Distinct from the phononic valley pseudo-spin, the real physical spin of elastic waves adds a novel tool-kit capable of envisaging the valley-spin physics of topological valley phononic crystals from a local viewpoint. Here, we report the observation of local elastic valley spin as well as the hidden elastic spin-valley locking mechanism overlooked before. We demonstrate that the selective one-way routing of valley phonon states along the topological interface can be reversed by imposing the elastic spin meta-source at different interface locations with opposite valley-spin correspondence. We unveil the physical mechanism of selective directionality as the elastic spin controlled chiral coupling of valley phonon states, through both analytical theory and experimental measurement of the opposite local elastic spin density at different interface locations for different transport directions. The elastic spin of valley topological edge phonons can be extended to other topological states and offers new tool to explore topological metamaterials.

The valley in the momentum space that provides an extra degree of freedom (DOF) to manipulate particles has attracted tremendous interests in the field of topological materials in parallel to charge and spin [1–3]. Beside electron systems, the valley DOF has been successfully extended to classical wave systems like optical [4–9], acoustic [10–15] and elastic [16–24] waves. Regarding elastic wave, the valley-dependent phenomena, e.g., the valley edge states [17, 18] and topological transportation [19, 20] are demonstrated experimentally. The topological phase transition of these lattice could be characterized by the valley Chern number [22, 25] and carried out by the honeycomb lattice with broken symmetry [26, 27]. Due to topological protection, these elastic topological edge states (ETES) based on valley DOF are immune to sharp corners and structural defects [16, 18].

The elastic valley pseudospin-up (or -down) states of ETES are mathematically described by the effective Dirac Hamiltonian [18]. As such, the elastic pseudospin has been underlined with the help of chiral vibration [18] and the energy flux [22, 28], which deepens the understanding about the relationship between chiral vibration modes and pseudospin [29, 30]. However, pseudospin fails to represent the detailed properties of a finite inhomogeneous area that contains rich information. At given position, a local real physical quantity with measurable effects is desired to help people to identify or manipulate the ETES.

Recently, research in optical [31–34], acoustic [35–39] and elastic [40–42] systems show that the real physical quantity, spin angular momentum (spin for short) in classic waves plays an important role in the topological and unidirectional transportation. For example, the elastic spin demonstrates the local chirality locking mechanism of Rayleigh wave in conventional semi-infinite medium [40, 42]. The elastic spin is different from pseudospin [29, 30], the latter of which is not spin angular momentum, but represents a SU(2) spin-like mathematical structure in various systems. Pseudospin does not

have the unit of angular momentum, but is a dimensionless quantity. In contrast, the elastic spin is a real physical quantity as angular momentum of the SO(3) structure [40, 43], which dose not rely on abstract analogue of SU(2) mathematical structure.

Therefore, on one hand, although it is well accepted that the pseudospin-momentum locking is crucial for ETES, how the real local elastic spin locked with the directionality at different locations is not yet uncovered in topological elastic metamaterials. On the other hand, although the elastic spin could unveil more local physics in 3D complex structures, the application of elastic spin to study topological metamaterials is yet absent so far, let alone the valley elastic metamaterials.

Here, we construct topological phononic crystal (PC) plates based on valley DOF, and create ETES in between PC plates with opposite valley Hall phases. Particularly, we introduce the elastic spin into the valley PC plates and show the local elastic spin-momentum locking mechanism in valley metamaterials. We observe the unidirectional wave propagation according to both the spin distribution of edge states and position of meta-sources with sub scale in PC plate. The direction of spin density inside the edge states can give a clear guidance for selectively chiral manipulation. Our results advance the knowledge of local features of topological meta-materials, build a bridge between topological meta-materials and intrinsic elastic spin, and provide a flexible tool to investigate spin related phenomena in integrative on-chip devices [18, 21, 44].

Figure 1a shows the photograph of a valley PC plate fabricated by erecting triangular aluminum pillars in hexagonal lattice on an aluminum plate using epoxy adhesiv(see also Supplementary Fig. 1a [45]). The topological properties of PC plate with phase A and B are opposite with each other due to the converse rotation of pillars (Figs. 1b and 1c). Then, two ETES branches with positive and negative slopes occur in between the bulk band gap(Fig. 1e) [18]. The primary interest here is unveiling the hidden spin momentum locking mech-

FIG. 1. Valley PC plate interface and scheme of elastic spin-valley locking mechanism. a Photograph of experimental valley PC plate and scheme of elastic spin-valley locking mechanism. As an example, opposite spin sources at p points can generate the opposite directional ETES, but opposite spin source at p and q point can generate the same directional ETES. **b** Band structures of PC plate when θ = 0° (grey dots) and $\theta = \pm 22^{\circ}$ (orange dots). The local extreme values of first and second bands are labeled as K_1 and K_2 , respectively. Bottom panel shows the first Brillouin zone of unit cell. c In-plane mechanical energy flux (black arrows) and elastic spin density S_z (twilight color table) at valleys K_1 (bottom) and K_2 (top) on top surface of substrate, respectively, when $\theta = +22^{\circ}$ and $\theta = -22^{\circ}$. (Insets) The S_z distribution in unit cell. **d** Elastic spin density S_z distribution on states of ETES with positive (k > 0) and negative (k < 0) group velocity at 25.8 kHz on substrate aluminum plate. The high-symmetry point around interface ϕ are labeled as q_A , p_A , q_E, p_E, q_B, p_B in order. The subscripts A, B or E present the points in phase A, B or along interface edge. e Dispersion of supercell containing interface ϕ with phase B ($\theta = -22^{\circ}$) up and phase A ($\theta =$ $+22^{\circ}$) low. The color scale indicates the spin density obtained at p_E and q_E points, respectively.ETES branches ϕ^+ and ϕ^- feature the positive and negative group velocity, respectively.

anism which predicts multiple selective excitation of ETES, as shown in Fig. 1a. For example, the spin-up source at p point or spin-down source at q point can generate the leftward (k < 0) wave; while the reversed condition leads to the rightward (k > 0) wave.

