#### INTRODUCTION

There is an extensive program dedicated to dark matter searches worldwide. Dark matter particles might leave imprints at direct and indirect detection experiments. However, due to the nature of these searches which are subject to nuclear and astrophysical uncertainties, respectively, it is desirable that one could also observe a dark matter signal at colliders or accelerators. The properties of the dark matter particle dictate the type of signals one may observe. Several collider searches have been conducted at the Large Hadron Collider (LHC) and other accelerators, but thus far no positive result signal has been found.

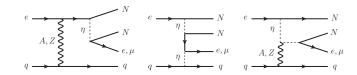

The LHC is an excellent probe when dark matter particles interact with quarks. Vector boson fusion production of dark matter yields interesting but less restrictive constraints [1]. If dark matter features leptonic interactions, obviously an  $e^+e^-$  collider [2] or an LHeC that features an electron beam allowing synchronous operation of epwith pp collisions at the LHC [3] would be helpful. Future colliders such as the Future Circular Collider [4] and the International Linear Collider [5] are very long-term proposals, and LHeC can be seen as a very important step towards this major new facilities in terms of physics as well as technology. That said, could LHeC probe weak scale dark matter? As usual, dark matter particles are missing energy at colliders as they simply leave no imprint at the detectors, and a necessary visible counterpart is required as a trigger.

If dark matter can be produced via *s*-channel diagrams, one can take advantage of resonance production of the mediators and quickly conclude that LHeC cannot be regarded as the best probe for such dark matter particles. However, if dark matter is produced via leptonic processes, LHeC stands out. We will present here the LHeC sensitivity to dark matter particles that have couplings to leptons. Without loss of generality, we assume the following Yukawa interaction

$$\mathcal{L}_Y \supset y_{N\ell} \eta \overline{N} L_\ell + \text{h.c.} \tag{1}$$

Here N is a Majorana singlet fermion and our dark matter particle,  $\eta$  is a scalar SM doublet, L is a lepton doublet, and  $\ell = e, \mu$ . This Yukawa interaction is often present in neutrino mass models [6], but in our work it is treated more generally. A  $Z_2$  symmetry has been imposed to the new particles to forbid the Majorana fermion to couple with other SM states, warranting its stability, as long as its mass is lighter than that of the inert doublet. The doublet is inert either by symmetry requirements or by theoretical constructions. The dark matter abundance of the Majorana fermion occurs solely through t-channel processes into SM leptons in the standard freeze-out regime. There are no dark matter direct detection signals at tree level. At one-loop level, one can potentially induce dark matter-nucleus scattering with charge-charge, dipole-charge, and dipole-dipole interactions [7]. After investigating the collider phenomenology, we put our findings into perspective with lepton flavor violation, namely  $\mu \to e\gamma$  [8, 9], and discuss the importance of direct dark matter detection.

In summary, Eq. (1) is commonly presented in a multitude of models, and has implications for dark matter, lepton flavor violation as well as neutrino mass models. In what follows, we will assess the LHeC potential to discover such dark matter particle to solidly conclude that LHeC offers a unique opportunity to discover a weak scale dark matter particle.

### SIGNATURE OF WEAK SCALE DARK MATTER AT THE LHEC

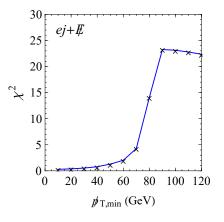

As explained above, there are benefits of the electronproton collider: a relatively clean environment for new physics searches, and the possibility to probe weak scale dark matter that couples to leptons.

## **Relevant Event Topologies**

The relevant Feynman diagrams are shown in Fig. 1. We consider each channel at a time. We find that the effective Lagrangian can induce the following event topologies from electron-proton scattering at LHeC:

- $ej + \not\!\!\!E$ : The contributed signal process reads  $ep \rightarrow ejNN$ , where the dark matter N generates missing energy. The SM backgrounds for this channel include the following: (i)  $ep \rightarrow ejX$  with  $X (\gamma, G,$ etc.); (ii)  $ep \rightarrow ej\nu\nu$ ; (iii)  $ep \rightarrow ej\nu X (X = \ell)$ ; (iv)  $ep \rightarrow ejXX (X = \gamma, G, q, \ell)$ . Here and in the following, X denotes an in principle visible particle that however escapes the angular acceptance of the detector. Note that we use  $\nu$  in the final state to denote both neutrino and antineutrino for all possible flavors. In this analysis, we do not distinguish light quarks and gluons in the final state. Processes with even higher orders, e.g.,  $ep \rightarrow ej\nu\nu X$ , are neglected.
- $\mu j + \not\!\!\!E$ : The final state with muons has fewer SM backgrounds because of the suppression of lepton flavor violation. In comparison to the  $ej + \not\!\!\!E$  final state, we identify three types of SM backgrounds: (i)  $ep \to \mu j \nu \nu$ ; (ii)  $ep \to \mu j \nu X$   $(X = e^-, \mu^+)$ ; (iii)  $ep \to \mu j XX$   $(X = e^-, \mu^+)$ .
- Mono j + E: The mono-jet topology corresponds to the process eq → jνNN. There are the following SM backgrounds: (i) eq → jν(X); (ii) eq → jνX; (iii) eq → jν(X)ν(X)ν(X). The leading-order process eq → jν will be an overwhelmingly large background and cannot be reduced by imposing missing energy cuts. Thus, we will focus on the previous two topologies in our analysis.

