ABSTRACT

Obscuring winds driven away from active supermassive black holes are rarely seen due to their transient nature. They have been observed with multi-wavelength observations in a few Seyfert 1 galaxies and one broad absorption line radio-quiet quasar so far. An X-ray obscuration event in MR 2251-178 was caught in late 2020, which triggered multi-wavelength (NIR to X-ray) observations targeting this radio-quiet quasar. In the X-ray band, the obscurer leads to a flux drop in the soft X-ray band from late 2020 to early 2021. X-ray obscuration events might have a quasi-period of two decades considering earlier events in 1980 and 1996. In the UV band, a forest of weak blueshifted absorption features emerged in the blue wing of Ly α λ 1216 in late 2020. Our XMM-Newton, NuSTAR, and HST/COS observations are obtained simultaneously, hence, the transient X-ray obscuration event is expected to account for the UV outflow, although they are not necessarily caused by the same part of the wind. Both blueshifted and redshifted absorption features were found for He I λ 10830, but no previous NIR spectra are available for comparison. The X-ray observational features of MR 2251-178 shared similarities with some other type 1 AGNs with obscuring wind. However, observational features in the UV to NIR bands are distinctly different from those seen in other AGN with obscuring winds. A general understanding of the observational variety and the nature of obscuring wind is still lacking.

Keywords: black hole physics – quasars: individual (MR 2251-178) – X-rays, ultraviolet, infrared: galaxies – techniques: spectroscopic

At the center of almost all galaxies, there is a supermassive black hole (Netzer 2015). Active Galactic Nuclei (AGN) are the observed manifestation of the inflow of matter onto supermassive black holes. The textbook anatomy of an AGN not only includes a supermassive black hole fed by an accretion disk but also clouds in the broad- and narrow-line regions, as well as the dusty torus (Antonucci 1993). Clouds in the broad- and narrow-line regions account for the broad

(with a typical velocity width $\gtrsim 1000 \; \rm km \; s^{-1}$) and narrow ($\lesssim 1000 \; \rm km \; s^{-1}$) emission lines observed in the optical spectra (Padovani et al. 2017).

Ionized winds driven away from black holes have also been observed (Crenshaw et al. 2003; Tombesi et al. 2013; Kaastra et al. 2014), which might be another key element to be included in the textbook anatomy of AGN (Antonucci 1993). These ionized winds are thought to play an important role in the evolution of black holes and their host galaxies (Laha et al. 2021). In the X-ray band, three types of ionized winds have been observed so far: warm absorbers, ultrafast outflows, and obscurers. The classical warm absorbers are identified with multiple narrow absorption lines with a typical outflow velocity of $\lesssim 10^3 \text{ km s}^{-1}$ (Crenshaw et al. 2003). Ultrafast outflows are mainly inferred from the absorption features of highly ionized Fe XXVI and/or Fe XXV in the hard X-ray band (e.g., Reeves et al. 2003; Tombesi et al. 2013; Parker et al. 2017). The outflow velocity of ultrafast outflows can reach up to about a third of the speed of light ($\sim 10^{4-5} \text{ km s}^{-1}$). Obscuring winds have outflow velocities up to $\sim 6000 \text{ km s}^{-1}$ (Kaastra et al. 2014; Mehdipour et al. 2017), larger than that of the warm absorber but smaller than that of ultrafast outflows. The outflow velocities are currently measured through discrete blueshifted absorption features in the UV band during the soft X-ray obscuration period, where the soft X-ray flux are significantly lowered with no discrete absorption features observable with current instruments (Mao et al. 2022). Furthermore, ultrafast outflows occupy the high column density and ionization parameter $(N_{\rm H} - \xi)$ part of the parameter space, while warm absorbers occupy the other side of the parameter space. Obscuring winds are in between, overlapping more with the warm absorber.

In the past few years, transient obscuring winds have been reported with multi-wavelength observations in a few nearby ($z \lesssim 0.16$) Seyfert galaxies: NGC 5548 (Kaastra et al. 2014), NGC 985 (Ebrero et al. 2016), NGC 3783 (Mehdipour et al. 2017; Kaastra et al. 2018b), Mrk 335 (Longinotti et al. 2013, 2019), Mrk 817 (Miller et al. 2021; Kara et al. 2021), and NGC 3227 (Mehdipour et al. 2021; Mao et al. 2022). In addition, obscuring winds were also inferred from archival joint X-ray and UV observations of the broad absorption line (BAL) quasar PG 2112+059 at $z \sim 0.46$ (Saez et al. 2021). The duration of the obscuration varies from hours (e.g., NGC 3227, Wang et al. 2022) to years (e.g., NGC 5548, Mehdipour et al. 2016b). During the obscuration period, the wind properties (e.g., the line-of-sight hydrogen column density, ionization parameter, and covering factor) can also change over time (De Rosa et al.

2015; Mehdipour et al. 2016b; Cappi et al. 2016). In UV grating spectra, the obscurers might leave their fingerprints as blueshifted broad absorption troughs in the blue wing of prominent broad emission lines like Ly α λ 1216 and C IV $\lambda\lambda$ 1548, 1550 (e.g., Kriss et al. 2019a). For the long-lasting obscurer in NGC 5548, a blueshifted broad absorption trough of He I* λ 10830 was observed in the NIR (Landt et al. 2019; Wildy et al. 2021). The obscurers are also expected to screen photons from the central engine to the distant narrow-line region (Kaastra et al. 2014; Mehdipour et al. 2017). This shielding effect (Proga & Kallman 2004) can give rise to the emergence of low-ionization narrow absorption lines in the UV and NIR bands (Arav et al. 2015; Kriss et al. 2019a; Wildy et al. 2021).

Obscurers might contribute to the weakening and disappearance of broad emission lines if the obscuration effect is not limited to our line-of-sight. For NGC 5548, a "broad-line holiday" (from April to July 2014) was discovered (Goad et al. 2016), where broad emission lines of highly-ionized species like C IV $\lambda\lambda 1548, 1550$ decorrelate from the variations of the FUV continuum. From the theoretical perspective, Dehghanian et al. (2019a,b) suggest that a dense wind with its base extended down to the accretion disk might provide the physical explanation of the "broad-line holiday", as well as the aforementioned UV and X-ray spectral features observed in NGC 5548. Moreover, if the wind is adequately dense, even the "changing-look" behavior of some AGN might be explained (Dehghanian et al. 2019b). For Mrk 817, in a period of 55 days in late 2020, when the target was heavily obscured, the UV continuum and the UV broad emission line variability decoupled (Kara et al. 2021).

MR 2251-178 is the X-ray brightest radio-quiet quasar (Cooke et al. 1978; Ricker et al. 1978). It has a black hole mass of $(2.0 \pm 0.5) \times 10^8 \ M_{\odot}$ (Lira et al. 2011) and is at z = 0.06398 (Beckmann et al. 2006). By comparing two X-ray spectra observed with the Einstein Observatory in 1979 and 1980, Halpern (1984) noticed an increase in the absorbing column density by a large factor over the ~ 1 yr interval. Using Rossi X-ray Timing Explorer (RXTE) data from 1996 to 2012, Markowitz et al. (2014) also identified a clear obscuration event in 1996. Here, we present another obscuration event in MR 2251-178 in late 2020 caught with multi-wavelength observations, including a Swift monitoring campaign, coordinated observations with Hubble Space Telescope (HST), XMM-Newton, and NuSTAR on 2020-12-16, and NIR and optical spectroscopy using NASA's Infrared Telescope Facility, Gemini, Keck, and Palomar from September to December 2020.

