ABSTRACT

The evidence of a relation between the mass accretion rate and the disk mass is established for young, Class II pre-main sequence stars. This observational result opened an avenue to test theoretical models and constrain the initial conditions of the disk formation, fundamental in the understanding of the emergence of planetary systems. However, it is becoming clear that the planet formation starts even before the Class II stage, in disks around Class 0 and I protostars. We show for the first time evidence for a correlation between the mass accretion rate and the disk mass for a large sample of Class I young stars located in nearby (< 500 pc) star-forming regions. We fit our sample, finding that the Class I objects relation has a slope flatter than Class II stars, and have higher mass accretion rates and disk masses. The results are put in context of the disk evolution models.

Keywords: Star formation; Stellar accretion disk; Protostars; Low mass stars; Planet formation; Circumstellar disks; Circumstellar dust

1. INTRODUCTION

Young stellar objects (YSOs) evolve as a result of a complex interplay between the forming star, the circumstellar disk, where planet formation occurs, and the envelope. Modeling efforts to describe such intricate interplay span all ranges of the protostellar lifetime from pre-stellar cores to non-accreting young stars. However, the comparison of theoretical predictions with observations of stellar properties is limited to the well-characterized Class II disks of the pre-main-sequence phase (Manara et al. 2022, and references therein).

Observations of the Class 0/I stages are especially important in the context of constraining the initial conditions for the models of disk evolution. In particular, a fundamental parameter which describes part of this interplay is the mass accretion rate (\dot{M}_{acc}) which correlates with the disk mass (M_{disk}). This correlation was predicted by viscous model (Hartmann et al. 1998), and recently confirmed by observations (Manara et al. 2016) for Class II objects.

Since the advent of submillimeter interferometry and complete surveys of planet-forming disks, our knowledge of the disks around the youngest protostars has greatly expanded (Sheehan & Eisner 2017; Williams et al. 2019; Maury et al. 2019; Tychoniec et al. 2020; Tobin et al. 2020; Miotello et al. 2022). At the same time, thanks to new infrared (IR) facilities, some efforts to characterize stellar properties of the youngest stars (e.g., Laos et al. 2021; Fiorellino et al. 2021) as well as available archival observations (Muzerolle et al. 1998; White & Hillenbrand 2004; Doppmann et al. 2005; Connelley & Greene 2010) show a promising way to investigate M_{acc} in the protostellar phase.

In this letter we put recent observations of Class I protostars in the context of disk evolution models, both in the viscous and disk wind paradigms (Lodato et al. 2017; Tabone et al. 2021), and models of early stages of core collapse and disk formation (Zhao et al. 2020; Hennebelle et al. 2020). We present and discuss the

\dot{M}_{acc} vs. M_{disk} relation for the first time for Class I protostars.

2. SAMPLE & METHOD

This work is based on the already existing observations of protostellar sources. The sample analysed here is composed of 26 Class I young stars (whose spectral index between 2 and $24\ \mu\text{m}$ is $\alpha > -0.3$, i.e. we include also Flat spectrum objects) located within 500 pc of the Sun. The choice of these sources is driven by the need of an homogeneous computation of the mass accretion rate and the disk mass. Therefore, we collect sources whose accretion analysis is based on near-IR (NIR) spectroscopic tracers, and for which millimeter archival data from which we calculate the disk dust mass are available. These criteria were satisfied by the 3 objects from Nisini et al. (2005a) in Corona Australis cloud; the 3 objects from Antonucci et al. (2008) all within 450 pc; 6 objects out of the 10 analysed by Fiorellino et al. (2021) in NGC 1333 cluster in the Perseus star-forming region; and 14 objects from Fiorellino et al. (submitted) out of the 40 protostars analysed therein. The list of targets included in the analysis is reported in Appendix A.

