ABSTRACT

Analyzing and predicting brain aging is essential for early prognosis and accurate diagnosis of cognitive diseases. The technique of neuroimaging, such as Magnetic Resonance Imaging (MRI), provides a noninvasive means of observing the aging process within the brain. With longitudinal image data collection, data-intensive Artificial Intelligence (AI) algorithms have been used to examine brain aging. However, existing state-of-the-art algorithms tend to be restricted to group-level predictions and suffer from unreal predictions. This paper proposes a methodology for generating longitudinal MRI scans that capture subject-specific neurodegeneration and retain anatomical plausibility in aging. The proposed methodology is developed within the framework of diffeomorphic registration and relies on three key novel technological advances to generate subject-level anatomically plausible predictions: i) a computationally efficient and individualized generative framework based on registration; ii) an aging generative module based on biological linear aging progression; iii) a quality control module to fit registration for generation task. Our methodology was evaluated on 2662 T1-weighted (T1-w) MRI scans from 796 participants from three different cohorts. First, we applied 6 commonly used criteria to demonstrate the aging simulation ability of the proposed methodology; Secondly, we evaluated the quality of the synthetic images using quantitative measurements and qualitative assessment by a neuroradiologist. Overall, the experimental results show that the proposed method can produce anatomically plausible predictions that can be used to enhance longitudinal datasets, in turn enabling data-hungry AI-driven healthcare tools.

1 Introduction

Brain aging is usually associated with cognitive decline and an increased risk of neurological disorders [Popescu et al., 2021]. For example, several cognitive disorders are associated with aging, such as Alzheimer’s disease (AD) and stroke [Ma et al., 2022]. Research on brain aging can reveal the underlying spatio-temporal structure of brain changes due to aging [Giorgio et al., 2010, Peters, 2006], which is important for the early prognosis and the accurate diagnosis of diseases such as AD [Alberdi et al., 2016, Mueller et al., 2005]. In the last decades, the collection of longitudinal brain images has facilitated research on brain aging by enabling a noninvasive way to track brain changes and observe disease progression over time [Resnick et al., 2003]. For example, one of the most-known data-sharing initiatives, the Alzheimer’s Disease Neuroimaging Initiative (ADNI) [Mueller et al., 2005] has collected images using different modalities of subjects at different stages of Alzheimer’s Disease. Compared with other modalities, Magnetic Resonance Imaging (MRI) has superior soft-tissue contrast. This has fostered the use of MRI-based biomarkers for tracking aging or disease-related neurodegenerative changes [Njeh, 2008, Devic, 2012, Schmidt and Payne, 2015, MacDonald and Pike, 2021].

Recent studies have demonstrated the potential of using Machine Learning (ML) techniques to study brain aging [Choi et al., 2018, Anatürk et al., 2021, Ouyang et al., 2021, Popescu et al., 2021, Cole et al., 2015]. However, it has rarely been straightforward to follow or analyze the age and disease progressions via those learning-based methods. On the one hand, ML-based methods, especially Deep Learning (DL)-based methods, are designed to distill knowledge from data. Therefore, the availability of ground truth data is crucial to feed the data-hungry DL models. Nevertheless, the sensitive nature of medical data makes it usually difficult to access. Moreover, brain aging research needs longitudinal data, which is even less available or unstable due to, for example, scans taken at different intervals of time or scanners. On the other hand, the high dimensionality of the brain images exponentially increases the resource demands of training DL models [Wegmayr et al., 2019]. For this reason, many studies have limited their scope to generating 2-Dimensional (2D) slices extracted from the 3-Dimensional (3D) MRI scan, e.g., Bowles et al. [2018], Kim et al. [2021], Pathan and Hong [2018]. Although the 3D MRI scan can be reconstructed by concatenating 2D slices, it is difficult to assess its internal consistency, with a risk of losing its anatomical plausibility. For all these reasons, it is becoming increasingly necessary to develop **Medical Image Generation (MIG)** models, which aim at generating trusted and accurate synthetic high-dimensional medical images according to the applications.

In this study, we propose a 3D MIG model based on diffeomorphic registration, aiming at synthesizing MRI scans with increasing age, in which subject-level predictions can be derived from individualized image pairs. With our model, the aging progression of the brain can be simulated rapidly with high-dimensional MRI scans. For example, it could synthesize brain atrophy progression from age 60 to age 80 as represented by MRI scans for a particular subject. The main contributions of the proposed method can be summarized as follows: i) we develop a new MIG pipeline that can synthesize subject-specific and anatomically plausible MRI series in a computationally efficient manner; ii) we introduce an aging generative module (AGM) that does not require a training phase and can be applied to any framework that is based on diffeomorphic registration; iii) we introduce the Quality Control Module (QCM) working in conjunction with AGM, which is used to assess the quality of the synthetic images according to the input pair; iv) we augment the existing longitudinal MRI scans with corresponding segmentations by around three times and make them public, enabling the development of data-hungry AI-driven healthcare tools, for instance, developing registration and segmentation algorithms for high-resolution predictions, which always require more data to achieve.

2 Related work

The aging population has increased concern for age-related neurodegenerative diseases and so, aging cohorts and studies have attracted growing interest. MRI scans can clearly illustrate the anatomical structure inside the brain and thus have been used in research on aging. To analyze aging or chronic disease progressions of the brain, AI-based MIG models have been introduced to synthesize scans at different stages of diseases or at different ages.

A commonly used architecture in MIG models is Generative Adversarial Networks (GANs) [Creswell et al., 2018]. GANs are designed to generate new data from the same distribution, which consists of two parts: a discriminator to distinguish fake and real samples and a generator to learn new plausible samples to deceive the discriminator. Several GAN-based methods have been introduced to model the aging progression, e.g., Wegmayr et al. [2019], Bowles et al. [2018], Kim et al. [2021]. Training GANs with 3D brain images is challenging mainly due to the high dimensionality of the brain images. As a result, most of the previous studies have simplified the problem by either using only a single slice per subject [Wegmayr et al., 2019] or by downsampling the original images, which might result in poor resolution predictions [Ravi et al., 2022]. To alleviate these limitations, [Jung et al., 2021] proposed a method to synthesize high-quality 3D medical images by introducing a 3D discriminator in a normal 2D GAN architecture. A depth-wise concatenation module was introduced to concatenate separate 2D slices into a whole 3D image. Apart from the technical

challenges, the main issue of GAN-based methods is that they are unable to guarantee the anatomical plausibility of the generated images due to the lack of biologically informed constraint in the generation. This issue becomes relevant if the synthetic images are expected to be used for answering clinical questions.

Apart from the aforementioned issues when using GAN as the architecture, another critical factor for analyzing aging is individualization. Personalized healthcare and individualized medicine are important since each patient has different physical conditions that may cause the same disease. With regard to the aging-related processes, it is even more complicated since aging-related brain changes can be influenced or driven by several factors, such as Alzheimer’s disease (AD) [Song et al., 2020], traumatic brain injury (TBI) [Cole et al., 2015], even different regions of the brain might follow a different aging pattern [Popescu et al., 2021]. Image regression is therefore introduced as a means to encode personalized information in GANs.

Image regression was introduced with the aim of estimating images as a function of associated variables such as age [Niethammer et al., 2011, Beg et al., 2005]. The complexity of analyzing age or disease progressions was alleviated by modeling regression approaches at the population level Dukart et al. [2013], Huizinga et al. [2018]. For example, those group-level methods aim at simulating spatio-temporal changes during aging across all subjects. Even though these methods capture the time-varying changes of a population well, the way to leverage and extrapolate this to the target subject is still under development [Campbell and Fletcher, 2017]. The work of Pathan and Hong [2018] has addressed this extrapolation problem by incorporating the regression model based on the framework of Large Deformation Diffeomorphic Metric Mapping (LDDMM) [Pathan and Hong, 2018] with convolutional neural networks (CNN) and recurrent neural networks (RNN). Their model, however, generated a sequence of vector moments under the LDDMM framework before model training, so performance and the model were highly dependent on the LDDMM output.

The fundamental tool for performing image regression is diffeomorphic image registration, which aims at estimating spatial correspondences between images [Zitova and Flusser, 2003]. Traditional methods for diffeomorphic image registration are very time-consuming, which has limited the application of image regression in different contexts. Recently, many deep-learning-based diffeomorphic registration methods have emerged [Fu et al., 2020, Dalca et al., 2019a, Hoffmann et al., 2022, Balakrishnan et al., 2019, Chen et al., 2021, Li et al., 2022] with the aim of reducing the computational burden. These methods have shown a comparable registration accuracy to that of the traditional methods, especially for brain images.