Figure 1d shows the spin density S_z of ETES at 25.8 kHz on the substrate aluminum plate, where the elastic spin density is governed by [40, 43]

$$\boldsymbol{S} = \frac{\rho\omega}{2} \text{Im}(\boldsymbol{u}^* \times \boldsymbol{u}), \tag{1}$$

while the component along z axis is then calculated by $S_z = \frac{\rho \omega}{2} \text{Im}(u_x^* u_y - u_x u_y^*)$. \boldsymbol{u} is the displacement vector. The time term is $\exp(-i\omega t)$ for monochromatic wave. The elastic spin is related to the spin angular momentum of media par-

cel with chirally polarized displacement vector. Elastic spin depends only on the displacement vector at selected location, which is different from the orbital angular momentum that relates also to the choice of coordinate origin [40]. In this work, the clockwise (resp. anticlockwise) polarized displacement vector in x-y plane yields the negative (resp. positive) spin density for S_z , respectively.

From Fig. 1d, the p_A , p_B and p_E points all have negative S_z on the state of ETES with positive group velocity (k > 0, ϕ^+), but the q_A , q_B and q_E all have positive S_z . The S_z shows reversed distribution on state of ETES with negative group velocity (k < 0, ϕ^-). For comparison, Supplementary Fig. 3 [45] shows the in-plane energy flux arrows near the interface that do not maintain distribution as clear as the elastic spin density. Note that we only show the spin density and distribution of energy flux on substrate, considering the spin meta-source is erected on the substrate.

To show the theoretical origin of S_z distribution, we return to the basic topological properties of valley PC plates and ETES branches. Figure 1b shows the band structures of valley PC plate based on the milestone work [18]. When $\theta = 0^{\circ}$, two degenerate states occur at K and they are separated by the rotation of pillars, as shown in Fig. 1b. The positive (resp. negative) distribution of spin density S_z near p and q points is similar to the anti-clockwise (resp. clockwise) polarization of p and q sites in the mass-spring model [45]. This is because the elastic spin [40] is related to the mechanical angular momentum of media parcel [46]. Supposing the medium parcel at p and q point as the mass and the rest of medium as the elastic springs, the spin of eigen states at p and q point are related to the circular motion of the eigenstates in mass-spring models [29, 30, 47] that can be described by the effective Dirac Hamiltonian [45].

When the C_{3v} symmetry is broken by the rotation of triangle pillars, the eigen frequencies of two states at K are shifted to open a band gap for flexural plate wave. As shown in Fig. 1c, the frequency of eigen state with negative spin density at p point decreases when $\theta = 22^{\circ}$ but increases when $\theta = -22^{\circ}$. Regarding both θ values, the spin inside triangle pillars is reversed between K_1 and K_2 . For example, when $\theta = 22^{\circ}$, S_z in triangular pillar at K_1 is purely positive, indicating the anti-clockwise polarization of in-plane displacement field anywhere inside the pillar and therefore the anticlockwise motion of single pillar. This is well consistent with the reported anti-clockwise motion of pillar of valley chiral state [18]. Furthermore and qualitatively, the spin direction (up or down) of S_z at p or q point agrees with the in-plane energy flux rotation (anti-clockwise or clockwise) therein. This lies in the phase difference of $\pm 2\pi$, e.g., the u_z around p or q points have experienced $\pm 2\pi$ phase difference [48]. This applies also to meta-source where the input signal on PZT S1-S4 experiences $\pm 2\pi$ phase difference [45].

Now let us combine PC plates with opposite rotational angle, i.e phase B up and A down. Figure 1e shows the projected dispersion curves of supercell of ϕ , magnifying two ETES branches with forward (ϕ^+) or backward (ϕ^-) group veloc-

ity, respectively. The distribution of S_z along both ETES is already shown in Fig. ${\bf 1d}$, while Fig. ${\bf 1e}$ further summarizes the S_z value along both ETES branches, e.g. at p_E (left panel, also for p_A and p_B) and q_E (right panel, also for q_A and q_B), respectively. Figure ${\bf 1e}$ yields a novel and important deduction: the $S_{pz} < 0$ or $S_{qz} > 0$ located at p or q, respectively, is tightly bonding to the ϕ^+ ETES due to spin-momentum locking, while the $S_{pz} > 0$ or $S_{qz} < 0$ located at p or q allows for ϕ^- ETES, in the frequency range of ETES with nearly linear slope.

The elastic spin at p and q points near the interface can be qualitatively understood by analytically solving the simplified mass-spring model [45], as:

$$S_{pz} = -\frac{\rho\omega\tau}{4}e^{-2\lambda|y|}, \qquad S_{qz} = \frac{\rho\omega\tau}{4}e^{-2\lambda|y|}. \tag{2}$$

 S_{pz} and S_{qz} are elastic spin density derived from the displacement vectors of p and q sites. λ denotes the decaying rate of the ETES apart from the interface. τ = +1 (-1) is associated with K (K') valley or k > 0 (k < 0). Obviously, the sign of elastic spin density depends on propagation direction of ETES, and S_{pz} and S_{qz} are opposite with each other, magnifying well the calculated results in Figs. 1d and 1e.