Table 1. Observation log of MR 2251-178 used in the present work. All archival Swift observations were also used, but are not listed here. The Swift target IDs are 00049534, 00092238, 00093126, 00093159, 00094001, 00095001, 00095654, 00081592, and 00089190.

Observatory	Date	Note (e.g., ObsIDs and duration)

2. OBSERVATIONS AND DATA REDUCTION

Apart from the archival Swift observations from 2014-01-09 to 2021-05-10, NIR to X-ray observations used in the present work are provided in Table 1. In the same table, some archival observations are also included for comparison purposes. Note that MR 2251-178 was put in the spotlight by Chandra (in coordination with HST/COS) and XMM-Newton (about one month after the Chandra observations) in 2011. The high-quality X-ray data were analyzed extensively in Reeves et al. (2013, for Chandra) and Nardini et al. (2014, for XMM-Newton). We do not include these observations in this work because our main focus is the transient obscuring wind observed in late 2020 with multi-wavelength observing facilities. We do not find obscuring winds in the 2011 X-ray (and UV) data, where the broadband continuum level was much higher than those in 2002 and 2020.

2.1. *Swift*

The Neil Gehrels Swift Observatory (Gehrels et al. 2004) provides the most efficient way to track the long-term variation of the X-ray and UV flux of AGN. The X-ray flux was provided by the X-ray telescope (XRT, Burrows et al. 2005) operating in imaging photon counting (PC) mode. The soft $(0.3-1.5~{\rm keV})$ and hard $(1.5-10~{\rm keV})$ band flux were obtained with the online XRT pipeline (Evans et al. 2009). The UV flux was covered by the UltraViolet and Optical Telescope (UVOT, Roming et al. 2005). The UVW2 (centered around 1928 Å) flux, which historically has shown the

strongest UV variability, was used here. The *uvotsource* tool was used to perform aperture photometry.

The obscurer can absorb a large fraction of the soft X-ray flux, thus, leading to an elevated X-ray hardness ratio. Simultaneous UV and X-ray data enable us to distinguish variability caused by an obscurer from that of the AGN continuum (e.g., Mehdipour et al. 2016b, 2017, 2022b).

For MR 2251-178, archival Swift observations date back to 2014-01-09 (Figure 1). Since the summer of 2020, the Swift X-ray hardness ratio has been gradually increasing (Figure 2). Therefore, we requested multi-wavelength spectroscopic observations of MR 2251-178 with facilities on the ground and in space from September to December 2020, including a coordinated campaign with XMM-Newton, HST/COS, and NuSTAR on 2020-12-16, to confirm the obscuration event and to study the nature of the obscuring material. The Swift X-ray hardness ratio of MR 2251-178 remained at a relatively high level up to 2021-01-05. The target was out of visibility between January and April 2021. In May 2021, the hardness ratios returned to the historical average value.

2.2. XMM-Newton

XMM-Newton (Jansen et al. 2001) observations provide high-quality X-ray spectra in the energy band of 0.3-10 keV. The Reflection Grating Spectrometer (RGS, den Herder et al. 2001) provides high-resolution soft X-ray spectra below ~ 2 keV, which can reveal discrete emission and absorption features. The

Figure 1. Archival Swift XRT and UVOT observations of MR 2251-178 from 2014-01-09 to 2021-05-10. The top panel is the UVW2 flux. The two middle panels are the count rates in the hard (H: $1.5-10~{\rm keV}$) and soft (S: $0.3-1.5~{\rm keV}$) X-ray bands. The bottom panel shows the X-ray hardness ratio R = (H-S)/(H+S). The horizontal solid line in red is the historical average hardness ratio before late 2020. The vertical dashed line in purple marks the joint XMM-Newton + HST/COS + NuSTAR observation on 2020-12-16.

Figure 2. A close-up view of the Swift UVW flux and X-ray hardness ratio from Aug. 2020 to May. 2021, as well as in 2002. The uncertainties of the observed UVW2 flux are too small to be seen in the plotting scale. The 2002 UVW2 flux is obtained with the XMM-Newton Optical Monitor, while the Swift X-ray hardness ratio is simulated based on the best-fit model to this XMM-Newton observation.

positive-negative junction (pn) CCD (charge-coupled device) camera of the European Photon Imaging Camera (EPIC) instrument can cover hard X-ray spectra in the $2-10~{\rm keV}$ energy band. Adding EPIC/MOS data does not significantly increase the statistics and will

complicate the analysis due to cross-calibration among different instruments. We used the XMM-Newton Science Analysis Software (SAS) v19.0 for data reduction following standard procedures. We also include an XMM-Newton observation of MR 2251-178 obtained on 2002-05-18 (observation ID: 0012940101) for comparison purposes. Both 7-38 Å RGS data and 1.55-10 keV EPIC/pn data were used for spectral analysis (Sect. 3). To correct for the cross-calibration between RGS and EPIC-pn spectra, the latter were re-scaled by a factor of 0.950 (2002) and 0.966 (2020) to match the flux level in the 7-8 Å overlapping wavelength range.

2.3. NuSTAR

NuSTAR (Harrison et al. 2013) complements X-ray spectra obtained with XMM-Newton in the energy band up to 79 keV. Our NuSTAR data were reduced with the NuSTAR Data Analysis Software (NUSTARDAS) and CALDB version 20201101. The FPMA and FPMB source spectra were extracted from a circular region centered on the point source with a radius of 80 arcsec. The background spectra of equivalent extraction radius were extracted from a nearby source-free region. The 5 – 78 keV NuSTAR data were used for spectral analysis (Sect. 3). To correct for the cross-calibration among spectra collected by XMM-Newton and NuSTAR, the latter were re-scaled (with respect to RGS) by a factor

of 0.962 (FPMA) and 1.045 (FMPB) to match the flux level in the 5-10 keV overlapping energy range.

2.4. HST/COS

The Cosmic Origin Spectrograph aboard the Hubble Space Telescope (HST/COS, Green et al. 2012) provides high-quality FUV spectra in the wavelength range 1070 - 1800 Å at a resolving power of $R \sim 15000$. We use both the archival observations in 2011 and the new single-orbit observation in 2020. The archival observations used grating G130M with central wavelength settings of 1291 Å, 1300 Å, 1309 Å, and 1318 Å, and G160M with central wavelengths settings of 1589 Å, 1600 Å, 1611 Å, and 1623 Å. In 2020, we used G130M at the 1222 Å central wavelength setting and all four FPPOS locations along with G160M at central wavelengths settings of 1533 Å and 1589 Å. The multiple central wavelengths and FPPOS settings permit our spectra to span the gaps between detector segments and enable us to eliminate detector artifacts and improve the flat-field properties by sampling each wavelength at different detector locations. We retrieved calibrated data from the Mikulski Archive for Space Telescopes (MAST) and reprocessed with COS pipeline version 3.3.10, which incorporates all improvements related to wavelength scales, error propagation, and time-dependent sensitivity. Measurement of the centroids of interstellar absorption features revealed no need for any zero-point corrections to the wavelength scale, which is accurate to 5 km $\rm s^{-1}$ (Dashtamirova & Fischer 2020).

To extend the archival 2011 spectrum to shorter wavelengths, we used FUSE observations from 2001 with optimal reprocessing as described by Kriss (2006), and scaled the flux of the FUSE spectrum to match that of COS in the overlapping wavelength range of 1135 – 1180 Å. An archival HST Faint Object Spectrograph (FOS) observation from 1996 was also used for comparison purposes.