Inspired by the aforementioned methods for simulating brain aging on longitudinal data, we found it necessary to develop a computational effective and anatomically plausible MIG model for 3D scans. Most of the GAN-based methods use one input image to generate synthetic images. Instead, we use two scans at different time points. Aging is a complex process that is influenced by many factors, such as lifestyle factors, cognitive diseases, education, etc. Using a pair of inputs from the same subject can provide a more accurate picture of the individual aging. With this feature, we can obtain images of a higher quality which can be used to augment the available longitudinal datasets.

3 Method

Figure 1 shows the framework of the proposed aging generative method. As shown, we assume that the input is an image pair of the same subject acquired at different time points, the objective of aging generation is to synthesize images of aging overtime for that subject. The framework consists of three main parts as shown in Fig.1: 1) the skeleton of diffeomorphic registration; 2) the proposed Aging Generative Module (AGM) aiming at simulating linear aging MRI scans; and 3) the proposed Quality Control Module (QCM), which provides the subject-specific hyperparameter s for AGM and that is fulfilled by imposing an accurate-preserve constraint on the synthetic MRI scans.

3.1 Diffeomorphic Registration

Image registration is a fundamental step for analyzing medical images either in clinics or for downstream tasks such as segmentation, regression, or classification. In its simplest form, image registration involves estimating a smooth, continuous mapping between the points in one image and those in another. Specifically, given a moving image I_m and a fixed image I_f , the goal of image registration is to find a deformation field ϕ to map I_m into I_f . Preserving the topology is crucial when registering biological image pairs in order to avoid the folding of tissues. Diffeomorphic registration has the advantage that it computes deformation fields that are both differentiable and invertible, which means that it can preserve the topology.

Traditional diffeomorphic registration methods are computationally intensive. Benefiting from the vigorous development of machine learning (ML), many ML-based registration methods have been proposed to shorten the registration time in the testing phase from tens of minutes to hours for the traditional methods, to a few minutes or even seconds for the

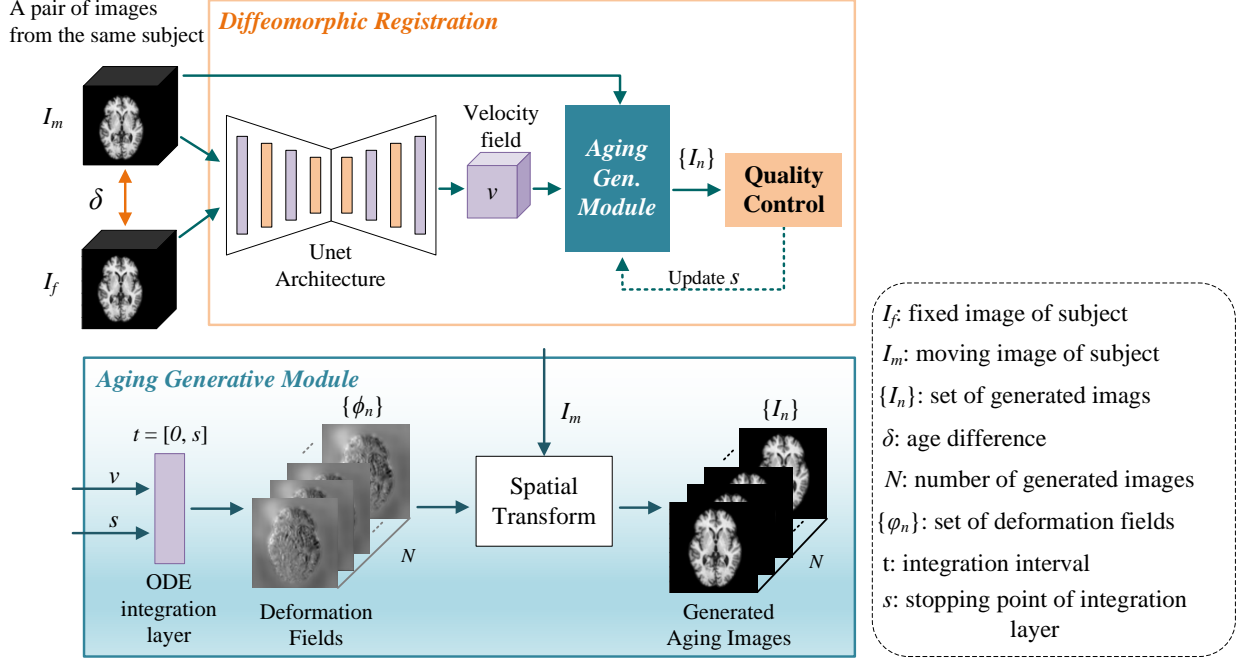

Figure 1: Architecture of the proposed Medical Image Generation (MIG) model. The input is an individualized image pair, where I_m stands for *moving* image, I_f *fixed* image. The proposed two modules take *velocity field* as input. *Aging Generative Module (AGM)* and *Quality Control Module (QCM)* are introduced within the skeleton of diffeomorphic registration. The details of AGM are shown in the bottom blue shadow part. The *deformation fields* can be derived from *velocity field* given the subject-specific stopping point s and corresponding number of generated MRI scans N . At the end, aging MRI sequences can be derived through Spatial Transform. The *Quality Control Module (QCM)* can provide the subject-specific s by applying quality measurements between generated and fixed MRI scans.

ML-based ones [Fu et al., 2020]. Several ML-based diffeomorphic registration methods have been proposed [Krebs et al., 2018, 2019, Dalca et al., 2019b, Hoffmann et al., 2022, Dalca et al., 2019a, Li et al., 2022]. We chose SynthMorph [Hoffmann et al., 2022] in this study because of its good performance for brain registration. The architecture of SynthMorph is summarized in the upper part of Fig.1. One of the issues of using ML for diffeomorphic registration is that it is difficult to make sure that the learned deformation fields are diffeomorphic. To solve this issue, SynthMorph divides the problem into two steps. First, a U Net-like neural network [Ronneberger et al., 2015] is trained to learn a stationary velocity field representation, v , following a similar approach to the Diffeomorphic Anatomical Registration using Exponentiated Lie algebra (DARTEL) method [Ashburner, 2007], in which a single velocity field is involved which remains constant over unit time. In a second step, this vector field is used for estimating the actual diffeomorphic deformation field by solving the ordinary differential equation (ODE):

$$\frac{d\phi^{(t)}}{dt} = v(\phi^{(t)}) \quad (1)$$

where $\phi^{(0)}$ is initialized with an identity transform. The final deformation field $\phi^{(1)}$ is obtained by integrating over unit time as follows:

$$\phi = \phi^{(1)} = \int_0^1 v(\phi^{(t)}) dt. \quad (2)$$

From group theory, the velocity field v can be seen as a member of the Lie algebra, which is exponentiated in order to produce a deformation $\phi^{(1)}$. The resulting deformation is a member of a Lie group: $\phi^{(1)} = \text{Exp}(v)$.

Eq. (2) can be solved with the Euler method, which involves calculating a new solution after a series of successive small steps h .

$$\phi^{(t+h)} = (\mathbf{p} + hv) \circ \phi^{(t)} \quad (3)$$

where \circ denotes the composition operation and \mathbf{p} is a map of spatial locations. As an example, a relatively accurate solution can be obtained by using eight time-steps as follows:

$$\phi^{(1/8)} = \mathbf{p} + \mathbf{v}(\mathbf{p})/8 \quad (4)$$

$$\phi^{(2/8)} = \phi^{(1/8)} \circ \phi^{(1/8)} \quad (5)$$

$$\phi^{(3/8)} = \phi^{(1/8)} \circ \phi^{(2/8)} \quad (6)$$

$$\dots \quad \dots \quad (7)$$

$$\phi^{(1)} = \phi^{(1/8)} \circ \phi^{(7/8)} \quad (8)$$

If the number of time steps is a power of 2, then it is called *scaling and squaring* [Ashburner, 2007, Arsigny et al., 2006]. The main advantage of this implementation is its relatively low computational cost due to the simplifying of internal points.