Some of those backgrounds have a similar diagrammatic pattern as the signal channel, hence irreducible. How-

ever, some of them can be reduced by choosing proper cuts which we will describe later.

#### Sensitivity to the Parameter Space

The sensitivity is obtained by a simple count analysis of total events without involving detailed event distributions. Hence, the present analysis represents a conservative result. We adopt the following chi-square to estimate the sensitivity:

$$\chi^2(M_N, M_\eta, y_N) = \frac{N_{\rm sig}^2}{N_{\rm sig} + N_{\rm bkg}} , \qquad (2)$$

where  $N_{\rm sig}$  and  $N_{\rm bkg}$  are the total signal and background event numbers, respectively. The following cut will be implemented at the parton level:  $p_{\rm T}(j/b) > 20$  GeV,  $p_{\rm T}(\ell) > 10$  GeV, and the pseudorapidity  $|\eta(j/b/\ell)| < 5$  [10] (see also [11]).

For the topology  $ej + \not\!\!\!E$ , we further impose a cut on  $p_{\rm T} = |p_{\rm T}(e) + p_{\rm T}(j)|$  to reject the *t*-channel backgrounds from direct two-body scattering  $eq \rightarrow ej$  (fully),  $eq \rightarrow ej\gamma$  (partly) and  $ep \rightarrow ejXX$  (partly). The process  $eq \rightarrow ej\gamma$  contains the initial state radiation of collinear photons and can be efficiently reduced by imposing the missing energy cut. The effectiveness of the cut is shown in Fig. 2 in terms of  $\chi^2$  defined in Eq. (2), where the model parameters have been taken as  $M_N = 100 \text{ GeV}$ ,  $M_{\eta} = 300 \text{ GeV}$  and  $y_{Ne} = 1$ . We highlight that  $y_{Ne}$ is the Yukawa couplings between the electron and the fermion N, whereas  $y_{N\mu}$  the Yukawa coupling between the muon and the fermion N. Notice, there is only one Majorana fermion N in our collider study, and that for the  $\mu j + \not\!\!\!E$  signal to exist,  $y_{Ne}$  ought to be non-zero (see of couplings to muons, however.

[	Event Topology	Signal $\sigma$ (fb)	Background $\sigma$ (fb)			
	ej + E	24.4 (16.6)	ejX	e j  u  u	$e j \nu X$	ejXX
			$1.83 \times 10^5 (0)$	92.9(33.1)	73.1(2.20)	$5.20 \times 10^5 (0)$
	$\mu j + \not\!\!\! E$	24.5	$\mu j X$	$\mu j \nu \nu$	$\mu j \nu X$	$\mu j X X$
			0	63.8	3.01	0.140

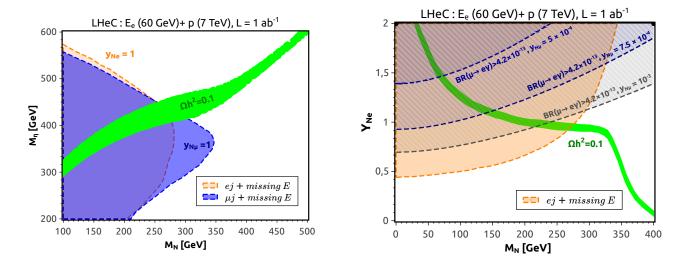

Figure 3. The  $3\sigma$  sensitivity region for the LHeC setup based on 60 GeV electrons colliding with 7 TeV protons with an integrated luminosity of L = 1 ab<sup>-1</sup>. In the left panel, we show the sensitivity to the inert scalar mass  $M_{\eta}$  and Majorana fermion mass  $M_N$  by fixing the Yukawa coupling  $y_{Ne}, y_{N\mu} = 1$ . In the right panel, we fix the inert scalar mass  $M_{\eta} = 400$  GeV instead, and scan over  $y_{Ne}$  and  $M_N$ . The sensitivities for the  $ej + \not E$  and  $\mu j + \not E$  topologies are displayed with orange and blue regions, respectively. See text for details.