FIG. 2. Experimental observation of unidirectional wave transportation. a The mapping of normalized $|u_z|$ measured along interface ϕ from x= -125 mm to 125 mm every 5 mm with elastic spin meta-source centered at p_E , where x=0 is at the middle position along interface ϕ . b The difference ratio of $|u_z|$ between right and left side of meta-source, defined as $\lg(\overline{|u_R|}/|u_L|)$, where $\overline{|u_R|}$ (resp. $\overline{|u_L|}$) is the averaged amplitude of $|u_z|$ measured at the right (resp. left) side of source, when meta-source is centered at p_E . The red solid and black dashed lines present the result with spin-up (spin \uparrow) and spin-down (spin \downarrow) sources, respectively. c,d The mapping of normalized $|u_z|$ (c) and difference ratio (d) measured along interface ϕ with meta-source locating at q_E .

For experimental measurement, we put up elastic spin meta-source centered at p_A , q_A , p_E , or q_E with both spin-up and spin-down settings. The meta-source is made of four small lead zirconate titanate piezoelectric ceramics (PZT) disks with radii r=2.5 mm arranged in square lattice [49] (see Supplementary Figs. 1c and 1d [45]). Although the assembly of the meta-source occupies area about 11 mm×11 mm, the effective area of meta-source is the center position

(about 2.5 mm \times 2.5 mm) with highly confined S_z of the same sign. Figure 2a shows the $|u_z|$ measured along interface ϕ with meta-source central at p_E . Notice that for each measurement position, the amplitude of u_z is retrieved from the time resolved profile by using Fourier transformation (FFT) of the recorded wave package at the target frequencies [42]. In Fig. 2a, the asymmetric rightward and leftward wave propagation are successfully generated by spin-down and spin-up source, respectively. This asymmetric propagation is observed in broad frequency range, as shown by the ratio $\lg(|u_R|/|u_L|)$ in Fig. 2b: the positive (resp. negative) value indicates the rightward (resp. leftward) wave propagation generated by the spin down (resp. up) source. These experimental results agree with and must be ascribed to the S_z distribution in Fig. 1e: at p_E , the S_z is negative for ϕ^+ but positive for ϕ^- . The spin-down (resp. spin-up) source central at p_E with $S_z < 0$ (resp. $S_z > 0$) generates the ϕ^+ (resp. ϕ^-). Hence, the unidirectional transport is determined by both the source spin S_z and the local elastic spin density distribution around interface ϕ , which demonstrates strongly the elastic spin-momentum locking in valley topological phononic materials.

To further shed lights on this spin-momentum locking, we show in Figs. 2c and 2d the mapping of $|u_z|$ and the difference $\lg(\overline{|u_R|/|u_L|})$ along interface ϕ , with the meta-source central at q_E . In this case, the leftward and rightward wave propagation are realized by using spin-down and up source, respectively, which is opposite to the situation shown in Fig. 2a. Notably, the amplitude of asymmetric elastic wave between right and left side can reach a difference of 15.8 times $(\lg(\overline{|u_R|/|u_L|}) = 1.2)$. Supplementary Figs. 6a-6d [45] detail the experimental results when the source is central at p_A (resp. q_A), and the spin source generates asymmetric transportation in a way similar to those results by putting the source central at p_A (resp. q_A). The observation of broadband unidirectional ETES agrees well with the S_z distribution in Figs. 1b and 1e.

It is noteworthy that Fig. 2 excludes frequencies up 30 kHz, considering that ETES branches are nearly flat with small spin density at p or q, together with the possible perturbing by some bulk modes, as shown in Fig. 1e. The calculated ratio $\lg(\overline{|u_R|}/|u_L|)$ (see Supplementary Fig. 8 [45]) shows similar results above 30 kHz. In addition, the relatively weak asymmetric propagation at lower frequencies ($<\sim$ 24 kHz) may come from the experimental factors, e.g. installation errors of meta-source, and the possible influences from bulk modes. Besides, we must note that when using even smaller PZT disk (with radii r=1.5 mm) to construct meta-source, the installation process introduces even strong imperfection and downloads the ratio $\lg(\overline{|u_R|}/\overline{|u_L|})$, e.g., at p_A position. Yet, the broadband asymmetric wave transportation is still observable (see Supplementary [45]).

Finally, we turn to the experimental characterization of S_z at p or q points. Figure $\bf 3a$ shows the zooming in of experimental sample for interface ϕ . Without losing generality, one PZT disk is chosen to generate both ϕ^+ and ϕ^- instead of meta-source. The yellow triangles stand for the position of subwavelength triangular pillars at high-symmetry points $(p_A,$

FIG. 3. Measured displacement $\mathbf{u} = (u_x, u_y)$ polarization and elastic S_z at representative p and q points. a Zooming in of photograph of experimental sample, and the measured displacement polarization at each p and q point in phase A and B, at 28 kHz. A single PZT disk is set up around interface. b,c Measured S_z at the left (b) and right (c) side of PZT source, normalized to the maximum in each panel. Experiments show that in both phases A and B, the elastic spins at locations p and q feature opposite spins, which further reverse the sign when the propagation direction of ETES is reversed. This observation clearly demonstrates the hidden elastic spin-momentum locking and elastic spin-valley locking.

 $q_A, p_B,$ and $q_B)$ but on the bottom surface of PC plate. By measuring the displacement that is perpendicular to the side surface of subwavelength triangular pillars (see Supplementary [45]), we can obtain the u_x and u_y at the selected points. After making FFT of u_x and u_y , we can extract the amplitude and phase information of FFT components of u_x and u_y at the given frequency, e.g. 28 kHz. Then, we draw the displacement polarization by using the retrieved amplitude and phase value of u_x and u_y at the given frequency, and obtain the elastic spin density [42]. Figure 3a shows the experimentally obtained displacement polarization at both p and q points. At the left side of wave source, the $\phi^-(p_A)$ and $\phi^-(p_B)$ feature anticlockwise polarized u, resulting in positive S_z . While the $\phi^-(q_A)$ and $\phi^-(q_B)$ feature clockwise polarized \boldsymbol{u} with the negative S_z . Regarding the right side of wave source, the situation is reversed: both p sites, i.e. $\phi^+(p_A)$ and $\phi^+(p_B)$, show clockwise polarized \boldsymbol{u} with negative S_z , while both q sites, i.e. $\phi^+(q_A)$ and $\phi^+(q_B)$, demonstrate the anticlockwise polarized \boldsymbol{u} with positive S_z .