2.1. The Mass Accretion Rate

The mass accretion rate for all these sources was computed by using similar methods that provide comparable results. The main common assumption is that the accretion during the Class I stage can be described through the magnetospheric accretion scenario (for a recent review, see Hartmann et al. 2016) and computed with the related equation:

$$\dot{M}_{\text{acc}} \sim \left(1 - \frac{R_{\star}}{R_{\text{in}}}\right)^{-1} \frac{L_{\text{acc}} R_{\star}}{GM_{\star}} \quad (1)$$

where R_{in} is the inner-disk radius which we assume to be $R_{\text{in}} \sim 5R_{\star}$ (Hartmann et al. 1998), and G is the gravitational constant. Nisini et al. (2005a) computed the accretion luminosity by the difference between the bolometric and the stellar luminosity. They found that their results for Class I protostars were in agreement with L_{acc} computed using empirical relations which link the HI emission lines, Pa β and Br γ , with the accretion luminosity in Class II PMS stars from Muzerolle et al. (1998). Antonucci et al. (2008) derived the accretion rates using a self-consistent method based on the aforementioned empirical relations, the assumption that the bolometric luminosity is the sum of the accretion and stellar luminosity ($L_{\text{bol}} = L_{\text{acc}} + L_{\star}$), the equation of the bolometric magnitude in K band: $M_{\text{bol}} = BC_K + m_K + 2.5 \log(1 + r_K) - A_K - 5 \log(d/10\text{pc})$, and the assumption that these sources lie on the birthline (as described by Palla & Stahler 1990). Later on,

Fiorellino et al. (2021) and Fiorellino et al. (submit.) adopted the same self-consistent method by using the most recent empirical relations by Alcalá et al. (2017) and assuming the age of these sources is between the birthline and 1 Myr, based on *Spitzer*-based lifetime estimates for Class I and Flat objects (Enoch et al. 2009; Dunham et al. 2014). For a detailed description of the self-consistent method we refer the reader to Antonucci et al. (2008) and Fiorellino et al. (2021). Average errors on the mass accretion rate is 0.8 dex (Fiorellino et al. 2021). However, we note that since young stars variability, a further 0.5 mag uncertainty in flux (Lorenzetti et al. 2013) should be considered. This propagates a variation on the flux of about 50%, enlarging the uncertainties on the \dot{M}_{acc} as a consequence.

We would like to focus the attention of the reader on the following observational limit. This kind of mass accretion analysis is possible only for sources where the IR veiling due to the disk and envelope is sufficiently low that we can see the photosphere. Usually, according to the current correspondence between Classes based on the SED spectral index and evolutionary path, the less embedded objects are the more evolved ones. Therefore, we can consider this sample of Class I representative of the brightest and more evolved Class I protostars.

2.2. The Disk Dust Mass

For the overall sample we performed a coordinate and sources name search across the literature and also looked for archival interferometric data. We included a dust mass measurement in our analysis if the flux measurement was available at $<1''$ resolution. In the sub-arcsecond regime with size of the beam comparable to the disk size, the envelope contribution is usually negligible, especially for Class I systems where the envelope is largely dissipated. In the sub-arcsecond regime with size of the beam comparable to the disk size, the envelope contribution is usually negligible, especially for Class I systems where the envelope is largely dissipated (Tychoniec et al. 2020). If there was no flux reported in the literature but data was available in the archive, we performed 2D Gaussian fit to the continuum image to extract the flux density.

ated (Tychoniec et al. 2020). If there was no flux reported in the literature and data was available in the archive, we performed 2D Gaussian fit to the continuum image to extract the flux density. This was done on the pipeline processed products in the archive, without any additional processing.

From the flux density (F_{ν}) we calculated the dust mass by inverting the modified black-body equation:

$$M_{\text{dust}} = \frac{d^2 F_{\nu}}{\kappa_{\nu}(\beta) B_{\nu}(T_{\text{dust}})}, \quad (2)$$

where d is the distance to the source, B_ν is the Planck function for the dust temperature T_{dust} , and κ_ν is the dust opacity at the frequency of the observation ν . The disk mass (M_{disk}) is obtained from the dust mass assuming a typical dust-to-gas ratio of 1:100. Eq. 2 is accurate for optically thin emission, otherwise it provides a lower limit on the dust mass measurement. An isothermal disk with $T = 30 \text{ K}$ is assumed, which is the temperature typically used for young, embedded disks. If the disks are colder, similar to the Class II systems, this would result in the increase of the total dust mass. Dust opacity value at 1.3 mm is $0.00899 \text{ g cm}^{-2}$ from Ossenkopf & Henning (1994) and for observations at different wavelengths the spectral emissivity is scaled with $\beta = 1$, which assumes some degree of grain growth (Natta et al. 2005). With uniform assumptions on dust properties we are not introducing additional discrepancy between the disks measured within different observing projects. The accuracy of the disk mass estimation is a matter of ongoing debate (see Miotello et al. 2022; Manara et al. 2022, and references therein). Several studies point to severe underestimation of the disk mass due to optical thickness or dust scattering (Zhu et al. 2019). Recent work of Sheehan et al. (2022) shows that Class 0/I disk dust masses can be overestimated – especially on the low-mass end – if the simplistic assumption of isothermal disk is used. Combined, these effects would result in increased spread of the disk masses (i.e., more massive disks would be even more massive while the low-mass end would have even lower masses).