That said, we find that a cut  $p\!\!\!/_{_{\rm T}}\gtrsim 100~{\rm GeV}$  can nearly optimize the signal-to-background ratio of  $e_j + E$ , for which the backgrounds enhanced by collinear processes are almost vanishing. After the cut, the dominant background stems from the process  $ep \rightarrow ej\nu\nu$ . The cut adopted on  $p_T$  is based on the  $\chi^2$  study (see Fig. 2). For  $\mu j + \not E$ , we find that the leading background is from the irreducible process  $eq \rightarrow \mu q \nu_e \overline{\nu}_{\mu}$ . The obtained background event numbers for two major signal channels are collected in Table I. Before the missing energy cut, the cross sections for  $ej + \not\!\!\!E$  and  $\mu j + \not\!\!\!\!E$  are almost identical, as their contributing diagrams are the same. The backgrounds from ejX and ejXX are overwhelmingly large due to the collinear enhancement and can be almost completely removed by imposing the cut  $p_{\rm T} \gtrsim 100$  GeV. LHeC's sensitivity to the model is given in Fig. 3. The sensitivity is obtained for the  $3\sigma$  confidence level with  $\chi^2=11.83$  for two degrees of freedom. In the left panel, we fix the Yukawa coupling to one, and then vary the masses of the inert scalar,  $M_{\eta}$ , and Majorana fermion  $M_N$ . In the right panel, we fix the inert scalar mass to be  $M_{\eta} = 400$  GeV, and scan over the Yukawa coupling

# DARK MATTER ABUNDANCE

We emphasize that our entire study is based on three quantities, the mass of the dark matter particle,  $M_N$ , inert doublet mass,  $M_\eta$ , and the corresponding Yukawa coupling in Eq. (1). We remind the reader that we consider each lepton generation at a time. Nevertheless, as far as the dark matter relic density is concerned, they yield the same result. The dark matter relic density is computed under the standard freeze-out regime, where the dark matter decoupling occurs in an epoch in which the Universe is radiation-dominated, via the Boltzmann equation

$$\frac{dn_N}{dt} + 3Hn_N = -\langle \sigma v \rangle (n_N^2 - n_{N,\text{eq}}^2) \,. \tag{3}$$

Here  $n_N$  is the number density, H the Hubble rate and  $\langle \sigma v \rangle$  the annihilation cross section. The abundance is driven by *t*-channel annihilation processes into leptons mediated by the inert doublet,  $\eta$ , as dictated by Eq. (1). We have solved the Boltzmann equation numerically with the MicrOMEGAs package [12], and used it to plot the region of parameter space that reproduces the right relic density (green curve) in Fig. 3. In the left panel, we take  $y_{Ne} = 1$  and  $y_{N\mu} = 1$  at a time, and perform a scan in the masses. In the right panel, we take  $M_{\eta} =$ 400 GeV, and scan over  $y_{Ne}$ . We assumed  $y_{N\mu}$  to be sufficiently small such that the process involving muon pairs is irrelevant for the relic density. The reason for taking a suppressed value for  $y_{N\mu}$  has to do with lepton flavor violation probes, but we will address this later. Anyway, looking at Fig. 3, one can clearly conclude that LHeC can detect a weak scale dark matter candidate that reproduces the right relic density with masses up to 350 GeV. The relic density curve is subject to shifts if one embeds Eq. (1) in a non-standard cosmology scenario [13], allowing one to get the right relic density for larger dark matter and inert scalar masses.

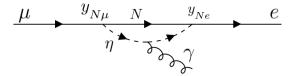

Figure 4. Feynman diagram that leads to  $\mu \to e\gamma$  in our model, when both  $y_{N\mu}$  and  $y_{Ne}$  are different from zero. See text for details.

