew, Burke and Ernzerhof (PBE)³⁸, a 300 eV cutoff energy for the plane-wave-basis set, and a $15 \times 15 \times 7$ Monkhorst-Pack grid sampling³⁹ in the reciprocal space. The Z_2 topological invariants are computed using the Fu-Kane parity formula with inversion symmetry⁴⁰.

VI. ACKNOWLEDGEMENTS

This work was supported primarily by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0020149 (electrical measurements, tr-ARPES, and analysis) and also by the Gordon and Betty Moore Foundation's EPiQS Initiative, Grant GBMF9070 to J.G.C. (materials synthesis and DFT calculations).

VII. AUTHOR CONTRIBUTIONS

J. Z. and T. S. synthesized the single crystals. J. Z. performed the transport and torque measurements and analyzed the subsequent data. C. L. and F. M. performed the tr-ARPES measurements and analyzed the subsequent data. S. F. performed the density functional theory calculations. J. Z. wrote the manuscript with input from all authors. N. G. and J. G. C. coordinated the project.

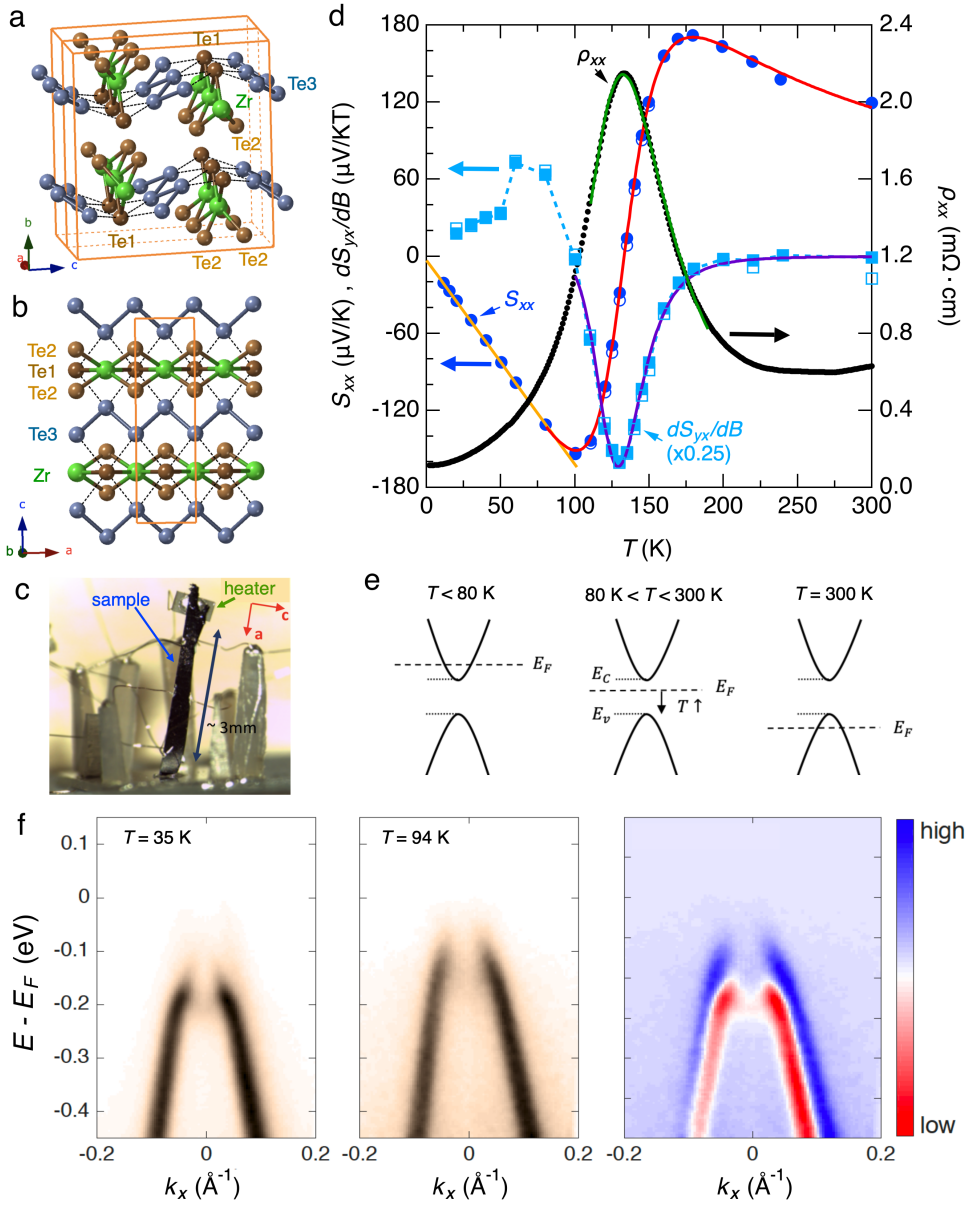

FIG. 1. (a,b) Crystal structure of layered compound ZrTe_5 . (c) Photo of thermoelectric measurement setup. (d) Resistivity and thermoelectric response for the zero magnetic field limit. The solid and open blue circles (cyan squares) of S_{xx} (S_{yx}) refer to data with heater power 0.25 mW and 0.5 mW. Solid lines in (d) are fittings according to the Fermi level shifting model sketched in (e) (see text). (f) ARPES Energy-momentum cuts across the Γ point taken at temperatures of 35 K (left) and 94 K (middle); darker color denotes higher intensity. The intensity difference (high temperature minus low temperature) is shown in the rightmost panel.