3. RESULTS AND DISCUSSION

Viscous models of disk evolution predict a strong correlation between \dot{M}_{acc} and M_{disk} (e.g. Hartmann et al. 1998; Dullemond et al. 2006; Rosotti et al. 2017). In the last years, this relation has been investigated in CTTSs samples thanks to accurate measurements of the mass accretion rate and disk mass for several nearby ($< 500 \text{ pc}$) star forming regions (see Manara et al. 2022, and references therein). In brief, these works show that the predicted trend is confirmed by observations with a spread of about $\sim 1 \text{ dex}$ (Manara et al. 2016). Moreover, the spread is still present for old star-forming regions as Upper Scorpius (Manara et al. 2020). This is contrary to expectations of the viscous model which predicts a decrease of the spread with the age of the CTTSs population. An interesting missing piece of information in this debate is whether the strong correlation is still valid in the earlier stages, where the viscous timescale starts to be comparable or larger than the YSOs lifetime itself. In particular, with information of the accretion rates and disk masses in the earlier stages of evolution

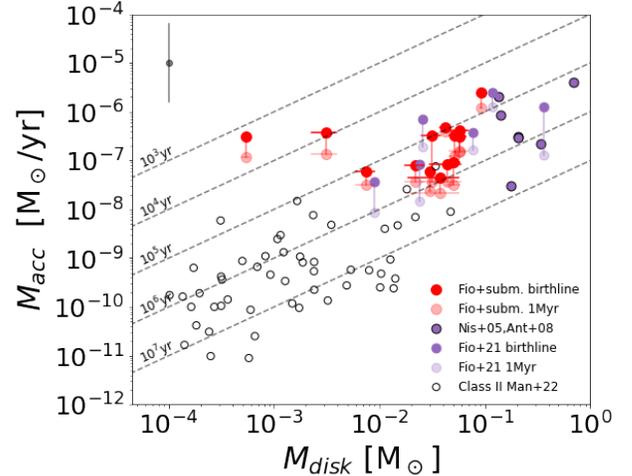

Figure 1. Mass accretion rate vs. disk dust mass. Red filled circles are the Class I sources where \dot{M}_{acc} is the mean value between results assuming the birthline and 1 Myr old evolutive track. Purple filled circles are other Class I from the literature. Empty circles are Class II from Lupus sample. Black dashed lines correspond to several disk depletion times $t_\nu = \dot{M}_{\text{acc}}/M_{\text{disk}}$, from 10^3 yr (top) to 10^7 yr . A representative error bar for the mass accretion rate is shown in grey on the top left corner of the plot.

we can constrain initial conditions for the disk evolution models.

3.1. $\dot{M}_{\text{acc}}/M_{\text{disk}}$ in Class I protostars

Fig. 1 shows the mass accretion rate as a function of the total disk mass for our sample of Class I protostar. For each source, we plot the \dot{M}_{acc} derived assuming the sources on the birthline and the one derived assuming they are 1 Myr old, which correspond to the edges of the possible values. We also plot Class II disks in Lupus, for which properties were obtained by Manara et al. (2022), for a comparison of our sample with more evolved sources. The depletion time $t_\nu = \dot{M}_{\text{acc}}/M_{\text{disk}}$ from 10^3 yr to 10^7 yr are plotted (black dashed lines).

The plot shows that the more disk massive Class I systems are matching a trend seen for Class II disks in Lupus star-forming region from Manara et al. (2016) with depletion times $10^4 \text{ yr} < t_\nu < 10^7 \text{ yr}$. An exception is represented by two protostars, the ones with the less massive disk, and the only two sources laying on a region of the \dot{M}_{acc} vs. M_{disk} described by depletion times shorter than 10^4 yr . Considering the overall sample of Class I, there is a large scatter on \dot{M}_{acc} vs. M_{disk} distribution. This trend is particularly notable in sources with $M_{\text{disk}} < 10^{-2} M_\odot$.