Figure 3b summarizes the measured S_z at points p and q at the left side of source. In short, the S_z features positive value on p points but negative value on q points within broad

frequency range. The situation at points p or q at right side of source, as presented in Fig. 3c, shows the reverse scenario: the S_z is negative on p points but positive on q points. These experimental results agree well with the numerical ones shown in Supplementary. In Figs. 3b and 3c, the normalized S_z features smaller value than the numerical counterparts (Supplementary Fig. $absoledampset{1}{3}$ (Supplementary Fig. $absoledampset{2}$) at lower frequency, due to the imperfect installation of source, the possible influence of bulk edge modes and some other factors in experiment. Nevertheless, both experimental and numerical results confirm that the unidirectional wave transportation is spin-momentum locking between the spin of meta-source and the spin density distribution on PC plate at discrete points.

In conclusion, we have successfully observed the elastic spin density at selected local points in valley topological materials and the hidden elastic spin-valley locking resulted unidirectional transport. The selective chiral coupling to the propagating direction is mostly determined by the local spinmomentum locking according to the elastic spin of source and local spin density distribution in valley topological PC plate. In the future, the real measurable physical effects of elastic spin angular momentum, such as the spin-torque correspondence [35, 37, 50], could largely expand the application scenarios of topological valley phononic crystals. The local elastic valley spin as well as the hidden elastic spin-valley locking advances the knowledge about the conventional features in topological meta-materials and phononics [51, 52], which can be extended to other topological states and offers flexible tool to build up elastic devices like elastic (or phonon) logic devices [29, 53, 54], topological nonreciprocal transmitter [55, 56], unidirectional information transportation [28, 42, 49, 57], intriguing transport in novel valley system [58, 59], and etc.

The mass-spring model.

DESIGN OF CHIRAL ELASTIC SPIN META-SOURCE.

Our chiral elastic spin meta-sources are composed of four subwavelength PZT disks that are fixed to the thin aluminum plate by epoxy adhesive in square. We first evaluate the chiral elastic spin meta-source in theory. Consider a thin solid plate in x-y plane, the plate wave equation is then governed by [60]

$$\nabla^4 u_z(x, y, t) - \omega^2 \frac{\rho h}{D} u_z(x, y, t) = f(x, y, t)$$
 (3)

where ∇^4 is the biharmonic operator, $u_z(x,y,t)$ is the out-of-plane displacement along z axis, ω is the angular frequency, ρ is the mass density of plate, h is the plate thickness, $D=\frac{Eh^3}{12(1-\mu^2)}$ is the plate bending stiffness, E is the Young's modulus, μ is the shear modulus, and f(x,y,t) is the applied force along z axis.

For monochromatic wave, the out-of-plane displacement caused by the point source in thin plate can be assumed as

$$u_{zj} = u_{z0}e^{i(kr_j - \omega t)}e^{-\gamma r_j}e^{i\phi_j}$$
(4)

where u_{z0} is the initial amplitude, k is wave number of plate wave, γ is a positive number indicating the decay of propagating wave away from the point source, ϕ_j is an additional phase, $r_j = \sqrt{(x-x_j)^2 - (y-y_j)^2}$ and (x_j,y_j) is the j^{th} point source location. Notice that near-field evanescent wave of the point source is ignored in this equation.

Typically, for a thin plate in x-y plane, the stress components τ_{yz} , τ_{zx} , and σ_z are much smaller than other components σ_x , σ_y or τ_{xy} . As a consequence, the strain components relating to τ_{yz} and τ_{zx} satisfy condition

$$\varepsilon_{yz} = \frac{1}{2} \left(\frac{\partial u_z}{\partial y} + \frac{\partial u_y}{\partial z} \right) = 0$$

$$\varepsilon_{zx} = \frac{1}{2} \left(\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x} \right) = 0$$
(5)

where u_x and u_y are the in-plane displacement along x and y axes, respectively. Considering u_{zj} is only the function of x

and y, the in-plane displacement can be obtained as

$$u_{xj} = -z \frac{\partial u_{zj}}{\partial x} = -z(ik - \gamma)u_{z0} \frac{x - x_j}{r_j} e^{i(kr_j - \omega t)} e^{-\gamma r_j} e^{i\phi_j}$$

$$u_{yj} = -z \frac{\partial u_{zj}}{\partial y} = -z(ik - \gamma)u_{z0} \frac{y - y_j}{r_j} e^{i(kr_j - \omega t)} e^{-\gamma r_j} e^{i\phi_j}.$$
(6)

Here, the z = 0 is set at the middle plane of thin plate.