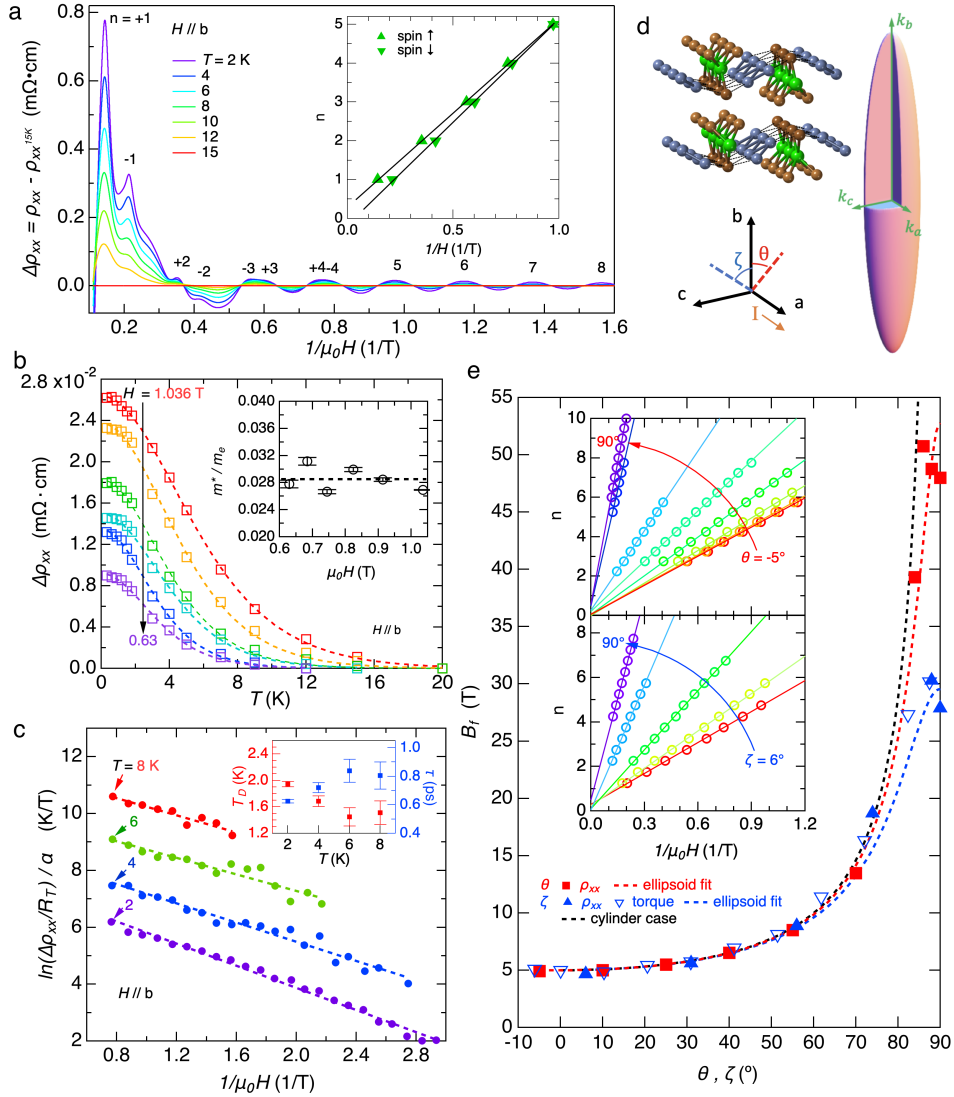

FIG. 2. (a) Oscillatory magnetoresistance $\Delta\rho_{xx} \equiv \rho_{xx}(H, T) - \rho_{xx}(H, T = 15 \text{ K})$. The inset shows the spin-split Landau fan diagram. (b) Oscillation amplitude $\Delta\rho_{xx}(T)$ at fixed field with $H||b$. Dashed lines are fittings according to thermal damping (see text) and the fitted effective mass is plotted in the inset. (c) Dingle analysis fits, where $\alpha = \frac{2\pi^2 k_B m^*}{he}$. The fitted Dingle temperature T_D and carrier lifetime τ are plotted in the inset. (d) Illustration of measurement configuration for quantum oscillations and relation to crystal structure along with a schematic depiction of the observed ellipsoidal Fermi surface. (e) Quantum oscillation frequency as a function of field angle. Red squares (blue triangles) refer to rotating from b to a (c) axis. Both transport (solid) and torque (open) results are plotted. Dashed lines are fits to either ellipsoid or cylinder Fermi surface. Landau fan diagrams are shown in the insets.