To investigate the relation between Class I and II YSOs samples, we performed a two-sample Kolmogorov-Smirnov test (KS test) to quantify the differ-

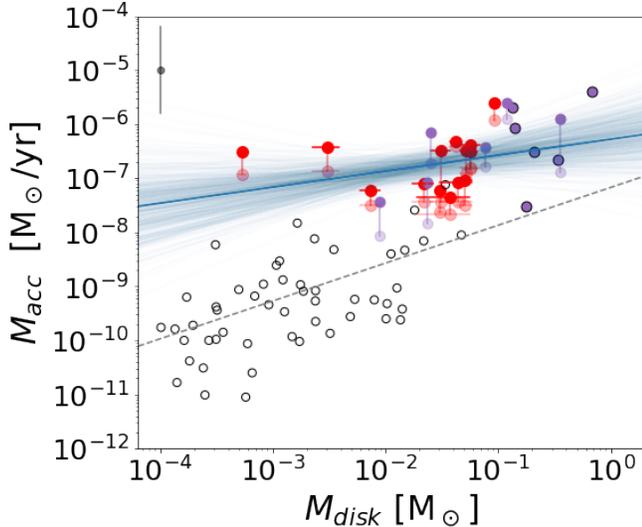

Figure 2. Mass accretion rate vs. disk dust mass. Symbols are as in Fig. 1. The blue line corresponds to our best fit for the overall sample of Class I YSOs, while the light blue lines are a subsample of the results of some chains. The dashed grey shows the best fit for Class II YSOs

(Manara et al. 2016).

ence of their $M_{\text{disk}}/\dot{M}_{\text{acc}}/\text{yr}$ distributions. We obtained that the probability that the Class I and II samples could have been drawn from the same probability distribution is 0.2 considering Class I on the birthline, and 0.4 considering Class I being 1 Myr old. Assuming the two ages as “limits” for our sample, the probability that our sample of Class I YSOs is drawn from the same probability distribution of the Lupus Class II is $0.2 < p < 0.4$. We note that by assuming 1 Myr as the Class I sample age, the probability to have the same statistical distribution of Class II is not negligible. This result shows that the $M_{\text{disk}}/\dot{M}_{\text{acc}}/\text{yr}$ distribution can be separated depending on the evolutionary stage of the disk, evolving with the age. This can be due to a different evolution of the disk during the Class I stage, when the refuel from the envelope is not negligible. Fig. 1 also suggests that Class I disks accrete more material on the central star than Class II.

In Fig. 2 we performed a linear regression fit of the Class I protostars sample (light-blue dashed line) considering the mean value of the \dot{M}_{acc} between the one computed assuming sources on the birthline and 1 Myr old, having as error the standard deviation plus the intrinsic uncertainty. We used the hierarchical Bayesian method by Kelly (2007) which considers error in both the axes of the plot. We found the following relation $\log(\dot{M}_{\text{acc}}) = (0.3 \pm 0.2) \log(M_{\text{disk}}) + (-6.3 \pm 0.3)$ with a standard deviation of 0.4 ± 0.1 . We compare our fit with the one performed for Class II (Manara

et al. 2016). The grey dashed line in Fig. 2 shows the Class II slope of 0.7 ± 0.2 moved upwards in the plot, at the same intercept we obtained. Our best fit shows a slope flatter than the one obtained for Class II, lying always above the Class II sample. We note that if we remove from the fitted sample the two sources with the smallest disk mass, we find a slope of 1.1 ± 0.2 , compatible within the error with the Class II slope. This could suggest that to determine how and how much the Class I and II YSOs $\dot{M}_{\text{acc}} - M_{\text{disk}}$ distributions are different, we should analyse Class I objects with low disk mass, comparable with the disk mass typical of Class II sources, to verify whether these two sources are outliers or Class I show a flatter slope in general. On the other edge of the distribution, we expect that more embedded (and younger) protostars, with $M_{\text{dust}} > 20 M_{\oplus}$ (i.e. $M_{\text{disk}} > 6 \times 10^{-4} M_{\odot}$), would lay above the current distribution, i.e. higher \dot{M}_{acc} and similar M_{disk} , as suggested by simulations by Hennebelle et al. (2020) which provide almost constant value of about $1.5 \times 10^{-2} M_{\odot}$ for protostellar disk mass until 0.16 Myr. In this case, it would be possible to exclude the same evolutionary path (same slope) with different initial disk conditions.