Motivated by this, we consider extracting the output deformation fields in the middle of the integration and applying them to the spatial transform block. The evolution between two ages associated with two input images can be simulated.

3.2 Aging Generative Module

Our approach for synthesizing images between the fixed and moving ones is to generate different deformation fields at different time steps between the paired input. In addition, the stopping point (i.e., s) of integration is set as the hyper-parameter to enable the input-specific focus. The main problem of the *scaling and squaring* approach for our purpose is that the deformation field is computed at irregular time steps (i.e. power of 2) in the integration range. Moreover, it is difficult to obtain fine-grained extrapolation points beyond the original stopping point when $t = 1$. Since our goal is to generate samples at more regular steps, it is beneficial to use a more standard ODE solver that allows us to generate deformation fields at any time t . In particular, we used the TensorFlow implementation of the ODE solver by [Petzold, 1983] to obtain linear intermediate outputs. This method is just slightly more computationally expensive than the *scaling and squaring* approach, so it is appropriate for our current goal.

The bottom part of Fig.1 shows the aging generative module (AGM) of the proposed method. First, given the velocity field \mathbf{v} estimated with the neural network, we generate N deformation fields at different regular time points in the range $[0, s]$, with s being a parameter. In a second step, we use the spatial transform block introduced by de Vos et al. [2017] to generate the images at different time points by warping the moving image I_m with the estimated deformation fields. Parameter s is referred to as the initial *stopping point*. This parameter is automatically adjusted later by the quality control module as described in the next subsection.

3.3 Quality Control Module

As already mentioned, in theory $\phi^{(1)}$ should be used to map I_m into I_f . In practice, this might not happen when using ML-based methods. While the neural networks learn the most likely vector field \mathbf{v} for the input images, some inaccuracies are expected due to the fact that the testing I_m and I_f are, in general, not used during training. In other words, deformation fields at time points different than one can yield a better matching for registering the two images. As it will be discussed, it is important for the method to accurately estimate this stopping point since the age estimation of the synthetic images is adjusted with respect to that point.

In order to tackle this issue, we introduce the quality control module (QCM) whose aim is to adjust the initial stopping point s of the integration layer of the AGM. Our approach is to assess which integration time point yields the most similar generated image compared to I_f . Based on previous studies and medical image generation literature (e.g., Lei et al. [2019], Emami et al. [2018], Gu et al. [2019]), we chose six different similarity measurements between two images I_1 and I_2 , namely the mean absolute error (MAE), structural similarity index (SSIM), normalized cross-correlation (NCC), peak signal-to-noise ratio (PSNR), normalized Frobenius norm (NFN), and Dice score (DSC).

Fig. 2 shows an example of how s is adjusted for the specific case of SSIM. We have chosen hyperparameter s as 2 in this case to facilitate understanding. As shown, the image at $t = 1.8$ is more similar to the fixed image than the one at $t = 1.0$ according to SSIM. Although the difference in SSIM is slight, the morphological differences are visible (see for example the ventricles).

The six measurements are computed as follows:

$$MAE = \frac{1}{N} \sum_{i=1}^N |I_1(i) - I_2(i)| \quad (9)$$

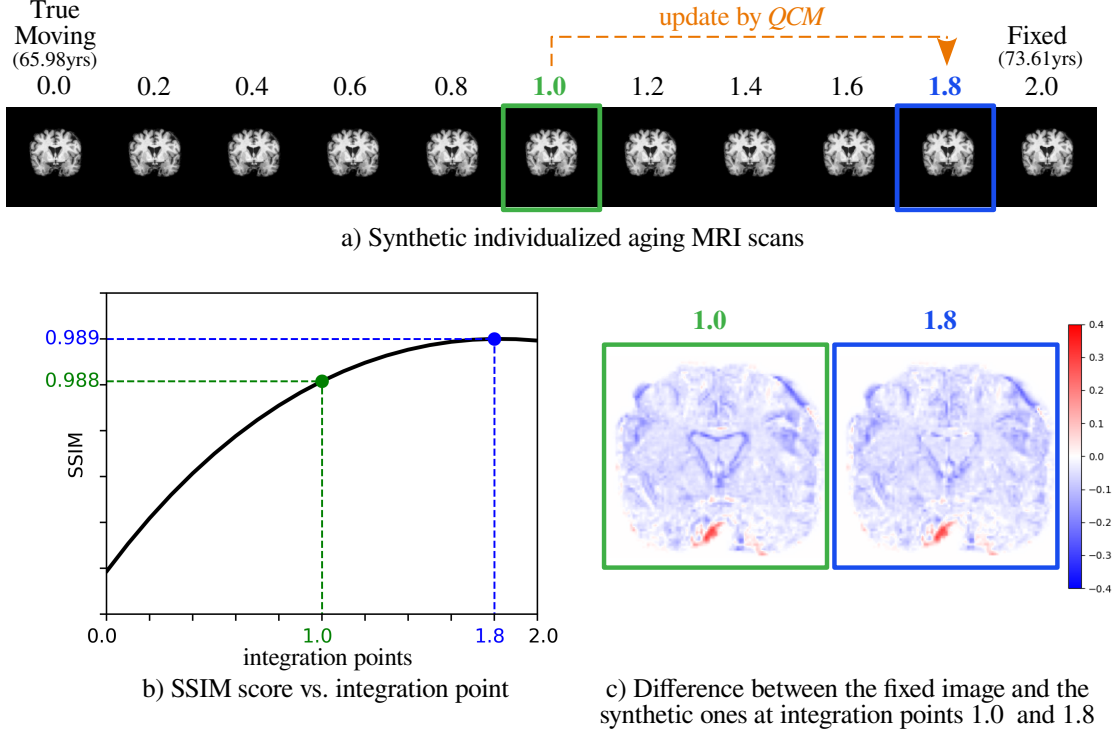

Figure 2: Adjustment of the stopping point s . a) Series of generated images for a specific subject for different integration points. The center coronal slice from the 3D volumes is depicted in these images. b) SSIM between the fixed image and the synthetic ones is maximum at $t = 1.8$. c) Local differences between the fixed image and the synthetic ones at $t = 1.0$ and the optimal stopping point at $t = 1.8$.

where N is the number of voxels.

$$SSIM = \frac{(2\mu_1\mu_2 + C_1)(2\sigma_{12} + C_2)}{(\mu_1^2 + \mu_2^2 + C_1)(\sigma_1^2 + \sigma_2^2 + C_2)}, \quad (10)$$

where μ_i and σ_i stand for the mean and standard deviation of image i , σ_{12} is the covariance, and the parameters $C_1 = (k_1Q)^2$ and $C_2 = (k_2Q)^2$ are used to stabilize divisions with weak denominators, with Q being the dynamic range of the MRI scans. We used $k_1 = 0.01$ and $k_2 = 0.02$ in the experiments.

$$NCC = \frac{\left| \sum_{j=1}^N (\hat{I}_1(j)\hat{I}_2(j)) \right|}{\left[\sum_{j=1}^N \hat{I}_1^2(j) \sum_{j=1}^N \hat{I}_2^2(j) \right]^{1/2}}, \quad (11)$$

with $\hat{I}_i(j) = I_i(j) - \mu_i$.

$$PSNR = 10 \log_{10} \left(\frac{Q^2}{MSE} \right), \quad (12)$$

with Q being the dynamic range of the MRI scans and MSE the mean squared error between the two images.

Further, we use the normalized Frobenius Norm (NFN) (also known as the sum of squared differences) [Van Loan and Golub, 2013] between the two images:

$$NFN = \sqrt{\frac{1}{N} \sum_{i=1}^N |I_1(i) - I_2(i)|^2} \quad (13)$$

Table 1: Summary of the datasets.

dataset	Complete dataset		Selected images			Synthetic images	
	# Images	# Healthy	# Sessions >1	# Subjects	Age range	# Images	Size increase
ADNI	5,097	1,489	1,393	347	59~95	2,500	179%
OASIS-3	2,044	1,310	1,066	353	42~95	3,948	370%
GENIC	539	406	203	96	34~79	1,100	542%
Total	7,680	3,205	2,662	796	34~95	7,548	284%

Whenever segmentation masks are available, the Dice score is applied to the segmentation. In order to get segmentation masks for the generated images, the same estimated deformation fields are used to warp the segmentation masks of the moving image. In this case, nearest-neighbor interpolation is used instead of linear used in the spatial transform. The formula is as follows:

$$DSC = \frac{2 \times (A \cap B)}{A + B} \quad (14)$$

with A and B being the two segmentation masks. The values range from 0 to 1, 1 representing a perfectly overlapping segmentation.