2.5. NIR and optical spectroscopy

We obtained NIR spectroscopy on three occasions. To our knowledge, these data are the first NIR spectra of MR 2251–178. On 2020-09-06, we used the SpeX instrument (Rayner et al. 2003) on NASA's Infrared Telescope Facility (IRTF) equipped with the short cross-dispersed mode (SXD, 0.7 – 2.55 μ m) and a 0.3" × 15" slit, which we oriented at the parallactic angle. This setup gives an average spectral resolving power of R=2000. The on-source exposure time was 60×120 s and the weather was photometric with a seeing of 0.46 arcsec, resulting in a high-quality spectrum with an average continuum $S/N \sim 60$. Before the science target, we observed the

nearby (in position and airmass) A0 V star HD 218639 and used this standard star to correct our science spectrum for telluric absorption and for flux calibration. We reduced the data using Spextool (version 4.1), an Interactive Data Language (IDL)-based software package developed for SpeX (Cushing et al. 2004) which carries out all the procedures necessary to produce fully reduced spectra.

On 2020-09-30, we obtained a similar cross-dispersed NIR spectrum with the Gemini Near-Infrared Spectrograph (GNIRS; Elias et al. 2006) at Gemini North in queue mode (Program ID: GN-2020B-FT-111). We chose a slit of $0.3'' \times 7''$, which we oriented at the parallactic angle, and obtained an on-source exposure time of 16×120 s. This setup resulted in a spectrum with an average resolution of R=1400 and a continuum $S/N \sim 100$. We reduced the data using the Gemini/IRAF package (version 1.13) with GNIRS specific tools (Cooke & Rodgers 2005). We again selected HD 218639 as our standard star for telluric correction and flux calibration.

Then, one week after the coordinated XMM-Newton, HST/COS, and NuSTAR observations, we obtained on 2020-12-23 a final cross-dispersed NIR spectrum, with TripleSpec (Wilson et al. 2004) at the Palomar 5 m. The entrance slit for this instrument is fixed at $1''\times 30''$, which gives a spectral resolving power of R=2700. The weather was good and the on-source exposure time of 32×120 s resulted in a spectrum with a continuum $S/N\sim 15$. The somewhat reduced quality of this spectrum relative to those from the IRTF and Gemini is due to a high airmass (sec z=1.782) and a higher spectral resolution.

We obtained optical spectroscopy on two occasions. On 2020-10-18, we used the Low Resolution Imaging Spectrometer (LRIS; Oke et al. 1995) mounted on the Keck 10 m telescope equipped with the 600/4000 and 400/8500 gratings for the blue and red arms, respectively, and the 1.5" slit. This setup gives a relatively large spectral coverage of $\sim 3100-10300$ Å, with a very small spectral gap of ~ 40 Å between the two arms. The average spectral resolving power is R=750. The slit was rotated to the parallactic angle, but note that LRIS has an atmospheric dispersion corrector. The onsource exposure time was 300 s at an average airmass of $\sec z=1.349$, and resulted in an average continuum $S/N\sim70$. The data were reduced using standard longslit routines from the IRAF software package.

Five days before the coordinated multi-wavelength observations, we obtained on 2020-12-11 an optical spectrum at the Palomar 5 m with the Double Spectrograph (DBSP) instrument (Oke & Gunn 1982). Similar

to LRIS, a dichroic splits the light into separate blue and red channels and we chose for these the 600/4000 and 316/7500 gratings, respectively. We observed through a 2" slit oriented at a parallactic angle for a total exposure time of 300 s. This setup resulted in a spectrum with an average resolving power of R=750 and a continuum $S/N\sim25$. The night was not photometric, hence, the entire DBSP spectrum needs to be increased by a factor of 1.7 to match the O [III] $\lambda5007$ line peak of Keck/LRIS.

3. SPECTRAL ANALYSIS

We use SPEX v3.05.00 (Kaastra et al. 1996, 2018a) and C-statistics for the X-ray spectral analysis (Kaastra 2017). Statistical uncertainties are quoted at the 68% confidence level. The protosolar abundances of Lodders & Palme (2009) were used for all the plasma models.

We include model components described as the following to account for continuum, emission, and absorption features simultaneously. For the intrinsic continuum, the NIR to UV data collected in 2020 provide constraints above the Lyman limit ($\lambda > 912$ Å), while the X-ray data provide constraints below the Lyman limit.

3.1. Spectral model components above the Lyman limit

The AGN continuum above the Lyman limit can be described as a disk blackbody model. We use the dbb in SPEX, which is a geometrically thin but optically thick Shakura-Sunyaev accretion disk (Shakura & Sunyaev 1973). Its normalization and temperature are left free during the fitting. The Milky Way reddening along our line-of-sight is taken into account with frozen parameters E(B-V)=0.039 (Schlegel et al. 1998) and $R_V=3.1$, as used by Nardini et al. (2014).

We use line-free zones in both the HST/COS spectrum ($\sim 1135-1205,\ 1356-1364,\$ and $1428-1442\$ Å) obtained on 2020-12-16 and the Keck/LRIS spectrum ($\sim 6000-6050,\ 6530-6580,\ 7350-7400,\$ and $7950-8050\$ Å) obtained on 2020-10-18 to constrain dbb parameters. To account for the host galaxy emission in the Keck spectrum, a template starlight emission from the bulge (Kinney et al. 1996) was included as a file model with its normalization free to vary (Mehdipour et al. 2015). The modeled luminosity of the host galaxy emission is $1.47\times 10^{43}\ {\rm erg\ s^{-1}}$ in the $1000-10000\$ Å wavelength range. The dusty torus (NIR excess in Figure 4), Balmer continuum and blended Fe II emission (the blue bump near UV) are not included in our modeling.

3.2. Spectral model components below the Lyman limit

To model the AGN continuum below the Lyman limit, we use a Comptonized disk component (*comt*, Titarchuk 1994), a power-law component, and a neutral reflection component (*refl*, Magdziarz & Zdziarski 1995; Życki

Figure 3. XMM-Newton spectra of MR 2251-178 from 2002-05-18 (black) and 2020-12-16 (pink). The 2002 observation used the UVW2, UVM2, UVW1, and V filters, while the 2020 observation used all six optical and UV filters. The apparent lowering of the soft X-ray flux in 2020 is due to the presence of the obscurer.

et al. 1999). The warm Comptonization (comt) is one of the possible interpretations of the soft X-ray excess in AGN (Crummy et al. 2006; Dauser et al. 2010; Done et al. 2012; Petrucci et al. 2013). As shown in our previous works (e.g., Mehdipour et al. 2015, 2017, 2021), it suits our purpose of building a broadband SED for photoionization modeling. The power-law component was cut-off exponentially below the Lyman limit and above 100 keV (Orr et al. 2001). We refer readers to A. Gonzalez et al. (in prep) for a detailed study on the X-ray continuum and its variability over the past two decades. The Galactic absorption in the X-ray band was modeled with a hot model in SPEX. The line-of-sight hydrogen (H I and H₂) column density was fixed to 2.71×10^{20} cm⁻² (Willingale et al. 2013).

The photoionization model pion (Miller et al. 2015; Mehdipour et al. 2016a; Mao et al. 2017) in SPEX was used for both the warm absorber and emitter (e.g., Mao et al. 2018, 2019). Similar to Reeves et al. (2013), three pion absorption components are required with distinct parameters (hydrogen column density, ionization parameter, and kinematics) for the warm absorber. For the warm emitter, two pion emission components are required.

As shown in Figure 3, while the flux in the optical, UV, and hard X-ray bands in 2020 are comparable to those in 2002, the soft X-ray flux was significantly lower due to the presence of the obscurer. The obscurer was modeled as an additional *pion* absorption component for the 2020 data set.