Limiting our discussion to the Class I we analysed, we can state that they tend to have higher mass accretion rate when contrasted with Class II disks with a comparable disk mass, and that the $\dot{M}_{\text{acc}}/M_{\text{disk}}$ distribution is flatter in Class I than in Class II YSOs. This implies that, assuming M_{disk} and \dot{M}_{acc} constant within the Class I lifetime (~ 0.54 yr, Enoch et al. 2009; Dunham et al. 2014), the disk should be dissipated within $10^5 - 10^6$ yr for most of the protostars in our sample. But we know that the presence of the disk on the YSOs systems last until $\sim 10^6 - 10^7$ yr. Possible solutions to this discrepancy are:

- (a) \dot{M}_{acc} is not constant. For example, it can be possible that during this so short evolutionary stage, \dot{M}_{acc} decreases rapidly, reaching lower values typical of Class II objects, not totally dissipating the disk;
- (b) \dot{M}_{acc} is constant during the Class I protostellar stage, but the disk is fuel by an “extra mass” coming from the envelope.

While we still have to collect suitable data to check predictions on the $\dot{M}_{\text{acc}}/M_{\text{disk}}$ distribution which consider a continuous fuel of material from the envelope to the disk (i.e. Hueso & Guillot 2005), the scenario in which \dot{M}_{acc} decreases rapidly to conserve the disk is described Lodato et al. (2017). To investigate this hypothesis, we plot on Fig. 3 the comparison between our results and isochrones by Lodato et al. (2017) for $M_{\text{disk}}/\dot{M}_{\text{acc}} = 10^4, 10^5, \text{ and } 10^5$ yr, and initial disk mass of 0.01, 0.1, and $1 M_{\odot}$. Results suggest that there is no

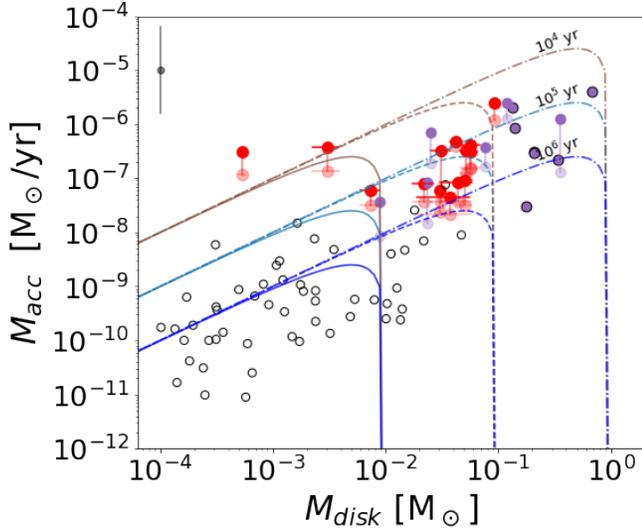

Figure 3. Mass accretion rate vs. disk dust mass. Symbols are as in Fig. 1. Brown, light blue, and blue dashed lines are isochrones from Lodato et al. (2017) at $t_\nu = 10^4$, 10^5 , and 10^6 yr, respectively. For each t_ν we show in solid, dashed, and dash-dotted lines isochrones for three different initial disk masses (0.01 , 0.1 , and $1M_\odot$, respectively).

correlation between the assumed age of the stars and the viscous timescales of the isochrones, and that our data can be reproduced by a variety of isochrones with different t_ν and initial disks conditions. We note that most of the sources cluster in the region between 10^5 and 10^6 yr and $M_{disk,0}$ between 0.01 and $1M_\odot$.

3.2. The \dot{M}_{acc}/M_{disk} Evolution

The comparison between Class I and Class II \dot{M}_{acc}/M_{disk} distributions leads to the question: are our Class I sources going to reproduce Lupus Class II population in 1 Myr? A positive answer to this question would imply not only that the disk is able to survive until Class II stage, but also that the \dot{M}_{acc} and M_{disk} values are compatible with the Class II population ones.

In order to put the measured accretion rates and disk masses in the context of disk evolution models, we plot in Fig. 4 evolutionary tracks of different evolution models, namely viscous evolution, pure disk wind evolution, and hybrid case in which both modes of evolution are in place. Each of the models is briefly described below.