The elastic spin density in isotropic solids is governed by [40]

$$\boldsymbol{S} = \frac{\rho \omega}{2} Im(\boldsymbol{u}^* \times \boldsymbol{u}). \tag{7}$$

The component of ${\bf S}$ along the z axis S_z is then calculated by $S_z = \frac{\rho \omega}{2} Im(u_x^* u_y - u_x u_y^*)$. When elaborating the meta-source by using multiple point sources, e.g., two point sources, S_z can then be written as

$$S_z = \frac{\rho\omega}{2} Im[(u_{xj} + u_{xl})^* (u_{yj} + u_{yl}) - (u_{xj} + u_{xl})(u_{yj} + u_{yl})^*] = \sum_{j,l=1,2} S_{z(jl)}$$
(8)

where

$$S_{z(jl)} = \frac{\rho\omega}{2} Im[(u_{xj})^*(u_{yl}) - (u_{xj})(u_{yl})^*]$$

$$= \frac{\rho\omega}{2} (zu_{z0})^2 (k^2 + \gamma^2) \frac{(x - x_j)(y - y_l)}{r_j r_l} e^{-\gamma(r_j + r_l)}$$

$$\times Im[e^{-ik(r_j - r_l)} e^{-i(\phi_j - \phi_l)} - e^{ik(r_j - r_l)} e^{i(\phi_j - \phi_l)}]$$
(9)

with * as the conjugate operator. When the meta-source is built by four point sources, the S_z can be derived as $S_z = \sum_{j,l=1,2,3,4} S_{z(jl)}$.

To give illustration, in Supplementary Figures 7 and 8, we show the theoretical results of meta-source consisting four point sources located as (x,y)=(-3 mm, 3 mm), (3 mm, 3 mm), (3 mm, -3 mm), (-3 mm, -3 mm) with additional phase $\phi=0, \pm \pi/2, \pm \pi, \pm 3\pi/2$, in accordance to the experimental configuration. γ is set as 0 for simplicity. Obviously, S_z presents good agreement between the theoretical, numerical and experimental results, and so is the u_z distribution. It is noteworthy that $S_z(jl)$ includes z^2 so that the value of S_z present the same sign along the thickness direction, with the maxima on both the top and bottom surfaces at z=-h/2 and z=h/2, respectively.

SAMPLE FABRICATION.

The phononic crystal (PC) plate is fabricated by erecting triangular pillars on substrate plate using epoxy adhesive. The triangular pillars and substrate plate are made of 6061-T6 aluminum. We first perforate triangular pillars from a 5 mm thick aluminum plate with geometric side length s=10 mm by laser cutting technique. Then we manually fix an array of 25×22 triangular pillars in hexagonal lattice to a 800 mm \times 700 mm

rhombus aluminum plate with epoxy adhesive. The rotation angle of pillars is $\theta=22^\circ$ and -22° , respectively. Meanwhile, the PC occupies a rhombus region to reduce the influence of wave reflection between PC plate and pure aluminum plate. After 24 hours at room temperature, the strength of the epoxy adhesive reaches their maximum, and these samples can be used for experiment.

EXPERIMENTAL MEASUREMENT.

To generate ultrasonic wave pulses, the subwavelength lead zirconate titanate piezoelectric ceramic (PZT) disks are used to excite point-like source and chiral elastic spin meta-source. The PZT disks are fixed to substrate plate by using epoxy adhesive. In both cases, the five-cycled tone burst electrical signals with central frequency f_c are issued from the function generator (RIGOL DG1032z) and then amplified by the power amplifier (Aigtek ATA-2022H). The every $\pm \pi/2$ phase difference against f_c in chiral meta-source is tuned by using function generator (RIGOL DG1032z). To measure elastic wave propagation, the laser Droppler vibrometer (LDV, Polytec vibrometer OFV 2570) is used to record the out-of-plane displacement u_z at any position on substrate surface, and the out-of-plane displacement perpendicular to each face of small triangular pillars for elastic SAM measurement (Supplementary Fig. 7). Each measurement comes from the averaging over 128 scans digitized by an oscilloscope (DPO 4102B) at sampling frequency of 250 MHz. This measurement allows for a good signal-to-noise (S/N) ratio.

NUMERICAL SIMULATIONS.

The numerical simulations are performed by finite element method using commercial software COMSOL Multiphysics. For the physical parameters of 6061-T6 aluminum, we chose the mass density $\rho_{Al}=2700kg/m^3$, Young's modulus $E_{Al}=67.7$ GPa, and Poisson's ratio $\nu_{Al}=0.35$. For the epoxy adhesive, we set the $\rho_{epoxy}=1.2kg/m^3$, $E_{epoxy}=5.1$ GPa, and $\nu_{epoxy}=0.38$. The geometric parameters include a=12 mm, e=1.5 mm, $h_g=0.14$ mm, $h_p=5$ mm, s=10 mm, $\theta=\pm22^\circ$.

DATA PROCESSING.

To get the displacement polarization and the maps of wave transportation, our experimental methods and detailed data analysis procedures are as what follows. In order to obtain the displacement polarization, we adopt an experimental method as shown in Supplementary Fig. 7d. We erect small subwavelength aluminum triangular pillars on the back surface of substrate, central at selected p or q point in phase A (B) or on interface. These small size pillars feature the side length 2.9

mm and height 3 mm that is much smaller than the triangular scatters for building PC plate. Then we use LDV to record the displacement that is perpendicular to the side surface of sub-wavelength small triangular pillars, as shown by the red arrows in Supplementary Fig. 7d. We label the displacement on +x side as u_1 with angle θ_1 , while the displacement on -x side as u_2 with angle θ_2 , so that u_x and u_y of the effective point can be obtained as $u_x = u_1 cos(\theta_1) - u_2 cos(\theta_2)$, and $u_y = u_1 sin(\theta_1) + u_2 sin(\theta_2)$, in the form of time evolution signal. Then by making the Fourier transformation (FFT) of u_x and u_y within the same time period including the same target wave package, we can extract the amplitude and phase information of FFT components of u_x and u_y at given frequency, e.g. 28 kHz. After that, we can draw the displacement polarization by using the retrieved amplitude and phase value of u_x and u_y at the given frequency with time term $e^{-i\omega t}$, and we obtain the elastic SAM density. To draw the maps of normalized $|u_z|$ along interface, we measure the out-of-plane displacement u_z at a series of points along interface ϕ on substrate, from x = -125 mm to 125 mm every 5 mm, and get the time evolution signal at each point. Then we make the FFT of measured time evolution signal and extract the amplitude information of FFT components of u_z in concerned frequency range. The assembly of all the extracted amplitude of u_z gives rise to the maps of u_z in Figs. 3a and 3c, and Supplementary Figs. 9 and 10.