Lastly, we combine the six similarity measurements by computing the mean updated s of the individual methods.

Once the stopping point s is adjusted, we can re-generate the synthetic images with this more accurate input-specific hyperparameter.

3.4 Age estimation

When conducting research on aging, age is a valuable piece of information. Once the images are synthesized, the next step is to estimate the age of every synthetic MRI scan. This step is important in order to match the synthesized images with real ones by age.

It is vital to know how anatomy changes with age when it comes to the age estimation of synthetic images. Walhovd et al. [2005] showed that the contraction of brain structures is linear with age. Moreover, Dukart et al. [2013] found linear decreasing age-related changes in one voxel considering GM volume at the age of 50 years as a baseline. Based on these findings, we assume that a linear increase in the integration time will lead to a linear change in the brain structures. Thus, the age of the synthetic image at time t , I_t , is computed as:

$$Age(I_t) = Age(I_m) + \frac{t}{s} [Age(I_f) - Age(I_m)]. \quad (15)$$

Notice that this age estimation depends on the stopping point s , which can be different depending on the applied measurement from the previous section. Since there are subjects with more than two acquired images in the datasets, it is possible to use the intermediate acquisitions to assess the error in the age estimation. With this, it is possible to determine which measurement is more appropriate for simulating aging with the proposed methodology.

4 Experimental Results

4.1 Datasets

We evaluated the generative performance of the proposed methodology on three datasets: two public available datasets, the Alzheimer’s Disease Neuroimaging Initiative (ADNI) [Jack Jr et al., 2008] and the Open Access Series of Imaging Studies (OASIS-3) dataset [LaMontagne et al., 2019]; and our own dataset, named GENIC. They all are 3D brain-MRI datasets. We focus only on the T1-w MRI scans in this study. The ADNI ³ was launched in 2003 as a public-private partnership, led by Principal Investigator Michael W. Weiner, MD. The primary goal of ADNI has been to test whether serial magnetic resonance imaging (MRI), positron emission tomography (PET), other biological markers, and clinical and neuropsychological assessment can be combined to measure the progression of mild cognitive impairment (MCI) and early Alzheimer’s disease (AD). OASIS-3 ⁴ is a retrospective compilation of data from more than 1,000 participants, including 609 cognitively normal adults and 489 individuals at various stages of cognitive decline. It contains more than 2,000 MR sessions and includes T1-w scans, among other sequences. GENIC is a population-based prospective

⁴<https://www.oasis-brains.org>

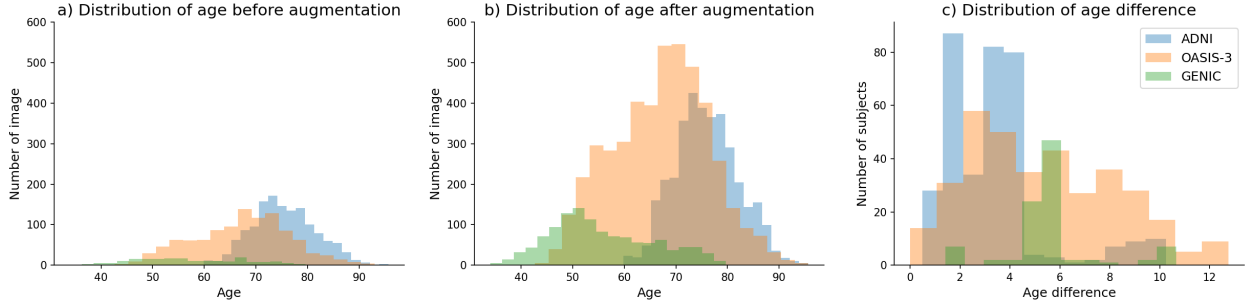

Figure 3: Age distributions in the three datasets. a) and b) show the histogram of age before and after augmentation. c) shows the distribution of age difference between the first and last acquired MRI scan per subject.

longitudinal study from the Canary Islands in Spain, which it was started in 2004 and is currently on-going [Machado et al., 2018, Nemy et al., 2020]. It includes T1-w scans, among other sequences.

Data setup. First, FreeSurfer [Fischl, 2012] was applied to all datasets. Image processing and data management of ADNI and GENIC were done in theHive database system [Muehlboeck et al., 2014], while OASIS FreeSurfer data was obtained from <https://www.oasis-brains.org/#access>. FreeSurfer performs skull-stripping and bias field correction. After that, we affine registered the images into FreeSurfer’s Talairach space using the *talairach.xfm* atlas transform generated by recon-all. Affine registration is necessary since we adopt the stationary velocity model, in which the evolution of the diffeomorphism is not invariant with respect to the affine transformations [Ashburner, 2007]. In order to harmonize medical data for the DL-based architecture, it is important to resample the intensity of images to a common shape and scale between 0 and 1. We also cropped the images to [160,160,192] in the experiments.

Many neurodegenerative diseases can affect brain aging [Popescu et al., 2021]. For example, it has been previously shown that the brains of patients with Alzheimer’s disease (AD) tend to look older than the brains they would have expected when healthy [Franke et al., 2012, Popescu et al., 2020]. Based on this, it is reasonable to separate healthy patients from diseased patients, especially for age estimation. Therefore, we only used images of cognitively healthy subjects, resulting in 1,489 images in ADNI, 1,310 images in OASIS-3, and 406 in GENIC. Further, the proposed methodology requires images acquired in at least two time points as input, so subjects with sessions fewer than two were excluded. Then 1,393 images were left in ADNI, 1,066 images in OASIS-3, and 203 images in the GENIC dataset. Details about the data included in the experiment appear in Table 1.

4.2 Image generation

As mentioned, SynthMorph [Hoffmann et al., 2022] was used as the backbone of the diffeomorphic registration due to its state-of-the-art performance for DL-based diffeomorphic registration. We used pre-trained weights which were trained with a set of brain-anatomy label maps (*sm-brains*)⁵. The number of images generated for each subject, N_i , is determined by the age difference (i.e., δ_i shown in Figure. 1) between the youngest and oldest sessions in the dataset, namely $N_i = 2 \times \delta_i$ for each subject i . We chose the two MRI scans with the greatest age gap from a subject for two reasons: i) it will result in the longest aging simulation and relatively large augmented data pool that can be used for developing data-hungry AI-enable tools, such as registration and segmentation of 3D MRI scans; ii) the remaining intermediate MRI scans can be used for the evaluation part. It was chosen here to use double age difference because we consider the acquisition of longitudinal data to be suitable every 6 months. The initial stopping point s is set as three in the experiments. The summary of the datasets and the generated synthetic images can be found in Table 1. It is worth mentioning that the original datasets can be augmented with high-quality MRI scans by 284%.

Fig. 3 shows the age distributions of the three datasets before and after the generation of synthetic data. As shown, GENIC contains younger subjects, ADNI older, and OASIS-3 subjects in the middle. The figure also shows that OASIS-3 covers a larger range of age differences between the first and last MRI acquisition compared to the ADNI, with GENIC in between. These differences determine that the number of synthetic images per subject in ADNI is on average smaller than in the other two datasets.