4. RESULTS

4.1. Broadband AGN SED

After taking into account all the obscuration, absorption, emission, and extinction effects, we derive the best-fit parameters of the broadband SED parameters for both 2002 and 2020 (Table 2). We used relatively simple spectral model components to construct the SED, which is sufficient for the purpose of photoionization modeling. In Figure 4, we illustrate the derived broadband 2020 SED model from NIR to X-ray.

The dbb parameters in Table 2 are obtained with NIR to UV data as described in Section 3.1. They are kept frozen for the X-ray analysis (Section 3.2). The dbb normalization equals to $R_{\rm in}^2$ cos i, where $R_{\rm in}$ is the radius at the inner edge of the disk, and i is the inclination angle of the disk. Here we assume i equals to the reflection angle 24° measured by Nardini et al. (2014). Following Mehdipour et al. (2021), with our best-fit dbb parameters (Table 2), we obtain $R_{\rm in}=0.10$ ld (or $\sim 4.4~R_S$) and a mass accretion rate of $\sim 2.5~M_{\odot}~{\rm yr}^{-1}$ for MR 2251-178.

From our broadband SED modeling, the bolometric luminosity of MR 2251-178 is $\sim 1.71 \times 10^{45}$ erg s⁻¹ in 2002 and $\sim 1.51 \times 10^{45}$ erg s⁻¹ in 2020. With the black hole mass of $(2.0 \pm 0.5) \times 10^8~M_{\odot}$ (Lira et al. 2011), which is consistent with $\sim 2.4 \times 10^8~M_{\odot}$ (Dunn et al. 2008), the Eddington ratio was $\sim 6.8~\%$ in 2002 and $\sim 6.0~\%$ in 2020. In 2011, using the XMM-Newton data (OM, RGS, and EPIC/pn), Nardini et al. (2014) derived a bolometric luminosity of $\sim (5-7)\times 10^{45}$ erg s⁻¹, which corresponds to an Eddington ratio of $\sim 20-28~\%^1$.

In Figure 5, we show the best fit to the observed X-ray data, as well as the transmission of the Galactic absorption, warm absorber (X-ray), and obscurer (2020 only). The best-fit C-statistics (Kaastra 2017) are given in Table 2, which includes the total C-statistics and statistics of individual instruments.

4.2. X-ray warm absorber and emitter

The presence of the obscurer can significantly lower the soft X-ray flux so that the warm absorber features are less prominent. Therefore, the warm absorber parameters are better constrained with the X-ray spectrum obtained in 2002, where no obscurer was present along our line-of-sight. The best-fit parameters of the warm absorber are given in Table 3. These parameters are

Table 2. Best-fit parameters of the broadband spectra of MR 2251-178 on 2002-05-18 and 2020-12-16. The C-statistics refer to the final best-fit, where all obscuration, absorption, and emission components are taken into account. All quoted errors (including the upper limits) refer to the statistical uncertainties at the 68.3% confidence level. Frozen and coupled parameters are indicated with (f) and (c), respectively.

consistent within the 1σ uncertainty of those reported by Reeves et al. (2013).

The hydrogen column density $(N_{\rm H})$, microscopic turbulence velocity $(v_{\rm mic})$, and outflow velocity $(v_{\rm out})$ of

 $^{^1}$ Nardini et al. (2014) adopted a black hole mass of 2.4×10⁸ M_{\odot} (Dunn et al. 2008), which led them to report an Eddington ratio of $\sim 15-25$ %.

Figure 4. Broadband SED model for the AGN continuum, which consists of a disk blackbody (dbb), a Comptonized disk component (comt), a power-law component (pow), and a reflection component (refl). NIR, UV, and X-ray spectra obtained with ground and space missions at different times are also shown. Both the model and data are corrected for the extinction (NIR and UV) and absorption (X-ray) effects. Observed data include emissions from warm emitter, BLR, dusty torus, and host galaxy, in addition to the intrinsic AGN SED. Data and model are rebinned for clarity.

Figure 5. Best-fit to the observed X-ray data of MR 2251-178 in 2002 and 2020. Transmission of the Galactic absorption (MW), warm absorber (WA), and X-ray obscurer (XO, 2020 only) are shown in the top panels. In the bottom panels, data (colored curved with 1σ uncertainties in gray) and model (black curves) of each instrument are rebinned for clarity. The flux differences in the hard X-ray band are due to the cross-calibration issue between XMM-Newton and NuSTAR.

the warm absorber derived from the 2002 X-ray spectrum are kept frozen when analyzing the 2020 X-ray spectrum. The warm absorber is expected to be less ionized in 2020 because photons from the central engine are screened by the obscurer before reaching the warm absorber. Since the warm absorber features are not detectable with the diminished soft X-ray flux, following our previous analysis on NGC 5548 (Kaastra et al. 2014) and NGC 3783 (Mehdipour et al. 2017; Mao et al. 2019), we simply assume that the product $n_e \ r^2$ of the warm absorber is constant, where n_e is the number density and r the distance of the warm absorber to the central engine. For the warm absorber in 2020, the ionization parameter (Tarter et al. 1969; Krolik et al. 1981)

$$\xi = \frac{L}{n_e \ r^2} \tag{1}$$

is then calculated with the 1 - 1000 Rydberg ionizing luminosity. In 2020 (Table 2), $\log\xi$ =1.96, 0.79, and -1.49 for components #1-3, respectively. Throughout this paper, the ionization parameter (ξ) is given in units of erg s $^{-1}$ cm.

Two X-ray emission components with distinct velocity broadening are required for the soft X-ray emission lines in the 2002 and 2020 spectra (Figure 6 and Table 4). The warm emitter features are not prominent though, partly due to the relatively short exposure time. To reduce the number of free parameters, based on experience

Figure 6. The soft X-ray spectra of MR 2251-178 in 2002 (top) and 2020 (bottom). The RGS spectra are rebinned for clarity. The black curves are the total flux, which consists of two warm emitter components (green and pink) and the continuum (blue).

Table 4. Best-fit parameters of the warm emitter (two components) in MR 2251-178 observed in 2002 and 2020. Frozen parameters are indicated with (f).

Date	2002-05-18	2020-12-16		
Warm emitter #1				
$N_{\rm H}~(10^{22}~{\rm cm}^{-2})$	$10.7^{+2.6}_{-1.6}$	$15.7^{+3.4}_{-3.1}$		
$\log \xi \text{ (erg s}^{-1} \text{ cm)}$	$0.73^{+0.14}_{-0.21}$	$0.97^{+0.12}_{-0.14}$		
$C_{ m em}$	0.005 (f)	0.005 (f)		
$v_{\rm mac}~({\rm km~s}^{-1})$	1330^{+340}_{-260}	2480^{+540}_{-530}		
Warm emitter #2				
$N_{\rm H} \ (10^{20} \ {\rm cm}^{-2})$	$9.5^{+10.7}_{-3.4}$	$20.1^{+12.1}_{-8.3}$		
$\log \xi \ ({\rm erg \ s^{-1} \ cm})$	$1.36^{+0.12}_{-0.11}$	1.36 (f)		
$C_{ m em}$	0.10 (f)	0.10 (f)		
$v_{\rm mac}~({\rm km~s^{-1}})$	410^{+230}_{-180}	630^{+260}_{-210}		

(e.g., Mao et al. 2018, 2019; Grafton-Waters et al. 2021), we fix the emission covering factor $C_{\rm em} = \Omega/4\pi$, where Ω is the solid angle subtended by the warm emitter with respect to the central engine. The emission covering factors of the two warm emitter components are 0.005 and 0.10, respectively. Both X-ray emission components are slightly (within $1-2\sigma$) broader and stronger in 2020. Nonetheless, the relatively short exposure for both X-ray spectra (Table 1) do not provide sufficient statistics to draw a firm conclusion.