## LEPTON FLAVOR VIOLATION

Thus far, our study was based on the presence of one Majorana fermion N that couples either to first or to second generation leptons. It is clear from Fig. 3 that LHeC stands an excellent probe for leptophilic dark matter. In the first setup, where only couplings to the first generation is present, there is no lepton flavor violation signal, but in the second case where both couplings to first and second generations are included, lepton flavor violation naturally occurs [14, 15], as we will explain below. When  $y_{N\mu}$  and  $y_{Ne}$  are non-zero as assumed in the second setup, the lepton flavor violation muon decay occurs are displayed in Fig. 4. The full analytical result for the branching ratio is lengthy, and it relies on the product  $(y_{N\mu} \times y_{Ne})^2$ . This product cannot be of order one, otherwise  $BR(\mu \to e\gamma) \sim 10^{-7}$ , which is orders of magnitude above the experimental limit  $BR(\mu \to e\gamma) < 4.2 \times 10^{-13}$ [16]. In the left-panel of Fig. 3 we have shown that one masses compared with the  $ej + \not\!\!\!E$  channel. Now comes the importance of complementary probes. Putting our collider findings into perspective with lepton flavor violation, we can fiercely exclude the entire  $\mu i + E$  region in Fig. 3 because there we had assumed  $y_{N\mu} = y_{Ne} = 1$ . Lowering  $y_{N\mu}$  to values consistent with  $\mu \to e\gamma$  would mean peter out the  $\mu j \not\!\!\! E$  signal. Focusing on the  $ej + \not\!\!\! E$ signal, we can estimate what should be the values of  $y_{N\mu}$ could yield a  $BR(\mu \rightarrow e\gamma)$  consistent with the current limit, while reproducing the correct dark matter relic density. With this in mind, we display in Fig. 3 the  $3\sigma$  signal region in  $M_N - y_{Ne}$  plane, and overlaid contours that yield a  $BR(\mu \to e\gamma)$  in agreement with current bounds for three different Yukawa couplings, namely  $y_{N\mu} = 10^{-3}, y_{N\mu} = 7.5 \times 10^{-4} \text{ and } y_{N\mu} = 5 \times 10^{-4}.$  The overlapping region between the green curve (dark matter relic density) and orange curve (LHeC signal) which is below the contours represents a region where LHeC can detect a weak scale dark matter candidate that reproduces the correct relic density, and could leave some imprints on  $\mu \to e\gamma$  probes in the next generation of experiments, for different coupling strengths to muons.

## DIRECT DETECTION

We have checked that direct detection bounds in this simplified case arise at one loop via Z-exchange, but at with very suppressed strength. Therefore, we do not expect any direct detection signal from Eq. (1). Considering an extended scenario where an additional neutral fermion  $N_2$  is present, and a potentially sizeable direct detection signal stems from dark matter-nucleus scattering[17]. At one-loop level, it leads to the effective Lagrangian,

$$\mathcal{L}_{eff} \supset \alpha \bar{N}_2 \gamma^{\mu} N \partial^{\nu} F_{\mu\nu} + \beta \bar{N}_2 \sigma^{\mu\nu} N F_{\mu\nu} + \gamma \bar{N}_2 \gamma^{\mu} N A_{\mu},$$

where  $\alpha$ ,  $\beta$ , and  $\gamma$  are coefficients that depend on the product  $(y_{N\ell} \times y_{N_2\ell})$ , which are the Yukawa couplings of the Majorana fermions with leptons. The terms proportional to coefficients  $\alpha$  and  $\gamma$  give rise to a charge-charge operator,  $\beta$  to a dipole-charge and dipole-dipole operators [7]. Anyway, any direct detection signal is limited by  $v_{\min}$ , which is the minimum velocity at which a dark matter particle can produce a measurable energy recoil,

$$v_{\min} = \left(\frac{M_A E_R}{\mu_{AN}} + \delta\right) \frac{1}{\sqrt{2M_A E_R}},\tag{4}$$

where  $\delta = M_{N_2} - M_N$ , and  $\mu$  is the dark matternucleus reduced mass. As we increase the mass difference between these two fermions, we can only induce dark matter-nucleus scattering for large values of  $v_{\min}$ , i.e. at the tail of the Maxwell-Boltzmann distribution [18], thus weakening the direct detection bounds. For concreteness, as long as  $\delta > 80$  keV, the bounds from direct detection are relatively weak [7], thus not shown in Fig. 3. Anyway, in our collider reach study, we have not made any assumption regarding the fermion  $N_2$ . Therefore, we take it to be sufficiently heavier than N, with no prejudice. In summary, direct detection yields less restrictive bounds compared to lepton flavor violation, even in this extended scenario with an additional SM singlet.

# LHC BOUNDS

There are constraints on this scenario from LHC, which arise from slepton searches. Since the inert scalar,  $\eta$  is a  $SU(2)_L$  doublet, one can use the limits from left-handed selectron and smuon searches;  $\eta$  will be pair-produced and then decays back to dark matter. This analysis has been carried out by the ATLAS collaboration [19], and they could probe inert doublet masses up to 170 GeV only. That is why we have not included those limits in Fig. 3.

### CONCLUSIONS

We have shown that LHeC, a collider that features a trade-off in the high energy and intensity frontier, can probe a weak scale fermion dark matter particle, N, for masses up to 350 GeV, through a generic Lagrangian containing an inert doublet. We found that the  $e_i + E_i$ and  $\mu j + \not E$  signal topologies are promising and derived  $3\sigma$  signal contours for a LHeC setup consisting of 60 GeV electrons colliding with 7 TeV protons and an integrated luminosity of  $\mathcal{L} = 1$  ab<sup>-1</sup>. We computed the dark matter relic density in the standard freeze-out regime, found that direct detection and LHC bounds are subdominant, and put our findings into perspective with the lepton flavor unique opportunity to detect a weak scale dark matter candidate that reproduces the correct relic density and yield a positive signal at  $\mu \rightarrow e\gamma$  probes in the next generation of experiments.