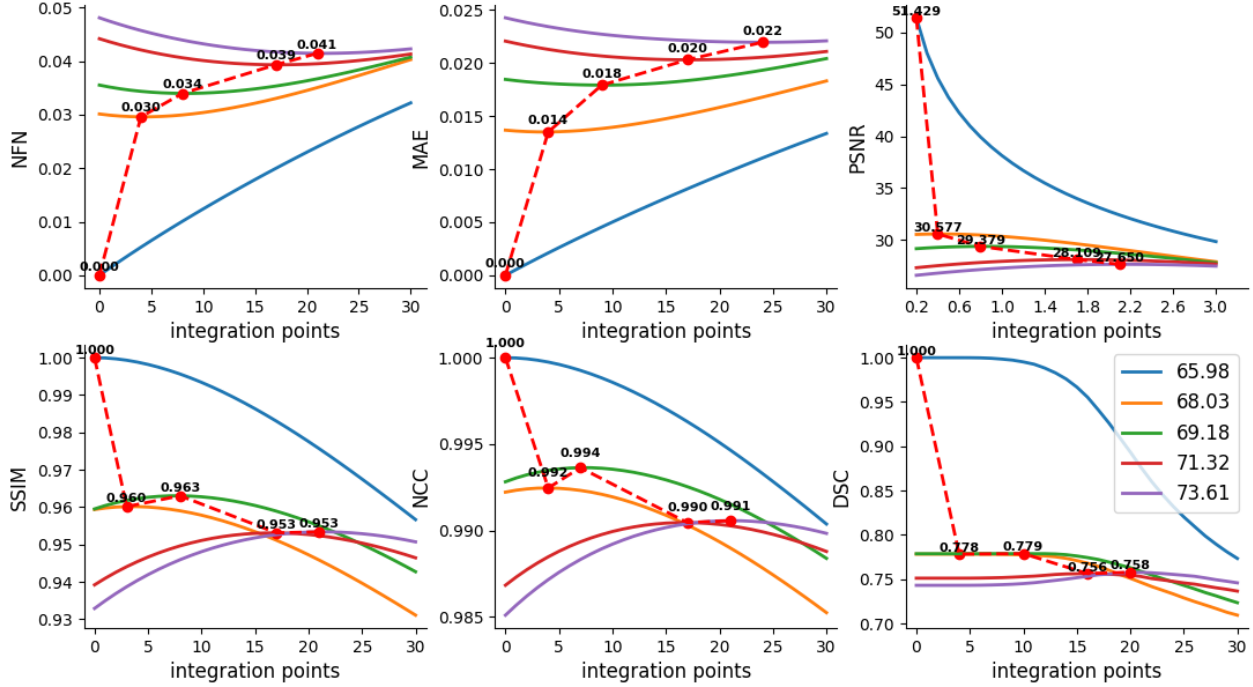

Figure 4: Trends of the six quality criteria for five images of the same subject. The legends indicate the *true ages* of the corresponding real MRI scans. For each curve, we calculate the "extreme" values and positions and connect them to a dashed red line. For NFN and MAE, the generated MRI scans that are most similar to the real ones are at the point of minimum value; for other measurements, it is at the maximum point.

4.3 QCM validation

Introducing QCM is one of the contributions of this work since it can take the quality of synthetic MRI scans into consideration by adjusting stopping points in the AGM at the inference phase, thus mitigating the effects of domain shift between training and test cohorts. Six similarity measurements are introduced in the QCM. The validity of QCM is evaluated from two perspectives: i) Selected measurements reflect aging-related changes; ii) The 'optimal' stopping point is mostly beyond the fixed one (i.e., $t = 1$).

As discussed, the stopping point can be different depending on the quality measures used for comparing the acquired images with the synthetic ones. To show this, we randomly chose a subject from OASIS-3 that was scanned five times and used them to assess their corresponding closest synthetic images according to the different criteria. Every curve in Fig. 4 shows the evolution of the different measurements for the five images with the integration points. Notice in Fig. 4 that the integration point of the closest synthetic image is always growing with the age of the acquired image for all measurements. Similar behavior was observed in subjects with more than two acquired images. This means that the chosen quality measurements are consistent and can capture aging-related changes.

Figure 5 shows box plots of the adjusted stopping points s per dataset for the different quality measurements. As shown, the stopping point is higher than 1.0 in the vast majority of the cases. ADNI tends to have lower values of s compared to the other datasets. This can be related to the fact that the age difference between the youngest and oldest image in ADNI was smaller than in the other datasets. Notice that the value of s is relatively similar for all quality measurements.

4.4 Validation of age estimation

At this point, it is not clear which quality measurement is the most appropriate for age estimation. To answer this question, we used the true age of the intermediate images, which were not used in the image generation, as ground truth to test the error in the age estimation. We used the root mean square error (RMSE) between the true ages and the

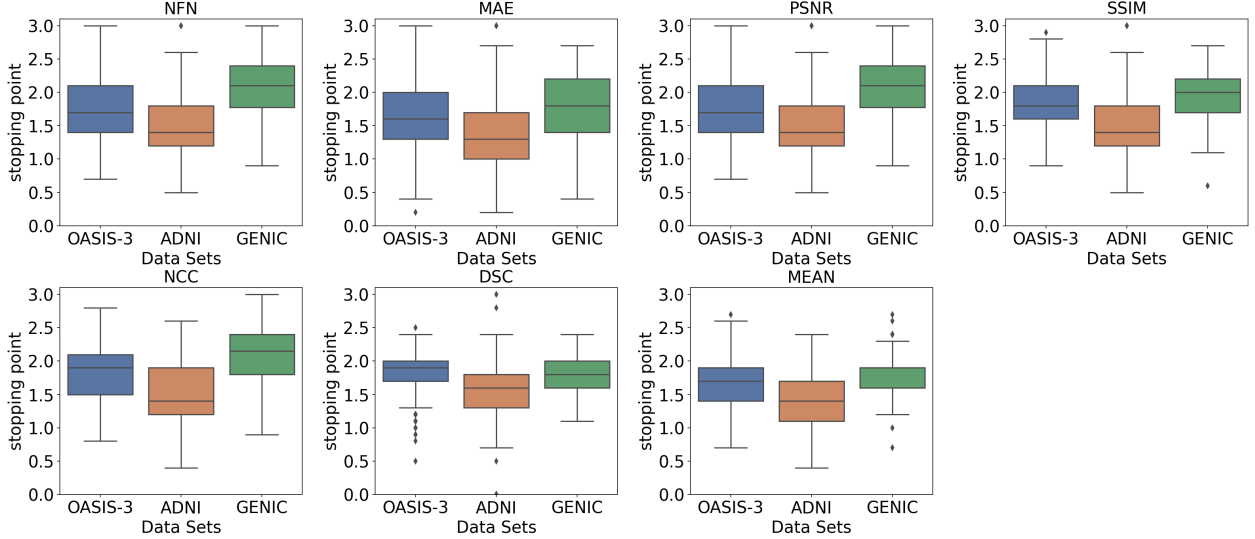

Figure 5: Distribution of the stopping point per dataset for the tested quality measurements.

Table 2: RMSE of the age estimation for the tested quality measurements. Columns 1 to 4 show the error of the linear model, while the last one shows the RMSE of the fitted regression lines of Fig. 7.

Measurement	OASIS-3	ADNI	GENIC	Three datasets	Regressions of Fig. 7
NFN	2.78	1.67	2.80	2.13	2.02
MAE	2.94	1.84	2.69	2.28	2.18
PSNR	2.78	1.67	2.80	2.13	2.02
SSIM	2.93	1.80	2.88	2.26	2.14
NCC	2.80	1.67	2.83	2.13	2.02
DSC	3.00	1.92	2.73	2.35	2.27
MEAN	2.83	1.72	2.72	<u>2.17</u>	<u>2.10</u>

estimated ages as follows:

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (Age_{true}(I_i) - Age_{estimated}(\hat{I}_i))^2} \quad (16)$$

where N is the number of images in the ground truth, I_i is the i -th image in the ground truth, and \hat{I}_i is its closest synthetic image according to the tested quality measurement.

Table 2 shows the RMSE for the tested quality measurements. The corresponding box plots are shown in Fig. 6. We observe that the RMSE is around two years when the three datasets are combined. Again, the error is lower for ADNI. As shown, NFN, PSNR, and NCC are the best options for age estimation. Notice that the RMSE estimations might be affected by quantization errors since we generate images to simulate increments of 0.5 years of age.

As mentioned, previous studies have found that the brain changes linearly with age [Walhovd et al., 2005, Dukart et al., 2013]. In order to assess the validity of that hypothesis in our datasets, we performed linear regressions between the real age of the images used as ground truth and the estimated as described in Subsect. 3.4. Fig. 7 shows these plots for the tested quality criteria. According to the coefficient of determination R^2 , the linear regression is valid since all measurements are higher than 0.9, which usually indicates a strong correlation between variables thus demonstrating the goodness of this fit. Ideally, the fitting lines should be $y = x$. As shown, the slopes are close to one in all cases, which validates the hypothesis that the linear changes within the brain will cause linear age increments. However, the intercept varies between 0.15 (i.e., 1.8 months) and 1.23 (i.e., one year and 2.8 months). In order to assess the effect of the intercept in the estimation of age, we added an extra column in Table 2 where the regression was used instead of the linear estimation of age. The improvement is in the range of 0.07 to 0.12, which is equivalent to 0.84 to 1.44 months.