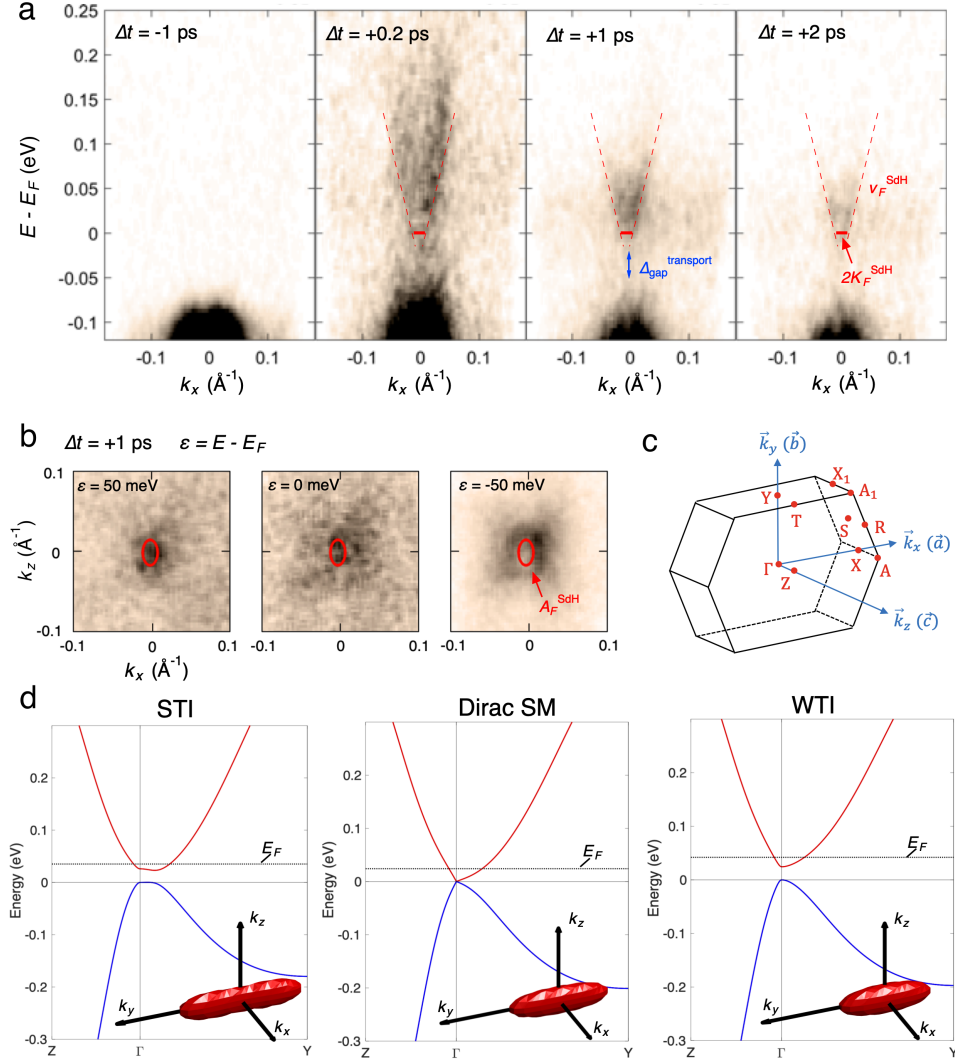

FIG. 3. (a) tr-ARPES energy-momentum cuts across the Γ point at different time delays, probed at $T = 35$ K. k_x is along the a -axis and $k_x = 0$ corresponds to the Γ point. At the Fermi level, the solid red bar and dashed line refer to k_F^a and v_F^c determined from quantum oscillations, respectively. The gap size Δ_{gap} is determined from the transport data analysis is also drawn. (b) Energy contours obtained 1 ps after photoexcitation, at energy $\epsilon = E - E_F = 50, 0, -50$ meV, where k_x is along the a axis and k_z is along the c axis. The integration window is 50 meV. The red ellipse represents the Fermi surface size obtained from quantum oscillations. (c) Brillouin zone and (d) band structure calculated by density functional theory. The