THE MASS-SPRING MODEL.

The SAM density of elastic wave is related with the mechanical angular momentum of the medium parcel which has a circularly polarized displacement vector [40]. We can understand the SAM properties of p and q points through the wellestablished mass-spring model [47], where the mass-spring model is widely used to build and understand physical models [16, 17, 26, 61–63]. Suppose the valley metamaterial in our work as a mass-spring system in Supplementary Fig. 13. We regard the medium parcel at p and q points as the masses and the rest medium as elastic springs.

In Supplementary Fig. 13, the unit cell has a pair of mass m_p and m_q at p and q point, respectively, and the springs between them. The stiffness of spring is g, and the length of spring is L_0 . Lattice vectors are $\mathbf{a_1} = (a_x, a_y) = (a/2, \sqrt{3}a/2) = (\sqrt{3}L_0/2, 3L_0/2)$ and $\mathbf{a_2} = (a_x, -a_y) = (a/2, -\sqrt{3}a/2) = (\sqrt{3}L_0/2, -3L_0/2)$. Consider a Bloch wave of unit cell (m,n) in the form: $\mathbf{u}_{m,n} = \mathbf{u}e^{i\mathbf{k}\cdot(m\mathbf{a_1}+n\mathbf{a_2})}$, where $\mathbf{u} = [u_{px}, u_{py}, u_{qx}, u_{qy}]$. The harmonic time term $e^{-i\omega t}$ is omitted here. By solving the equation of motion [47],

we can get the Hamiltonian of this model

$$\omega^2 \boldsymbol{u} = H(\boldsymbol{k}) \boldsymbol{u}; \tag{10}$$

$$H(\mathbf{k}) = -\mathbf{M}^{-1}\mathbf{K}(\mathbf{k}); \tag{11}$$

$$\mathbf{M} = \begin{bmatrix} m_p \mathbf{I} & 0 \\ 0 & m_q \mathbf{I} \end{bmatrix}; \mathbf{K} = \begin{bmatrix} \mathbf{K}_{pp} & \mathbf{K}_{pq} \\ \mathbf{K}_{pq}^{\dagger} & \mathbf{K}_{qq} \end{bmatrix}; \tag{12}$$

$$K_{pp} = K_{qq} = -\frac{3g}{2}I; \tag{13}$$

$$K_{pq} = g \begin{bmatrix} \frac{3}{2} e^{-ik_y a_y} \cos(k_x a_x) & -i\frac{\sqrt{3}}{2} e^{-ik_y a_y} \sin(k_x a_x) \\ -i\frac{\sqrt{3}}{2} e^{ik_y a_y} \sin(k_x a_x) & 1 + \frac{1}{2} e^{ik_y a_y} \cos(k_x a_x) \end{bmatrix}.$$
(14)

The subscript \dagger refers to the conjugate transpose, and I is the unit matrix. At Brillouin zone corner K, the two eigen states of this Hamiltonian are

$$\mathbf{u}_1(\mathbf{K}) = \frac{1}{\sqrt{2}}(i, 1, 0, 0)^T; \mathbf{u}_2(\mathbf{K}) = \frac{1}{\sqrt{2}}(0, 0, -i, 1)^T,$$
(15)

while at K', the two eigen states can be written as

$$\mathbf{u}_{1}(\mathbf{K}') = \frac{1}{\sqrt{2}}(-i, 1, 0, 0)^{T}; \mathbf{u}_{2}(\mathbf{K}') = \frac{1}{\sqrt{2}}(0, 0, i, 1)^{T}.$$
(16)

These eigen states show a clear picture of the circularly polarized displacements of mass. For example, at K, $u_1(K) = \frac{1}{\sqrt{2}}(i,1,0,0)^T$ means $u_{px}/u_{py} = i = e^{i\pi/2}$, and the displacement vector at p shows clockwise polarization but equates zero at q point. Thus, in continuum valley metamaterial, we shall get the negative SAM density at p point and the zero SAM density at q point. According to above theoretical eigen states, we can also see that at K, one state possess clockwise polarization at p site $(u_1(K))$ while the other state shows the anticlockwise polarization at q site $(u_2(K))$, explaining well the calculated negative SAM density at p point (K_1) and positive SAM density at q point (K_2) in continuum valley metamaterial.

The effective Hamiltonian near the Dirac point of this sys-

tem is expressed as

$$\Delta \boldsymbol{H}\psi = \Delta\omega\psi; \tag{17}$$

$$\Delta \boldsymbol{H} = m\boldsymbol{\sigma}_z + v(\tau \Delta k_x \boldsymbol{\sigma}_x - \Delta k_y \boldsymbol{\sigma}_y); \tag{18}$$

$$m = \frac{1}{2} \frac{m_q - m_p}{m_q + m_p} \omega_0; v = \frac{\omega_0 a}{4\sqrt{3}}; \omega_0 = \sqrt{\frac{3g}{m_p + m_q}},$$
 (19)

where $\tau = +1(-1)$ relates to the K(K') valley, $\psi = (c_1, c_2)^T$ is eigenvector related to the linear combination of degenerated states at K, i.e. $u(K) = c_1 u_1(K) + c_2 u_2(K)$.