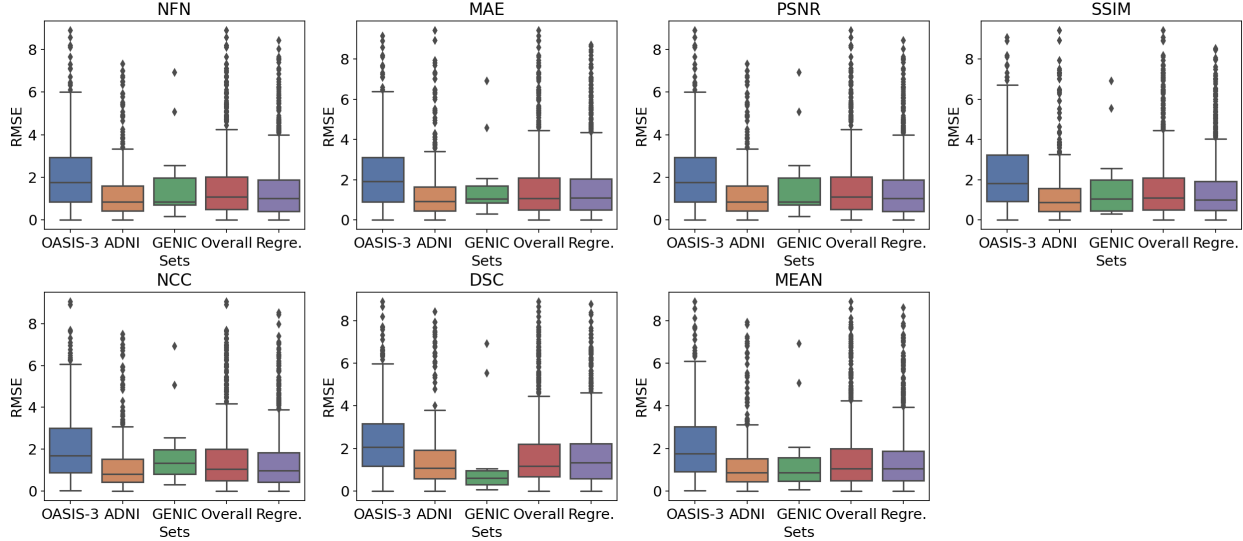

Figure 6: Box plots of the RMSE of the age estimation for the tested quality measurements.

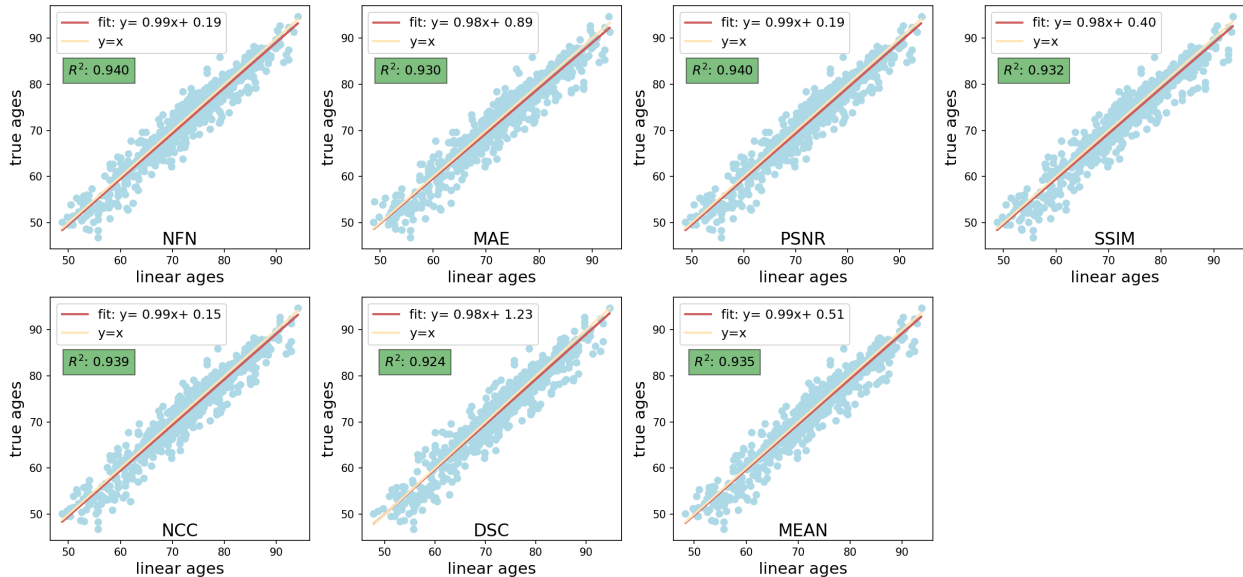

Figure 7: Correlation plots between the estimated linear ages and the true ages of the ground truth images. The coefficient of determination R^2 is used to determine the performance of the fitting.

4.5 Quantitative quality assessment

Table. 3 and Fig. 8, show the different quality measurements computed on the generated images that are most similar to the ground truth images. The obtained values cannot be directly compared with other generative models from the literature because of different experimental settings. Still, these values are competitive or superior to those from previous studies (e.g., Lei et al. [2019], Emami et al. [2018], Gu et al. [2019]). For example, in these studies, PSNR was around 28 (we got 27.87), SSIM was around 0.85 (we got 0.936), and NCC was around 0.93 (we got 0.982). We observed that NFN and MAE are very small as well.

Regarding the DSC, Hoffmann et al. [2022] reported values around 0.75, compared to the mean of 0.727 of our experiments. DSC is commonly used for assessing the performance of image segmentation methods. In such applications, DCS values of 0.70-0.75 are not considered accurate. However, it is important to consider that many brain structures are small, which usually have a direct impact on the DSC. Considering that, Hoffmann et al. [2022] used

Figure 8: Box plots of the quality measurements of the most similar generated images compared to the ground truth images for different datasets and criteria.

Table 3: Quality measurements of the most similar generated images compared to the ground truth images for different datasets and criteria.

Criteria	OASIS-3	ADNI	GENIC	Average
NFN	0.056	0.040	0.035	0.044
MAE	0.029	0.020	0.016	0.022
PSNR	25.81	28.73	29.07	27.87
SSIM	0.917	0.946	0.945	0.936
NCC	0.981	0.985	0.981	0.982
DSC	0.715	0.749	0.718	0.727

the 26 large brain structures for computing the DSC. We decided to report DSC considering 113 structures in total, on Table 3, to get a more comprehensive overview of the performance estimated with DSC.

4.6 Qualitative quality assessment

Figure. 9 shows an example subject of the generated aging images. The comparison between real aging MRI scans and synthetic aging MRI scans shows the good quality of the synthetic images. Figure. 10 shows the estimated aging progression of this subject, where the aging MRI scans are shown in three directions (coronal, sagittal, and axial), ranging from 51.7 years old to 63.7 years old. We report a magnified region to show the aging progression in the sagittal direction. As shown, the ventricles expand with increasing age. This can be seen as an indication that the proposed method is consistent with what is expected in the aging brain.

Although the synthetic images look realistic to untrained eyes, it is necessary to perform validation with a neuroradiologist in order to assess the quality of the generated images. This step is important towards the use of the synthetic data for answering clinical questions.

In order to accomplish this, we designed a discrimination task for the neuroradiologist (A.T.), who has 16 years of experience with neurological images. The discrimination task consisted of distinguishing real images from synthetic ones. From the pool of mixed generated and real images, 200 MRI scans were randomly selected. Because we are interested in knowing if there was any bias in different datasets and age difference between the oldest and youngest image of the subject used to generate the image, we selected the 200 samples proportionally for each subcategory. By dividing the age difference into six ranges, (i.e., 2 years per range), we got [0~2, 2~4, 4~6, 6~8, 8~10, 10+]. We included the generated MRI scans at time point s as the generated one in the pool.