4.3. Obscurer

The rising trend of the Swift X-ray hardness ratio since the summer of 2020 suggests an obscuration event, similar to those found in e.g., NGC 5548 (Kaastra et al. 2014) and NGC 3783 (Mehdipour et al. 2017). The apparent lowering of the soft X-ray flux in 2020, in comparison with that in 2002, supports the presence of an obscurer. We aim to constrain the physical properties of the obscurer with X-ray, UV, and NIR data.

4.3.1. X-ray spectra

The best-fit parameters of the obscurer are given in Table 5. The hydrogen column density is $(8.2\pm1.6)\times10^{22}~{\rm cm}^{-2}$, which is comparable (within 1σ) to the hydrogen column density $6.6^{+0.8}_{-1.4}\times10^{22}~{\rm cm}^{-2}$ reported by Markowitz et al. (2014). The line-of-sight covering factor is ~ 0.35 . Hence, only a small fraction of the SED is obscured (Figure 8). That is to say, a large fraction of the X-ray photons leak through the obscurer.

With the incident ionizing SED (Figure 4), and the hydrogen column density of the obscurer (Table 5), the ionic column densities can be calculated (Figure 7). For ξ spanning several orders of magnitude, the corresponding ionic column densities of H I, C IV, O VI, and so forth are well above $\sim 10^{15}~{\rm cm}^{-2}$. If the X-ray obscurer intercepts our line-of-sight to (a significant portion of) the UV emitting region, we expect to find absorption features in the HST/COS spectrum.

4.3.2. UV line profiles

In comparison with the archival HST spectra from 1996-2011, new Ly α absorption features emerged in the 2020 HST/COS spectrum. These new Ly α absorption features are blueshifted by more than 2000 km s⁻¹, well separated from the relatively slow warm absorber.

A new narrow absorption line was found in the blue wing of Ly α with an outflow velocity of \sim $-2530~\rm km~s^{-1}$ and a full-width-half-maximum (FWHM) of \sim 180 km s⁻¹ (Figure 9). This new absorption feature has an equivalent width of 3.1 ± 0.3 Å. There might be a counterpart in the blue wing of O VI, though the spectrum is noisy. No counterparts were found in lower ionization species (e.g., N V and C IV), which indicates

Table 5. Best-fit parameters of the obscurer in MR 2251-178 observed on 2020-12-16.

$\log \xi \text{ (erg s}^{-1} \text{ cm)}$	$ \begin{array}{c} 1.83 \pm 0.13 \\ 0.35 \pm 0.02 \end{array} $		
$f_{ m cov}^X$	0.35 ± 0.02		

Figure 7. Ionic column densities of the obscurer. This calculation is performed with the hydrogen column density and covering factor of the obscurer given in Table 5 and the incident ionizing SED shown in Figure 4. The pink shaded area marks the X-ray constraints (1σ uncertainty) of the ionization parameter.

Figure 8. The broadband spectral energy distribution (SED) of MR 2251-178 with and without obscuration and absorption effects of ionized absorbers (Galactic absorption and extinction effects are excluded here). The upper panel shows the obscuration effect due to the X-ray obscurer (XO) in 2020. The pink curve in the lower panel includes the absorption effect by the X-ray warm absorber (WA) in 2002, while the purple curve includes both the obscuration effect by the obscurer and the absorption effect by the de-ionized warm absorber in 2020.

that the ionization parameter of this UV absorber is relatively high.

Assuming $\log \xi = 1.8$ and $f_{\rm cov}^{\rm UV} = f_{\rm cov}^{\rm X} = 0.35$ (Table 5), a good fit to the new narrow absorption line of Ly α can be achieved with $N_{\rm H} \sim 3.2 \times 10^{20}$ cm⁻² (Figure 10). In this case, turbulent broadening with $v_{\rm turb} \sim 70$ km s⁻¹ is required, in addition to thermal

broadening, to account for the observed broadening. The hydrogen column density measured in the UV band is more than two orders of magnitude lower than the X-ray measurement in Table 5.

Moreover, a forest of weak absorption features appeared in the blue wing of Ly α in 2020, extending all the way down to $\sim -10400~\rm km~s^{-1}$ (Figure 11). The apparent broad absorption feature between $\sim -8000~\rm km~s^{-1}$ and $\sim -9000~\rm km~s^{-1}$ might consist of multiple blended narrow absorption lines, if it is not intrinsically broad. No convincing counterparts are found in the blue wing of C IV.

If the Ly α absorption features are all optically thin, then they cannot be the same gas responsible for the X-ray obscuration. Our fit to the strongest feature at $-2530 \text{ km s}^{-1} \text{ shows that it is optically thin, which}$ cannot be a counterpart to the X-ray obscuring gas. However, we have insufficient information to characterize the trough and forest extending to -10400 km s^{-1} . If these more extended features are optically thick and their weakness reflects low covering fractions, it is possible that this is the same gas as in the X-ray, but simply covering a much larger emitting area in the UV than for the compact X-ray source (as discussed in Sect. 5.4 below). Additional possibilities for linking the UV and Xray absorbing gas include a UV absorber with the same ionization and covering factor but a significantly lower column density, or UV absorbing gas with no parameters shared with the X-ray, and lying along a completely different line-of-sight.

In addition, a narrow absorption line in the red wing ($\sim +75~\rm km~s^{-1}$) of Ly α was present in the 2011-11-29 HST/COS spectrum but disappeared on 2020-12-16 (Fig. 9). The relatively low velocity shift makes it less likely to be associated with the X-ray obscurer.

Variations of UV warm absorber features ($v_{\rm out} \lesssim 10^3~{\rm km~s^{-1}}$) are found e.g., between $-600~{\rm km~s^{-1}}$ and $-800~{\rm km~s^{-1}}$) in the upper panel of Fig. 9. These variations are mainly due to an ionization response of the lower (a factor of \sim 3) flux of the UV and X-ray continuum in 2020 compared to 2011. The contribution from the lower ionizing luminosity caused by the obscurer is minor due to its relatively low covering factor (see also the upper panel of Fig. 8). This might be explained if our line-of-sights towards the X-ray and UV continuum intercept different parts of the obscuring wind.

4.3.3. NIR and optical line profiles

Three NIR spectra of MR 2251-178 were collected in late 2020. While the $Pa\alpha$ line shows no absorption, clear, strong absorbers are evident in He I* λ 10830. In Figure 12, we show the isolated blueshifted He I* ab-

sorption in the IRTF and Gemini NIR spectra and find them to be consistent with each other.

Since no previous NIR spectroscopy exists of MR 2251-178 from which we could extract an unabsorbed line profile, we reconstructed it using the strong $Pa\alpha$ broad line and [S III] $\lambda 9531$ narrow line profiles from the same spectra. As Landt et al. (2008) showed, the $Pa\alpha$ and He I* broad line profiles are very similar. Furthermore, in MR 2251-178 we find that the $Pa\alpha$ line lacks a narrow component, making it ideal to model the broad component. Following the approach in Landt et al. (2008), we also used the scaled $Pa\alpha$ line to remove the $Pa\gamma$ 10938 emission line from the blend with He I*.