According to Lodato et al. (2017), the evolutionary track of a viscously evolving disk is prescribed as :

$$\dot{M}_{acc} = \frac{1}{2(2-\gamma)} \frac{M_0}{t_\nu} \left(\frac{M_{disk}}{M_0} \right)^{5-2\gamma} \quad (3)$$

where M_0 is the initial disk mass, t_ν is the aforementioned viscous timescale, and γ is a factor depending on the value of the viscosity and the radius of the source.

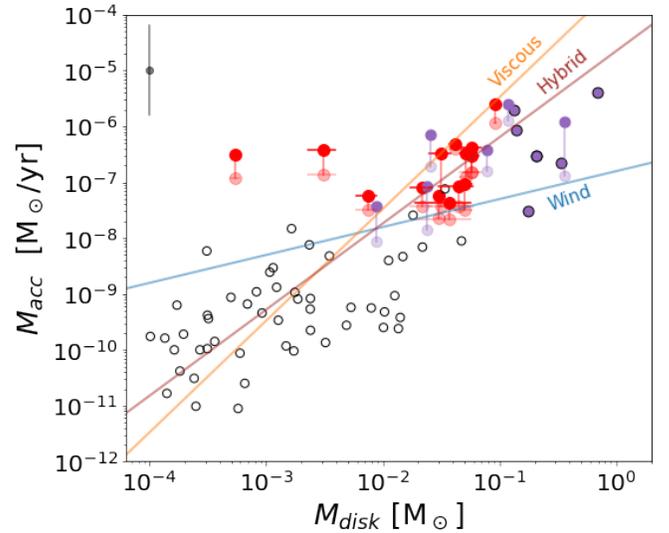

Figure 4. Mass accretion rate vs. disk dust mass. Symbols are as in Fig. 1. Solid lines represent evolutionary tracks assuming different models: purely viscous (orange), hybrid of viscous and MHD wind (brown), and dominated by MHD wind (light blue).

For γ we assume 1.5, following value assumed in Lodato et al. (2017), where 1.5 is shown to be consistent with Minimum-Mass Solar Nebula and the value between 1.2 and 2 is needed to reproduce the evolution of disks in Lupus. We set $M_0=1 M_\odot$ to match presented samples.

Evolution of the disk under both MHD disk wind and viscous effects (i.e. hybrid model) follows a relation described in Tabone et al. (2021):

$$\dot{M}_{acc} = \dot{M}_{acc,0} \left(\frac{M_{disk}}{M_0} \right)^{\frac{\psi+3+4\xi}{\psi+1+2\xi}}, \quad (4)$$

where $\dot{M}_{acc,0}$ is the initial accretion rate, ψ is the ratio between wind and turbulent torque, ξ is the mass ejection index, which is a derivative of $\ln(\dot{M}_{acc})$ over $\ln(r)$ as defined in (Ferreira & Pelletier 1995). Values of the parameters used to compare the model with our results on Fig. 4 are: $\psi=3$, $\xi = 0.1875$ following prescription in Tabone et al. (2021) and $\dot{M}_{acc,0} = 10^5$ yr is used to best fit the data. In a disk where accretion and mass-loss evolution is purely dependent on the MHD wind, the relation can be parametrized as follows (Tabone et al. 2021).

$$\dot{M}_{acc} = \dot{M}_{acc,0} \left(\frac{M_{disk}}{M_0} \right)^{1-\omega}, \quad (5)$$

where ω is an index that describes the dependence of the disk wind torque on characteristic surface density. For the representative comparison we select intermediate value of $\omega=0.5$ and $\dot{M}_{acc,0} = 10^5$ yr to best fit the data.

Tabone et al. (2021) showed that the slope of the evolutionary track changes when MHD disk wind effect are introduced. The slope becomes shallower for disk wind with magnetic field strength decreasing with time, up to becoming completely flat (constant accretion rate with decreasing mass) for constant magnetic field strength with disk evolution. The pure viscous model prescribed by Eq. 3 is shown in Fig. 4 (orange line), together with the evolutionary tracks of an hybrid model of viscous and MHD disk wind (brown line), and another hybrid model where MHD disk wind largely dominates the evolution (brown dashed line), reproduced using Eqs. 60 and 61 in Tabone et al. (2021), respectively. Fig. 4 suggests that we can conclude that the pure viscous model does not describe well the transition between our Class I sample and Lupus Class II, at least, not for the protostars with disk masses $\ll 10^{-2} M_{\odot}$ and $> 0.1 M_{\odot}$. Also the purely MHD disk wind evolution of the accretion disk seems unlikely to reproduce the evolution from Class I to Class II that we observe. But it is interesting to notice that the slope of the MHD wind model can reproduce the trend of the only Class I sample if shifted toward the top of the plot, i.e. by assuming higher \dot{M}_{acc} . However, the plot qualitatively suggests that the hybrid model can better represents both the Class I and II data distribution, therefore some wind contribution should be included in the viscous evolution to best reproduce the observations.