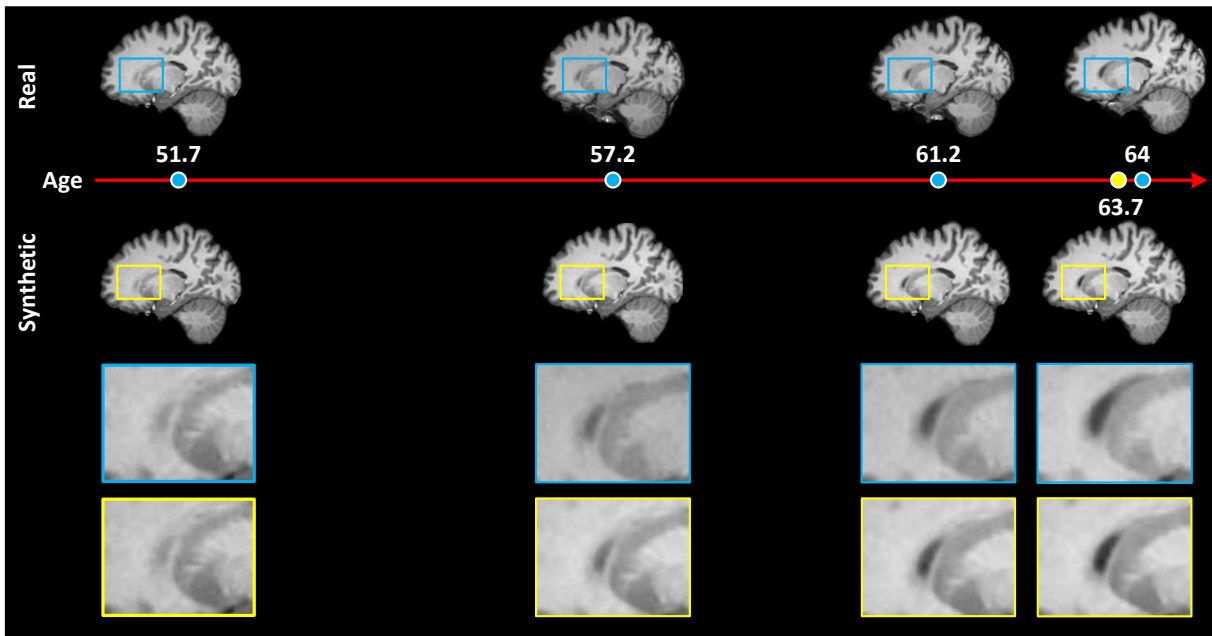

Figure 9: Qualitative assessment of the quality of the synthetic MRI scans vs. the real MRI scans. The first row indicates the real MRI scans in the longitudinal data set, and the second row shows synthetic aging MRI scans at different estimated ages. We also show a magnified region at the bottom of the figure for each row respectively (color figure online). As the synthetic MRI scans are acquired along with the same interval of 6 months, the last obtained brain age is 63.7 in this case, whereas the counterpart in real data is 64.

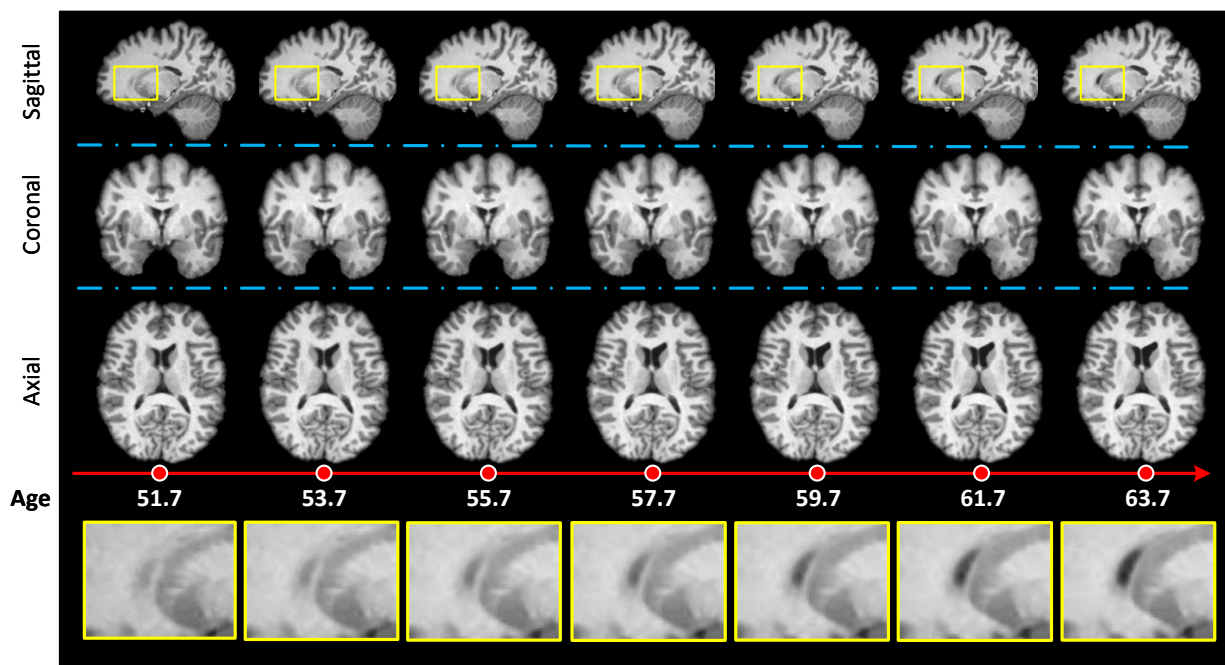

Figure 10: The aging simulations were synthesized using our methodology for a healthy subject from age 51.7 to age 63.7. The 3D MRI scans are shown in three directions sagittal, coronal, and axial, respectively. A magnified region is highlighted at the bottom of the figure for a better illustration (color figure online).

Table 4: Confusion matrix on the discrimination task performed by the neuroradiologist.

	Neuroradiologist Assessment	
	Real (P)	Synthetic (N)
Real	True Positive =41	False Negative =24
Synthetic	False Positive =49	True Negative =86

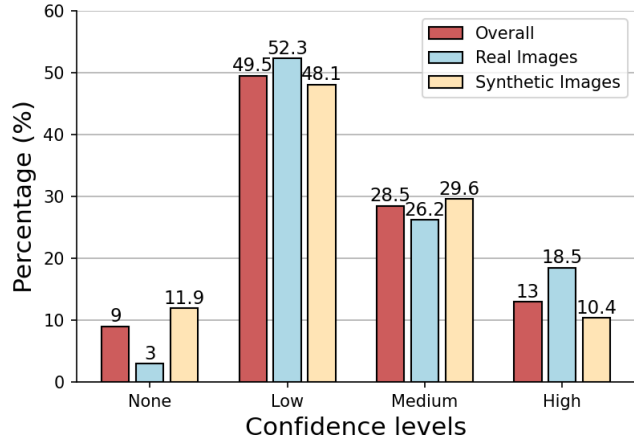

Figure 11: The distribution of confidence levels

Table 5: Comparison of the accuracy and F1-scores of the assessment performed by the neuroradiologist.

Criteria	Overall	Confidence Levels				Datasets			Age differences					
		None	Low	Medium	High	OASIS-3	ADNI	GENIC	0~2	2~4	4~6	6~8	8~10	10+
Accuracy	0.64	0.56	0.66	0.58	0.73	0.67	0.62	0.57	0.46	0.67	0.66	0.74	0.50	0.71
F1-score (overall)	0.62	0.45	0.62	0.57	0.73	0.65	0.62	0.42	0.41	0.66	0.61	0.73	0.49	0.71
F1-score (real)	0.53	0.20	0.51	0.50	0.74	0.58	0.56	0.13	0.24	0.60	0.47	0.70	0.44	0.67
F1-score (synthetic)	0.70	0.69	0.73	0.64	0.72	0.72	0.67	0.71	0.58	0.72	0.75	0.77	0.55	0.75

The neuroradiologist was completely blinded to the purpose and design of the study, as well as to the demographic and clinical characteristics of the study participants. The neuroradiologist used the 3D slicer⁶ for classifying the 200 selected MRI scans as real or synthetic. He completed the task in four consecutive days – one hour of assessment per day. Before doing the task, the neuroradiologist was exposed to three true MRI scans, one per dataset, in order to help the neuroradiologist to build a template of a real image in this dataset. Motivated by the experiments by Ravi et al. [2022], for each case, the expert was asked to assign a confidence level from the given list:

- None: 'I have no idea, I am guessing the class of this scan'
- Low: 'I have low confidence in my answer'
- Medium: 'I am reasonably confident in my answer'
- High: 'I am absolutely sure in my answer'

Table 4, shows the confusion matrix of the assessment in which the real class is marked as positive (P) and synthetic as negative (N). As shown, highly skilled experts struggle to recognize the real and synthetic images with an accuracy of 63.5%. Specifically, while even the expert can reach an accuracy rate of 63.5%, the precision for detecting real images (45.6%) is poor, suggesting our synthetic images look realistic.