We note that, in contrast to the broad-line AGN studied by Landt et al. (2008), MR 2251-178 shows a deficit of broad line flux in the red wing of He I* line relative to the $Pa\alpha$ profile. This finding is confirmed when comparing the isolated He I* $\lambda 10830$ line with the He I* $\lambda 3889$ line observed in the Keck optical spectrum, which is not blended with other ionic species on its red wing. The redshifted broad ($\sim 2200 \text{ km s}^{-1}$) absorption trough is observed at a velocity of $+2235 \text{ km s}^{-1}$. One of the possible interpretations is that this might be related to inflows fueling the accretion disk, as reported by Zhou et al. (2019) for eight other quasars. Another peculiarity that we find in MR 2251-178 is that all broad-line profiles are consistently blueshifted (by $\sim 300 \text{ km s}^{-1}$) and that narrow emission lines from very low-ionisation gas, such as, e.g. [O I], [N II] and [S II], are very weak and those from high-ionisation gas, such as, e.g. [O III], [Ne III] and [Ne V], are relatively strong.

The new narrow absorption line seen in Ly α with $v_{\rm out} = -2530 \text{ km s}^{-1} \text{ was not found in He I*, as ex-}$ pected given the high ionization parameter and low column density of this absorber. We have deblended the IRTF spectrum, which has the best combination of spectral resolution and S/N, with four Gaussian components in the He I* absorption; a broad feature at high velocity (width of 1443 km s⁻¹, $v_{\text{out}} = -2268 \text{ km s}^{-1}$), a deep feature at low velocity (width of 417 km s⁻¹, $v_{
m out} = -252~{
m km~s^{-1}})$ and two barely resolved features $(v_{\text{out}} = -1099 \text{ km s}^{-1} \text{ and } -823 \text{ km s}^{-1})$. We note that given the intermediate spectral resolution of the NIR spectrum, all these features could be composed of several narrower features. It is noteworthy the similarity in velocity (and width) between the redshifted absorption trough and the fastest velocity outflow.

It is tempting to associate the fastest velocity He I* outflow with the X-ray obscurer itself, similar to what was observed in NGC 5548 (Wildy et al. 2021). Then, if this is indeed a wind off the accretion disk, as suggested by Dehghanian et al. (2019a,b), the similarity in

Figure 9. The Ly α line profiles. The single-orbit 2020 spectrum is rebinned for clarity. Vertical dotted lines in pink mark the UV warm absorbers. Vertical dashed line in purple marks the new blueshifted ($\sim -2530~{\rm km~s^{-1}}$) narrow absorption line. A weak blueshifted broad absorption trough is observed between $\sim -3000~{\rm km~s^{-1}}$ and $\sim -10000~{\rm km~s^{-1}}$ accompanied by a forest of narrow absorption lines (the shaded area in light blue).

velocity (and width) between this feature and the redshifted absorption trough indicates that the geometry and viewing angle are such that we see also the far side, the receding part of this structure. This NIR absorber is likely co-located with the warm absorber and it must have only recently arisen due to a lower ionization parameter caused by the obscuration event. This situation is incompatible with the inflow scenario but would then be similar to what was recently observed in NGC 5548 (Wildy et al. 2021) and previously in NGC 4151 (Hutchings et al. 2002; Wildy et al. 2016). This interpretation is supported by the observed hydrogen Balmer line profiles (Figure 13). The four strongest lines in this series show in both optical spectra an absorption profile similar to that of He I* $\lambda 10830$. Notable is also the decreased absorption of the narrow line component as one goes up in the Balmer series (from $H\alpha$ to $H\delta$), indicating that the WA is co-located with that part of the narrow emission line region giving rise to permitted transitions and so of

a higher density than the one further out and giving rise to forbidden transitions only.

5. DISCUSSION

While there are more X-ray obscuration events in type 1 AGN in the literature (e.g., Rivers et al. 2015; Gallo et al. 2021; Serafinelli et al. 2021; Armijos-Abendaño et al. 2022), we limit our discussions on the physical properties of the obscurer in quasar MR 2251-178 in comparison with those observed with coordinated multi-wavelength observations. They are one radio-quiet quasar (PG 2112+059, Saez et al. 2021) and six Seyfert galaxies: NGC 5548 (Kaastra et al. 2014; Kriss et al. 2019b), NGC 985 (Ebrero et al. 2016), NGC 3783 (Mehdipour et al. 2017; Kaastra et al. 2018b; Kriss et al. 2019a), Mrk 335 (Longinotti et al. 2013, 2019; Parker et al. 2019), Mrk 817 (Miller et al. 2021; Kara et al. 2021), and NGC 3227 (Mehdipour et al. 2017; Wang et al. 2022; Mao et al. 2022).

Figure 10. Photoionization modeling of the new narrow absorption feature of Ly α using Cloudy (Ferland et al. 2017). With $\log \xi = 1.8$ and $f_{\rm cov}^{\rm UV} = f_{\rm cov}^{\rm X} = 0.35$, a good fit can be achieved with a hydrogen column density of 3.2×10^{20} cm⁻² and a turbulence velocity of 70 km s⁻¹. The lower panel shows the transmission.

Figure 11. Normalized flux of Ly α as a function of outflow velocity in 2011 (green) and 2020 (red) HST/COS spectra. In the 2020 spectrum, a forest of weak absorption features appear in the blue wing ranging from $\sim -2530~{\rm km~s}^{-1}$ to $\sim -10400~{\rm km~s}^{-1}$.

5.1. Obscuration duration

The obscuration events in NGC 5548 (Kaastra et al. 2014; Mehdipour et al. 2016b, 2022a) and Mrk 335 (Longinotti et al. 2019; Parker et al. 2019) lasted for years, while relatively shorter and recurrent obscuration events were found in NGC 985 (Ebrero et al. 2016), NGC 3783 (Kaastra et al. 2018b), Mrk 817 (Kara et al. 2021), and NGC 3227 (e.g., Mehdipour et al. 2017; Wang

Figure 12. Observed and reconstructed He I* $\lambda 10830$ line profile after removing the nearby Pa $\gamma \lambda 10938$ broad emission line. The dashed blue vertical lines mark the Ly α absorption components observed with HST/COS (upper left panel of Figure 9).

et al. 2022; Mao et al. 2022). For short-lived obscuration events, the duration of the obscuration can be as short as 20 ks (for NGC 3227, Wang et al. 2022).

For MR 2251-178, if we consider the obscurer is present when the Swift X-ray hardness ratio is $\gtrsim 0.20$ (Figure 2), the obscuration duration is $\sim 75-260$ days. If the threshold is set to $\gtrsim 0.25$, the obscuration duration would be ~ 75 days.