Consider an interface along x-axis at y=0 (y<0,m<0; y>0,m>0), and assume a Bloch type evanescent wave solution as $\psi(x,y)=(c_1,c_2)^Te^{-\lambda|y|}e^{i\Delta k_x x}$ with $\lambda>0$, one can get the eigenvector around boundary y=0

$$\psi = \frac{1}{\sqrt{2}} (1, -1)^T e^{i\Delta k_x x} e^{-\lambda |y|}, \tag{20}$$

which yields the displacement

$$\boldsymbol{u}(\boldsymbol{k}) = (\boldsymbol{u}_1(\tau \boldsymbol{K})e^{i\tau \boldsymbol{K}\cdot \boldsymbol{r}}, \boldsymbol{u}_2(\tau \boldsymbol{K})e^{i\tau \boldsymbol{K}\cdot \boldsymbol{r}}) \cdot \psi$$
 (21)

$$= \frac{1}{2}(i\tau, 1, i\tau, -1)e^{i\tau \mathbf{K} \cdot \mathbf{r}}e^{i\Delta k_x x}e^{-\lambda|y|}, \qquad (22)$$

so that the

Based on the definition of $S_z = \frac{\rho\omega}{2} \text{Im}(u_x^* u_y - u_x u_y^*)$, we can obtain the SAM density at p and q sites as

$$S_{pz} = \frac{\rho \omega}{2} \text{Im}(u_{px}^* u_{py} - u_{qx} u_{py}^*) = -\frac{\rho \omega \tau}{4} e^{-2\lambda |y|}$$
 (25)

$$S_{qz} = \frac{\rho\omega}{2} \text{Im}(u_{qx}^* u_{qy} - u_{qx} u_{qy}^*) = \frac{\rho\omega\tau}{4} e^{-2\lambda|y|}$$
 (26)

Here we only briefly demonstrate the eigen states of this mass-spring model in connection with our continuum structures. Detailed theory can be found in Ref. [47] with a similar and fine mass-spring model.

According to above equation, at the interface between the structures with converse topological phases (see Supplementary Fig. 13), both p and q sites magnify non-zero vibration states, but the circularly polarization direction is opposite between p and q sites. Note that the sign of τ determines the propagative direction and circularly polarization direction of p and q points. When the propagation direction is reversed, the circularly polarization direction of p and p sites is also reversed. These behaviors of polarization direction are same as the SAM direction of p and p points in the 3D continuum structures.

FIG. 4. Topological valley PC plate and chiral elastic spin meta-source. a Photograph of the PC plate fabricated by erecting triangular aluminum pillars in hexagonal lattice on an aluminum substrate. (Inset) The zoom in of the rectangular area inside yellow dashed box on the topological edge. The high symmetry points in each lattice are labeled as p/q in turn. b Schematic of unit cell with the geometrical parameters including lattice constant a=12 mm, thickness of substrate plate e=1.5 mm, thickness of epoxy layer $h_g=0.14$ mm, the height, side length, and the rotation angle of triangular pillar $h_p=5$ mm, s=10 mm, $\theta=\pm22^\circ$ respectively. Schematic (c) and photograph (d) of bottom view of chiral elastic spin meta-source consisting four small PZT disks, S1-S4, arranged in square with distance d=6 mm. The PZT disks are made of PZT-5H with thickness 1.25 mm and radii r=2.5 mm. Four independent electrical signals are loaded on S1, S2, S3 and S4 with the same amplitude but every $\pm \pi/2$ phase difference versus the central frequency of input signals. Although the assembly of the meta-source occupies area about 11 mm \times 11 mm, however the effective center area of meta-source has size only about 2.5 mm \times 2.5 mm.

FIG. 5. Band structure of unit cell and supercell with u_z proportion. a Band structure of unit cell with rotation angle $\theta=\pm22^\circ$. The color scale indicates the proportion of out-ot-plane displacement u_z against total displacement u_t in unit cell as $\int |u_z|^2 dV/\int |u_t|^2 dV$. There is a band gap for anti-symmetric plate wave between 23.8 kHz and 32.2 kHz. **b,c** The dispersion of supercell containing interface ϕ where phase B $(\theta=-22^\circ)$ up and phase A $(\theta=22^\circ)$ low, with the proportion of u_z against total displacement u_t in whole supercell (**b**) and only in substrate (**c**). Both of them show that the TES are dominated by the out-of-plane displacement.

FIG. 6. The in-plane mechanical energy flux arrows of states with positive (k > 0) and negative (k < 0) group velocity at 25.8 kHz in confined areas in main Fig. 1b. The energy flux has vortex somewhere, but it does not maintain distribution as clear as the elastic SAM density. In particular, the direction of energy flux is nearly flat at both p_E and q_E points. Thus, it is difficult to tell the difference about chiral properties between p_E and q_E points by using the vortex of energy flux. Note that we only show the distribution of energy flux on substrate, considering the meta-source is erected on the substrate and then the spin texture of meta-source is directly coupled to the substrate.