Limitations of comparing our observational results with models lies in the following two reasons. First, these models do not investigate the earliest stages of the star formation, in other words, both models by Lodato et al. (2017) and Tabone et al. (2021) set the disk mass to a fixed value which dissipates with time as mass is accreted on the forming star, while in the protostellar phase the disk mass is replenished by the envelope. Second, both the magnetic effects and the disk viscous timescale depends on the environmental effects, and our sample is composed by Class I stars belonging to very different regions in the solar neighborhood. Naturally, observations of single star-forming clouds and models that include the earliest stages of disk formation are necessary to further constrain the disk wind and viscous models. Also, the disk masses are highly uncertain, so obtaining disk masses at longer wavelengths like the upcoming Band 1 of ALMA or the shortest VLA wavelengths would improve this analysis. Moreover, the uncertainty on the protostars' age propagates to the mass accretion rate, providing uncertainties larger than for Class II PMS stars.

3.3. \dot{M}_{acc} vs. M_{disk} relation and planets formation

Assuming that planets form by accreting materials onto planetesimals, and given some assumptions on the disk structure and evolution, in the last decade many population synthesis models were developed to describe different kind of produced exoplanetary systems (see Benz et al. 2014, for a review). In particular, the population synthesis of planet formation by Lubow & D'Angelo (2006) predicts a population of disks with greatly decreased accretion rates onto protostars due to the presence of gas giant planets. We do not see this population in the $\dot{M}_{\text{acc}} - M_{\text{disk}}$ plot, as Manara et al. (2019) for CTTSs, showing that this effect is not present even in younger disks. It is unclear if those disks are massive enough to host gas giants or perhaps this effect is not present in general.

4. SUMMARY AND CONCLUSIONS

We presented for the first time in this letter the \dot{M}_{acc} vs. M_{disk} plot populated with also Class I YSOs, shifting to the protostellar stage the investigation of the disk initial conditions, crucial to understand the star and planet formation. Our data show that younger sources present higher mass accretion rate, more massive disks in general, and have “depletion times” (i.e. $M_{\text{disk}}/\dot{M}_{\text{acc}}$) faster than Class II YSOs suggesting an evolutionary trend between Class I and II YSOs. We also measure higher \dot{M}_{acc} in Class I than in Class II with the same disk mass. Since our sample is limited to brightest and, thus, older sources among Class I, we can consider our results as lower limits for Class I in general.

We fitted the $\dot{M}_{\text{acc}}/M_{\text{disk}}$ distribution of our Class I sample finding a slope flatter than the corresponding slope for Class II sources. But focusing only on the more massive disks, we found the Class I slope is in agreement with the Class II slope, suggesting that differences between the $\dot{M}_{\text{acc}} - M_{\text{disk}}$ distributions of Class I and II should be investigated in protostars whose disk mass is comparable with typical Class II M_{disk} .

We tested our results with most recent viscous and MHD wind models. We tentatively speculate that our data can be described by viscous model together with some contamination by MHD winds (hybrid model). However, we find no definitive conclusions about which of these models better represent our data. We associated this to the absence of an envelope feeding the disk in these models, and to the fact that even if our sample is analysed in an homogeneous way, it is affected by different environmental effects, since these protostars belong to different star-forming regions.

Uniform samples of Class I and Class II protostars with identical initial conditions, i.e. in the same star-

forming region, and theoretical models which describe both stages are necessary to draw solid conclusions on the evolutionary path of YSOs and to be able to set the initial conditions for stars and planets formations. While VLT/KMOS can be used efficiently on larger samples, JWST will deliver most sensitive information on photospheres with NIRSpec and eventually enable the investigation of the protostellar accretion rates for even more embedded sources with MIRI.