5.2. Obscuration recurrence

Short-lived obscuration events are found to be recurrent for NGC 3783, NGC 985, and NGC 3227. For NGC 3783, the Swift hardness ratios between 2008 and 2017 suggest that there were obscuration events in early 2009 (Kaastra et al. 2018b) and December 2016 (Mehdipour et al. 2017, with joint UV and X-ray observations). Furthermore, archival X-ray spectra obtained with the Advanced Satellite for Cosmology and Astrophysics (ASCA) in 1993 and 1996 also show evidence of obscuration events (Kaastra et al. 2018b). For NGC 985, an obscurer was present with joint X-ray and UV observations in August 2013 and January 2015 (Ebrero et al. 2016). Archival X-ray data suggest that there might have been another obscuration event in July 2003 (Ebrero et al. 2016). For Mrk 817, obscu-

Figure 13. Observed Balmer lines in the Keck (red) and Palomar (green) optical spectra compared to the observed He I* $\lambda 10830$ line profile (black) after removing the nearby Pa $\gamma \lambda 10938$ broad emission line. For H α , we show the line profile from the IRTF spectrum instead since this strong line was saturated in the Keck spectrum. The dashed blue vertical lines mark the Ly α absorption components observed with HST/COS (upper left panel of Figure 9).

ration has been persistent and variable from November 2020 through March 2021 (Kara et al. 2021), including a 55-day period similar to the "broad-line holiday" observed in NGC 5548. Moreover, an archival NuSTAR spectrum taken on 2015-07-25 suggests an earlier obscuration event, but less prominent than the late 2020 event (Kara et al. 2021). For NGC 3227, X-ray obscuration events were reported in 2000 – 2001 (Lamer et al. 2003; Markowitz et al. 2014), 2002 (Markowitz et al. 2014), 2006 (Wang et al. 2022), 2008 (Beuchert et al. 2015), 2016 (Turner et al. 2018; Wang et al. 2022), and 2019 (Mao et al. 2022).

For PG 2112+059, obscuration events were observed on 2014-12-20 and 2015-08-29, but not on 2002-09-01 (Saez et al. 2021). With no observations between 2014-12-20 and 2015-08-29, it is hard to tell whether it was a continuous obscuration event lasting for eight months or two short-lived events.

For MR 2251-178, X-ray obscuration events might have occurred in 1980 (Halpern 1984), 1996 (Markowitz et al. 2014), and late 2020 (present work). Compared to the Einstein X-ray spectrum of MR 2215-178 taken on

1979-07-01, the one on 1980-05-19 was significantly absorbed in the soft X-ray band below ~ 3 keV (Halpern 1984). Markowitz et al. (2014) identified a clear obscuration event in the RXTE observation on 1996-12-09. In the two BeppoSAX observations in June and November 1998, X-ray obscuration had disappeared (Dadina 2007). No other obscuration events were identified with the RXTE data up to January 2012 (Markowitz et al. 2014) and Swift data between 2014 and mid-2020 (Figure 1). With these X-ray observations and identified obscuration events, if there is a duty cycle, it would range from 16 to 24 years. Some periodic events might trigger the launch of the obscuring wind, or a warped accretion disk might cross our line-of-sight.

5.3. Distance of the obscurer to the black hole

It is not trivial to estimate the distance of the obscurer to the black hole since we cannot directly resolve it via imaging. Lamer et al. (2003) estimated the distance of the obscurer in NGC 3227 assuming it is a spherical cloud orbiting the black hole in a Keplerian orbit. To be more specific, the distance is derived by (1) assuming the radius of the obscurer is $N_{\rm H}/n_{\rm H}$; (2) the obscurer crosses our line-of-sight with a constant velocity $v_{\rm cross} = \sqrt{GM_{\rm BH}/r}$ in a Keplerian orbit; (3) the crossing time $t_{\rm cross} = N_{\rm H}/(n_{\rm H}~v_{\rm cross})$ is constrained from the observed duration of the event. We estimate the distance of the 2020 obscurer in MR 2251-178 following the above approach but also discuss alternative scenarios below.

5.3.1. Spherical clouds in Keplerian orbits

For the 1996 obscuration event (with a duration of 3-1641 days) of MR 2251-178, Markowitz et al. (2014) estimated its distance to the black hole to be $\sim 460-5700$ ld, implying a spherical obscurer with a size scale of 0.009-3.4 ld. They also estimated the H β distance (~ 27 ld) and the boundary of the dust sublimation zone (Nenkova et al. 2008) $r_d \sim 910$ ld. For $r \gtrsim r_d$, dust likely does not sublimate, while regions with $r \lesssim (0.3-0.5) \ r_d$ are dust-free. Thus, they expect the obscurer in 1996 to be dusty.

For the 2020 event, following the same approach, we would obtain $r \sim 155-255$ ld or $7000-11000~r_S$ and a size scale of (0.7-1.8) ld. According to Nenkova et al. (2008), with $L_{\rm bol} \sim 1.50 \times 10^{45}~{\rm erg~s^{-1}}$ (Section 4.1) and a dust temperature $T_d=1500~{\rm K}$, the boundary of the dust sublimation zone is $\sim 583~{\rm ld}$. We can also derive the luminosity-based dust radii following Landt et al. (2019), which yields $r_d \sim 166~{\rm ld}$ for MR 2251-178. These estimations suggest that the obscurer in 2020 is also likely dusty. With Equation 1, the number density of the obscurer is $n_{\rm H} \sim (1.8-4.8) \times 10^7~{\rm cm}^{-3}$, which

is significantly smaller than the typical number density ($\sim 10^{9-13} \text{ cm}^{-3}$) of BLR clouds (Peterson 2006).

5.3.2. Non-spherical clouds in Keplerian orbits

It is possible that the obscurer is not spherical in shape. As discussed in Mao et al. (2022), based on the distance estimate for spherical clouds in Keplerian orbits, we can correct for the non-spherical geometry effect by introducing the azimuthal to radial size ratio f. With f=1, we obtain the distance estimation equations used by Lamer et al. (2003) and Markowitz et al. (2014). For larger f values, the estimated distance would be closer to the black hole (scaled by $f^{-2/5}$). Since the geometrical shape of the obscurer is unknown, the distance estimates assuming f=1 might be under- or over-estimated by more than an order of magnitude if $f\lesssim 0.004$ or $f\gtrsim 300$.

5.3.3. Outflows launched from Keplerian orbits

Here, we estimate the distance that does not rely on the unknown geometrical shape of the obscurer. In the above scenarios (Sect. 5.3.1 and Sect. 5.3.2), the orbiting clouds are expected to have zero velocity in the radial direction. The observed Ly α absorption features are blueshifted with outflow velocities ranging from $-2530~{\rm km~s^{-1}}$ to $-10040~{\rm km~s^{-1}}$ (Fig. 11), indicating that the obscurer is outflowing in the radial direction.

Given the relatively low outflow velocity in the radial direction (Fig. 11) and short traveling time (Sect. 5.1), the obscurer is expected to be close to its launching radius. Assuming the obscurer was launched from a Keplerian orbit with a period of $P_{\rm orb} \sim 16-24 \ {\rm yr}$ around the black hole (Sect. 5.2), the distance of the obscurer is then $r = (GM_{\rm BH}P_{\rm orb}^2/4\pi^2)^{1/3} \sim 21.4 - 28.1$ ld (or $\sim 940-1200 r_S$). This is comparable to the H β distance $(\sim 27 \text{ ld})$ given in Markowitz et al. (2014). This is also in accordance with the line-driven disk winds launched at a few $\times 10^2 r_S$ radii in numerical simulations (e.g., Nomura et al. 2013; Mizumoto et al. 2021). We can further estimate the number density of the obscurer via Eq. 1, which yields $n_{\rm H} \sim (0.5 - 7.4) \times 10^{11} \ {\rm cm}^{-3}$. This value is within the range ($\sim 10^{9-13}$ cm⁻³) of typical number density of BLR clouds (Peterson 2006).