FIG. 7. Elastic spin of chiral elastic spin meta-source, a Theoretically calculated S_z (rainbow color table) with spin-down (spin \downarrow) or spin-up (spin \uparrow) excitation at 28 kHz on a 1.5 mm thick aluminum plate, whereby S_z show negative or positive high density spot in central area. Red dots indicate the position of point sources. **b** Numerically calculated S_z (twilight color table) and in-plane mechanical energy flux (black arrows) distribution for spin-down (spin \downarrow) or spin-up (spin \uparrow) source, whereby S_z magnifies negative or positive high density spot in the center, as well as clockwise or anti-clockwise vortex energy flux. Black circles indicate the position of sub-wavelength PZTs. c Measured time evolution of u_x (orange line) and u_y (blue line) at effective points at the center of meta-source on plate when excited with central frequency 28 kHz, and they are normalized to the maximum value of u_x at each effective point. Obviously, the u_x is later than u_y with with spin-down excitation. By extracting amplitude and phase information from displacement signals at given frequency (28 kHz here), the displacement polarization $\mathbf{u} = (u_x, u_y)$ and the elastic S_z can be obtained. The corresponding displacement polarization is clockwise and the S_z is negative. The phase of u_x is earlier than u_y when with spin-up excitation, and relevant displacement polarization is anti-clockwise and the S_z is positive. **d** Schematic diagram of experimental measurements of elastic SAM density anywhere of the PC plate (shown here) and blank aluminum plate. To measure S_z , we put subwavelength triangular aluminum pillars on the back surface of substrate plate. Then we use laser Doppler vibrometer (LDV) to record the out-of-plane displacement versus two side faces of triangular pillar. Because the triangular pillar has relatively much small size, i.e. side length 2.9 mm and height 3 mm, the measured displacement can be seen at an effective point inside the pillar. The S_z distribution inside triangular pillar has the same sign with corresponding point at our working frequency range. Here we label the displacement on +x side as u_1 with angle θ_1 , while the displacement on -x side as u_2 with angle θ_2 , so that u_x and u_y of the effective point can be obtained as $u_x = u_1 cos(\theta_1) - u_2 cos(\theta_2)$, and $u_y = u_1 sin(\theta_1) + u_2 sin(\theta_2)$.

FIG. 8. Out-of-plane displacement u_z by chiral elastic spin source. Theoretical (a), numerical (b) and experimental (c) out-of-plane displacement u_z distribution by chiral meta-source, all indicating clockwise (spin-down excitation) or anti-clockwise (spin-up excitation) rotation indicated by the arrows.

FIG. 9. Experimental observation of unidirectional wave transportation when meta-source located around p_A and q_A . a The map of normalized $|u_z|$ measured along interface ϕ from x=-125 mm to 125 mm every 5 mm with chiral elastic spin meta-source centered at p_A , where x=0 is at the middle position along interface ϕ . b The difference of $|u_z|$ between right and left side of meta-source, defined as $\lg(\overline{|u_R|}/|u_L|)$, where $\overline{|u_R|}$ (resp. $\overline{|u_L|}$) is the averaged amplitude of $|u_z|$ measured at the right (resp. left) side of source, when meta-source is centered at p_A . The red solid and black dashed lines present the result with spin-up (spin \uparrow) and spin-down (spin \downarrow) sources, respectively. c,d The map of normalized $|u_z|$ (c) and difference (d) measured along interface ϕ with meta-source locating at q_A . In panel a, the asymmetric rightward and leftward wave propagation are successfully generated by spin-down and spin-up source, respectively. In panel b, the asymmetric behavior is clearly observed in broad frequency range where the positive (resp. negative) value indicates the rightward (resp. leftward) wave propagation, reaching a huge difference of 15.8 times ($\lg(\overline{|u_R|}/\overline{|u_L|})=1.2$). While in panels c and d, the situations are reversed: the spin-down and spin-up source generate the asymmetric leftward and rightward wave propagation, respectively, instead. We note that the relatively narrower frequency range between 25 kHz \sim 31 kHz in panel d shall come from experimental factors including the the imperfect installation of meta-source and the sample parameter fluctuation.

FIG. 10. Experimental observation of unidirectional wave transportation by an array of four PZT disks with radii r=1.5 mm and distance d=4 mm. a The map of normalized $|u_z|$ measured along interface ϕ from x=-120 mm to 80 mm every 5 mm with chiral elastic spin meta-source centered at p_A . Here, x=0 is at the middle position along interface ϕ , and the meta-source is installed at $x\approx-25$ mm. b The difference of $|u_z|$ between right and left sides of meta-source, defined as $\lg(|u_R|/|u_L|)$, where $|u_R|$ (resp. $|u_L|$) is the averaged amplitude of $|u_z|$ measured at the right (resp. left) side of source. The red solid and black dashed lines present the result with spin-up (spin \uparrow) and spin-down (spin \downarrow) sources, respectively. When using spin-up (resp. spin-down) source, the leftward (resp. rightward) elastic wave is successfully generated. However, the difference is smaller than its counterparts when using larger meat-source. Here the assembly of the meta-source occupies area about 7 mm×7 mm, and the effective center area of meta-source has size only about 1.9 mm×1.9 mm.

FIG. 11. The simulated difference of $|u_z|$ between right and left side of meta-source. The average difference of u_z between right and left side of meta-source centered at p_A (a), q_A (b), p_E (c), q_E (d), p_B (e), and q_B (f), respectively. The positive (resp. negative) value indicates the rightward (resp. leftward) transportation. The unidirectional propagation is clearly observed in a broad frequency range, and the difference can be up to 31 times $(\lg(|u_{right}|/|u_{left}|)=1.5)$. Obviously, the plate wave transports to left side with spin-up source but to right side with spin-down source all centered at p_B points. On the other hand, the plate wave are rightward going with spin-up source but leftward going with spin-down source all centered at p_B points, just opposite to those at p_B points. The red solid (resp. black dashed) line presents the results with spin-up (resp. spin-down) source.

FIG. 12. Numerically simulated elastic S_z at effective p/q points. a,b Computed S_z at left (a) and at right (b) side of point source normalized to the overall maximum value in each panel. At left side and in a broad frequency range, S_z features positive value on p points but negative value on p points. The situation at right side is reversed: S_z is negative on p points but positive on p points.

FIG. 13. The mass-spring model. a The orange circles are p sites and blue circles are q sites. Here, we use the black dashed lines to mark the triangular pillar in relevant valley metamaterial. b The boundary between PC with effective mass m > 0 (up domain) and m < 0 (bottom domain).