left, middle and right panels correspond to strong topological insulator (TI), Dirac semimetal (SM) and weak TI phases, respectively. For each scenario, the low temperature Fermi level is denoted by the dashed line, determined by the Fermi surface volume from quantum oscillations. The corresponding Fermi pocket is depicted in the inset.

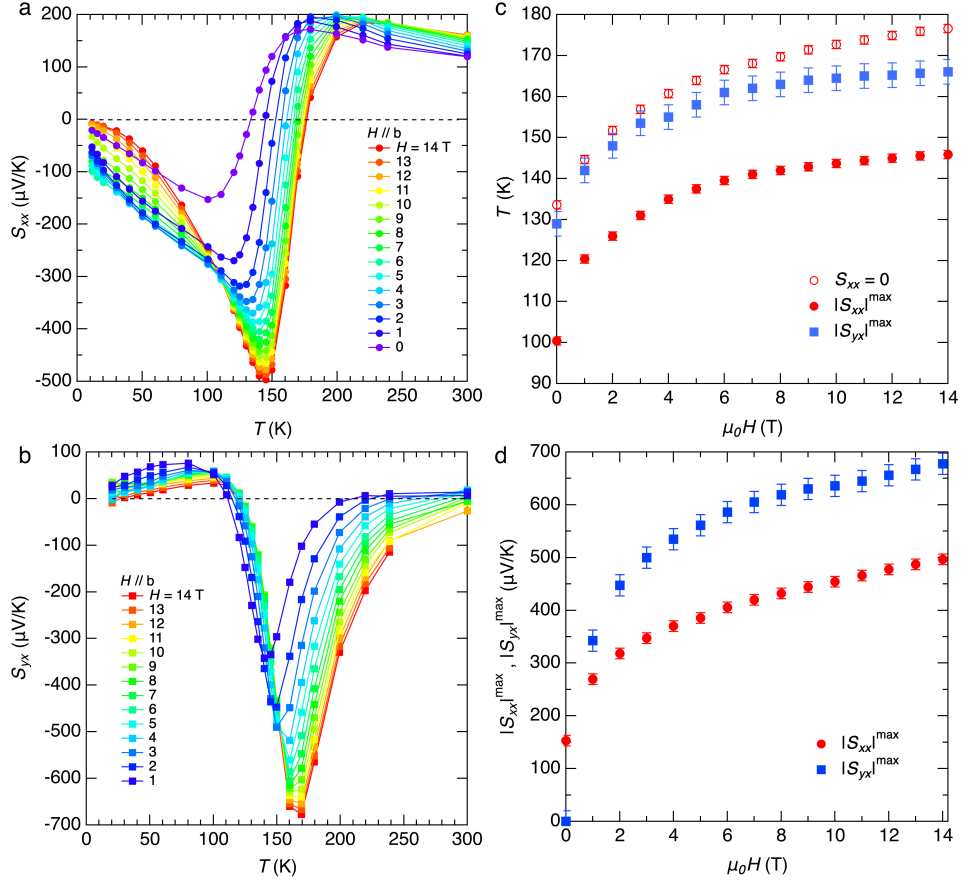

FIG. 4. (a) Thermopower S_{xx} and (b) Nernst coefficient S_{yx} as a function of temperature in different magnetic field H . (c) Shifting of the S_{xx} and S_{yx} peak temperature with H as well as the H -dependence of the zero-crossing of $S_{xx}(T)$. (d) The maximum value of S_{xx} and S_{yx} as a function of magnetic field. The error bars in (c) and (d) reflect the discreteness of the field-dependent data set.