5.4. X-ray and UV (dis)connection

During the X-ray obscuration period of NGC 5548 (Kaastra et al. 2014; Mehdipour et al. 2016b), NGC 985 (Ebrero et al. 2016), NGC 3783 (Mehdipour et al. 2017; Kaastra et al. 2018b), Mrk 335 (Longinotti et al. 2019; Parker et al. 2019), and Mrk 817 (Kara et al. 2021), prominent blueshifted broad absorption troughs were found in the simultaneous HST/COS spectra. For the

best-studied obscurer in NGC 5548, both its column density and covering fraction are variable on timescales of a few ks to a few months (Di Gesu et al. 2015; Mehdipour et al. 2016b; Cappi et al. 2016). The rapid variability and large velocity broadening support the scenario that the obscurer in NGC 5548 originates from the accretion disk (Kaastra et al. 2014). For NGC 3783, an additional high-ionization absorption component was also present in late 2016, leading to Fe xxv and Fe xxvI absorption lines in the Fe K band (Mehdipour et al. 2017). Through a detailed UV analysis, Kriss et al. (2019a) suggest that a collapse of the broad-line region (BLR) clouds triggered the launch of the obscurer. For Mrk 817, the obscurer is located at the inner BLR and partially covers the central source (Kara et al. 2021).

For NGC 3227, we do not find prominent blueshifted broad absorption troughs in the simultaneous HST/COS spectra when the target is obscured in the X-ray band (Mao et al. 2022). The lack of X-ray and UV association might be explained if the X-ray obscurer does not intercept our line-of-sight to (a significant portion of) the UV emitting region. If a compact X-ray obscurer intercepts our line-of-sight to the UV emitting region, it might cover $\lesssim 1~\%$ of the UV emitting region. It is also possible that the X-ray obscurer does not intercept our line-of-sight to the UV emitting region at all, although we cannot well constrain the distance of the obscurer.

For MR 2251-178, following Burke et al. (2021, Eq. S7), the effective UV emitting region radius (R_{2500}) can be estimated via

$$R_{2500} = 10^{14.95 \pm 0.05} \text{ cm } \left(\frac{L_{5100}}{10^{44} \text{ erg s}^{-1}}\right)^{0.53 \pm 0.04},$$
(2)

where L_{5100} is the optical continuum luminosity. With $L_{5100} \sim 1.4 \times 10^{44} \text{ erg s}^{-1}$, we obtain $R_{2500} \sim 1.1 \times 10^{15} \text{ cm}$ or $\sim 0.41 \text{ ld}$. This is equivalent to $\sim 18 R_{\rm S}$, where the Schwarzschild radius $R_{\rm S} = 2GM_{\rm BH}/c^2 = 5.9 \times 10^{13} \text{ cm}$ or 0.023 ld.

Assuming a fiducial X-ray emitting central engine with a size scale of $\lesssim 5~R_{\rm S}$ (e.g., Reis & Miller 2013; Fabian et al. 2015), the UV emitting region would be a factor of $\gtrsim 13$ larger. With the X-ray obscurer covering $\sim 35~\%$ of the X-ray emitting central engine (Table 5), it would then cover merely $\lesssim 2.7~\%$ of the UV emitting region.

The X-ray covering factor $(f_{\rm cov}^X)$ of MR 2251-178 is comparable to that reported by Ebrero et al. (2016) for the observation episode in NGC 985 observed with XMM-Newton in January 2015. In that case, only one narrow (FHWM $\sim 350 \pm 50 ~\rm km~s^{-1}$) blueshifted (-5300±10 km s⁻¹) absorption line of Ly α was present in the simultaneous HST/COS spectrum. The UV covering factors for the low er-ionization ions C III*, C IV,

and Si IV were $\lesssim 0.15$ and not visible at the signal to noise ratio of the UV spectra.

On one hand, if the obscuring wind barely intercepts the UV continuum region (e.g., the wind projected size is too small compared to the UV emitting region), we might not observe prominent blueshifted absorption lines in the UV band. On the other hand, when a transient obscuring wind is fading, we might not observe prominent blueshifted absorption lines in the UV band. Both might contribute to the lack of prominent UV absorption lines in MR 2251-178.

6. SUMMARY

We present the recent multi-wavelength observations of MR 2251-178, including a set of Swift snapshots in 2020 – 2021, a coordinated observation with HST/COS, XMM-Newton, and NuSTAR on 2020-12-16, and NIR to optical spectroscopic observations using NASA's Infrared Telescope Facility, Gemini, Keck, and Palomar from September to December 2020.

We construct a broadband spectral energy distribution of the AGN continuum with the multi-wavelength data. We perform a spectral analysis of the X-ray data, including the photoionization modeling of the newly discovered obscurer and the classical warm absorber in the X-ray band. The observational features in the X-ray band shared similarities with some other type 1 AGNs with obscuring winds. The observational characteristics of the spectral features associated with the obscuring wind in the UV to NIR bands are distinctly different from those seen in other AGN with obscuring outflows. A general understanding of the observational variety of obscuring winds in type 1 AGNs is still lacking. The main results are summarized as follows.

- 1. In the X-ray band, an obscuration event was present in late 2020, which led to a flux drop in the soft X-ray band without any detectable absorption line features. The obscurer has a hydrogen column density of $\sim 8.2 \times 10^{22}$ cm⁻², a relatively high ionization parameter (log $\xi \sim 1.8$), and a relatively low line-of-sight covering factor ($f_{\rm cov}^X \sim 0.35$).
- 2. In the UV band, a new blueshifted narrow absorption line of Ly α with an outflow velocity of $\sim -2530 \text{ km s}^{-1}$ was found in 2020. This new feature is accompanied by a forest of weak absorption features extending to $\sim -10400 \text{ km s}^{-1}$ in the blue wing of Ly α . No such absorption features are found in the blue wing of C IV. The new weak UV absorption features can only be produced by the same gas obscuring the X-ray if it has a much

lower covering fraction relative to the size of the UV-emitting regions.

- 3. In the NIR band, weak narrow absorption lines are present in the blue wing of He I 1.08 μ m down to ~ -2268 km s⁻¹. Although no previous NIR spectroscopy exists for MR 2251-178, we expect the de-ionized warm absorber gives rise to the narrow absorption lines. A redshifted broad absorption trough peaking around +2235 km s⁻¹ with a width of ~ 2200 km s⁻¹ was found for He I $\lambda 10830$. It might be due to an inflow fueling the accretion disk. Alternatively, considering absorption features on both sides of He I, it is possible that we are observing the far (receding) side of the obscurer.
- According to Swift hardness ratios in 2020 2021, the transient obscurer in MR 2251-178 might last for 75 – 260 days. X-ray obscuration events might have a quasi-period of two decades considering earlier events in 1980 and 1996.
- 5. It is hard to conclude the exact location of the 2020 X-ray obscurer. The inferred distance ranges from the BLR to the dusty torus. However, it is expected to be far beyond the UV emitting region.

ACKNOWLEDGEMENTS

We thank the referee for providing useful feedback to improve the quality of this work. A reproduction package is available at Zenodo DOI: 10.5072/zenodo.1107961. This package includes data and scripts used to reproduce the fitting results and figures presented here. This work is based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and the USA (NASA). This work was supported by NASA through a grant for HST program number 16465 from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS5-26555. This research was supported under NASA Contract No. NNG08FD60C, and has made use of data obtained with the NuSTAR mission, a project led by the California Institute of Technology (Caltech), managed by the Jet Propulsion Laboratory (JPL) and funded by NASA. We thank the Swift Science Operations team for approving Swift target-ofopportunity observations in August and December 2020, as well as May 2021. We thank Claus Leitherer for approving the Director's Discretionary program, Nick Indriolo and Tricia Royle for technical support and executing the HST observation. We thank Norbert Schartel for approving the XMM-Newton directory's discretionary time observation. We thank Fiona Harrison for approving the NuSTAR Target of Opportunity. We also thank the HST, XMM, and NuSTAR teams for coordinating the observations. SRON is supported financially by NWO, the Netherlands Organization for Scientific Research.