Figure 11 shows the distribution of confidence levels reported by the neuroradiologist in the experiment. As we can see, the expert has high confidence in only 13% of the cases. Moreover, the neuroradiologist has more uncertainty for synthetic images (i.e., None confidence in synthetic was 11.9% compared to 3% for real images, p-value = 0.042).

Table 5 shows the accuracy and F1-score of the neuroradiologist in distinguishing between real and synthetic images. Moreover, we independently report the F1-scores for the synthetic and real images in Table 5. To evaluate if the algorithm shows differences among different datasets and confidence levels, we also calculate the metrics for each subcategory. It is also worthwhile to analyze the age difference between the youngest and oldest images from the subjects since in our experiments we chose to generate N images for each subject based on such age difference. According to Figure 3, there is a large age difference between the three datasets, so we decided to divide the range of age differences into six small intervals, each of which contains 2 years.

As expected, the neuroradiologist was able to distinguish better the two classes when his confidence was high. Regarding confidence levels between none to medium, the performance was better for synthetic images for the same level of

⁶<https://www.slicer.org/>

confidence, because the neuroradiologist tends to be more synthetic-oriented as demonstrated by the precision for detecting real images of only 45.6%. The accuracy was similar for different datasets ($62\pm 5\%$), whereas the F1-score on overall for GENIC is about 0.2 lower than the other two datasets. One possible reason for this is that images from GENIC come from younger subjects that might have fewer visual distinctions due to age. This can make the deformation fields to be small, which increases the chances of synthetic being more similar to the real ones.

We conducted proportion hypothesis tests on the age differences in accuracy and corrected the resulting p-values by multiple comparisons ($p < 0.05$). Based on the results, we observed that there is no significant difference among subgroups even over a period of ten years, thus indicating the validity of QCM and robustness of the proposed method.

5 Discussion

We presented a method to efficiently generate 3D MRI scans of aging brains with the aim of augmenting the current longitudinal datasets with high-quality images. Our method is able to leverage DL-based methods to generate synthetic images while avoiding the time-consuming training process. In addition, we propose a series of strategies to ensure that the model can provide predictions of age for the generated images.

Image generation. The proposed method was evaluated on 2,662 T1-w MRI scans from 796 participants collected in three different datasets. While T1-w MRI is the only modality used, the methodology is applicable to any other modality. We synthesized 7,548 high-quality images from the three datasets, which corresponds to an increase of 284% in the number of images. Notice that the synthetic images were generated in the range between the youngest and oldest image per subject. It is actually straightforward to generate more images by extrapolating the images beyond the oldest one. In fact, we discarded approximately one-third of the synthetic images because we first generated images up to the integration point of three to estimate the stopping point s , which was close to two, so images beyond s were discarded. The reason for this decision is that we were focused on creating a dataset of high-quality images that can be combined with existing datasets for brain aging analysis. While we think images beyond the stopping point s are also of high quality, it is more difficult to assess that at this point. Future works may expand our current method in that direction.

Notice that we decided to exclude AD patients or subjects with mild cognitive impairment in this study. Indeed, it is straightforward to apply the method to these subjects. However, the aging patterns of these patient groups coexist with disease-related patterns, making the age estimation more difficult than in cognitively healthy individuals. This means that a synthetic dataset of aging in patients must consider this problem in order to make it useful for aging studies. Thus, we decided to develop and demonstrate the goodness of our method in healthy individuals, and future developments shall consider applying the method to disease populations such as Alzheimer’s disease.

QCM Verification. Generally speaking, DL models always face a problem that the performance of the model is limited to the distribution of training data. When the distribution of the prediction data and the distribution of the training are different, the performance of the model tends to drop. We tackled that problem by using quality measurements to estimate the most similar generated image to the acquired ones. As shown in Fig. 5, the closest image was almost always at a stopping point higher than one regardless of the used quality measurement, while theoretically that should be 1.0. This way, we managed to benefit from the speedup provided by DL-based registration methods while keeping image quality as high as possible.

We selected six different quality measurements for estimating the stopping point s and to estimate the quality of the images. All criteria gave consistent results as the closest synthetic image was always growing with the age of the acquired image for all criteria (e.g., Fig. 4).

The results also show that these measurements perform similarly for age estimation, with NFN, PSNR, and NCC being slightly better (cf. Table 2). Except for DSC, these measurements also show that the generated images are of good quality (cf. Table 3). However, the obtained DSC values are similar to the ones from previous studies, especially Hoffmann et al. [2022]. Moreover, the small size of some regions of the brain can be biased in the estimation of DSC.

While the focus of this paper has been to generate T1-w images, the method can be used for other modalities (e.g., T2w, FLAIR, etc.) without any change. More interesting would be to generate images of one modality using images from another modality. For example, let’s assume that in the first session, T1-w and T2w images were acquired, but only a T1-w was acquired in the second session. Then, the two T1-w images can be used to generate the deformation fields that can be applied to the only available T2w image. Another example would be if only a T1-w is available from the first session and only a T2w image is available for the second. In this case, it is necessary to use quality measurements that can deal with multimodality data, e.g., DSC or mutual information.

Qualitative assessment. From the experiments, the synthetic images are of high quality. The assessment performed by the neuroradiologist (A.T.) shows that it is difficult to distinguish between synthetic images and real ones, especially

when the neuroradiologist’s confidence was not high. As expected, the images generated between smaller age differences were more difficult for the neuroradiologist, since the deformation fields in those cases are very small as well as age-related brain changes like small silent infarcts, enlarged perivascular spaces, cortical atrophy, white matter changes, and microbleed were absent. An interesting result was that the neuroradiologist tends to think that real images from GENIC look synthetic. Something that we have to consider is that the real images were preprocessed with Freesurfer (e.g., they are bias-corrected and skull stripped), which can make the visual assessment of the neuroradiologist slightly different compared with everyday clinical praxis in a neuroradiology department.

It is worth mentioning that in Ravi et al. [2022], the same discrimination task was introduced. They found that neuroradiologists can achieve an accuracy of $68.0\% \pm 7.1\%$ on the synthetic images generated by their method, while our method can achieve a 64% accuracy on the generated images. Although these numbers cannot be directly compared, this indicates that our performances might at least be comparable to the results in Ravi et al. [2022].

Age estimation. Based on the literature, we assumed that the brain changes due to age were linear. Such an assumption was supported by the regression analysis of Fig. 7. After correcting the age estimation with the fitted lines, the age estimation was just slightly better (cf. Table 2 and Fig. 6). Notice that the research community has been very active in estimating age from images [Sajedi and Pardakhti, 2019, Lund et al., 2022]. Therefore, we foresee that the error in the age estimation of the generated images will decrease when using one of such methods. However, assessing different age estimation methods is beyond the aims of this study.

Future work. We can see many potential applications and improvement directions for the proposed method. First, as mentioned, the method can be used to synthesize high-quality and high-resolution images from various modalities rapidly by only changing to the suitable measurement. Second, our method could be applied to estimate the progression of neurodegenerative brain diseases, not just for normal aging. For example, with our methodology, we can synthesize subject-specific temporal estimations of undergoing neurodegeneration, which can then be compared with the healthy templates to provide cross-sectional comparisons that shall aid clinical diagnoses. Finally, although our method is able to provide personalized predictions via paired inputs, it cannot be currently used when a single image is available from the subject. Our plan is to extend our framework to deal with that case as well.

6 Conclusion

In this work, we proposed a methodology with the aim of simulating subject-specific aging in brain MRIs given two 3D images acquired at different time points. DL-based diffeomorphic registration was used as a backbone to generate deformation fields at different integration points. Quality measurements were used for controlling the age estimation of the generated images by using a linear assumption. The results show good performance from both quantitative and qualitative perspectives regarding both the image quality of the synthetic MRI scans and the estimation of age.

To help data-hungry AI models learn, we open-sourced our augmented data to the research community, which is available in this link <https://github.com/Fjr9516/Synthetic-Brain-Aging/blob/main/README.md>.
