ABSTRACT

Landau quantization associated with the quantized cyclotron motion of electrons under magnetic field provides the effective way to investigate topologically protected quantum states with entangled degrees of freedom and multiple quantum numbers. Here we report the cascade of Landau quantization in a strained type-II Dirac semimetal NiTe₂ with spectroscopic-imaging scanning tunneling microscopy. The uniform-height surfaces exhibit single-sequence Landau levels (LLs) at a magnetic field originating from the quantization of topological surface state (TSS) across the Fermi level. Strikingly, we reveal the multiple sequence of LLs in the strained surface regions where the rotation symmetry is broken. First-principles calculations demonstrate that the multiple LLs attest to the remarkable lifting of the valley degeneracy of TSS by the in-plane uniaxial or shear strains. Our findings pave a pathway to tune multiple degrees of freedom and quantum numbers of TMDs *via* strain engineering for practical applications such as high-frequency rectifiers, Josephson diode and valleytronics.

KEYWORDS: Vallytronics, Landau quantization, strain engineering, topological surface state, transition metal dichalcogenides

Lifting and controlling over the degeneracy of multiple degrees of freedom such as spin^{1,2}, valley^{3,4}, orbital⁵, helicity⁶ and pseudospin⁷ is the central goal of functional devices and electronics including spintronic and valleytronics. Quantum materials hosting spin-momentum-locked topological surface states (TSSs) that span the bulk bandgap⁸ are a promising candidate for such applications. Landau quantization, which is a fundamental phenomenon associated with the quantized cyclotron motion of electrons in a magnetic field^{9,10}, provides the effective way to investigate topologically protected quantum states with entangled degrees of freedom and multiple quantum numbers. To date, single-sequence Landau quantization of degenerate electron has been reported in graphene and other topological materials^{11–13}. However, investigation of multiple-sequence Landau levels emerged from the lift of multiple degrees of freedom to understand the origin of the exotic properties of quantum states^{15,16} remains experimentally rare¹⁴ and to further controlling the topologically-protected quantum states^{15,16}

Recently, the class of transition metal dichalcogenides (TMDs) has been identified to be a material system with rich topological properties, including Dirac points in the bulk bands characteristic of Dirac semimetals and band inversion induced helical $TSSs^{17,18}$ characteristic of strong topological insulators. The TMDs $NiTe_2^{19-22}$ and $PdTe_2^{23}$ exhibit such a dual character. For example, angle-resolved photoemission spectroscopy (ARPES) measurements¹⁹ demonstrate the type-II Dirac point sitting about 0.1 eV above the Fermi level (E_F), which originates from the transition metal *d* orbital states. In addition, helical TSSs are detected to cross the E_F , which are remarkably split into two branches of opposite helicity^{19,23}. The latter has recently been utilized to achieve the field-induced Josephson diode effect²⁴. Moreover, the TSSs produce rich multivalley Fermi surfaces with complex spin textures²³. Therefore, the TMDs provide a platform to investigate topologically protected quantum states with entangled degrees of freedom and multiple quantum numbers, which remains largely unexplored.

Here, we study the Landau quantization of the TSSs in type-II Dirac semimetal NiTe₂ single crystals by using scanning tunneling microscopy/spectroscopy (STM/S). We observe multiple groups of Landau levels (LLs) in the TSSs at a low temperature of 420 mK and in high magnetic fields applied perpendicular to the surface. In the uniform-height region, one group of LLs are observed in the energy range where the surface states are dominant. The LLs correspond to the quantization of TSS band across E_F resulting from the band inversion in the chalcogen *p*-orbital manifold. In contrast, we observe two and three groups of LLs in strained surface regions where the rotation symmetry is broken. Combined with the density functional theory (DFT) calculations, we attribute the multiple groups of LLs to the

lifting of the valley degeneracy that produces the additional valley-polarization of TSSs, as the strain breaks the rotation symmetry and causes anisotropic shifting of the surface bands along distinct momentum directions.

NiTe₂, crystallized in a trigonal structure with the $P\overline{3}m1$ space group²², is a van der Waals coupling material. The unit cell consists of one Ni atom and two Te atoms (Figure 1(a)). Basic structural measurements demonstrate the high quality of as-grown 1T-NiTe₂ crystal (Figure S1). The large-scale STM image (Figure 1(b)) shows a flat and clean Te-terminated surface of NiTe₂ with low defect density. The atomically-resolved STM image obtained at the Te-terminated surface of NiTe₂ (inset of Figure 1(b)) shows a hexagonal lattice with lattice constants $a=b\approx0.38$ nm which are consistent with the stoichiometric NiTe₂ in the literatures where a=b=0.38551 nm, and c=0.52660 nm^{20,21}.

To investigate the fine structure of the TSSs and their topological properties of NiTe₂, we perform the Landau-level spectroscopy of STM^{11,25–27} at 420 mK (electronic temperature is about 620 mK, see Methods) and strong magnetic field perpendicular to the surface (B_z). In the dI/dV spectra of the flat area with uniform-height distributions (Figure 1(b)) and negligible lattice distortions (Figure S2(a-d)), several sharp peaks emerge around the E_F at $B_z = 11$ T, which are absent at 0 T (Figure 1(c)). With increasing B_z , all the peaks shift significantly toward higher energy (Figure 1(d)), indicating that the peaks result from the Landau quantization of electron-like pockets with the band minimum lying below the E_F .

We then determine the band dispersion of the Landau quantized electron band based on the semiclassical Lifshitz-Onsager relation $S_n = 2\pi e(n + \gamma)B/\hbar$ ($\gamma = \frac{1}{2} - \frac{\phi_B}{2\pi}$, ϕ_B is the Berry phase enclosed by the cyclotron orbit). We assign the first peak of LLs at 9 T to different integers for a given value of γ (Figure S3, S4) and then analyze the dispersion using the obtained LL sequence for different γ values²⁸ (Figure S5). As a result, when we assign the quantum number of the first LL to n = 4 and the phase factor $\gamma = 1/2$ (Berry phase is zero), the LL peak energy E_n and the calculated k_n converge to an effective TSS band. In the energy range from -8 meV to 8 meV, the Fermi velocity of the band (v_F) is about 1.4×10^5 m/s with the band minimum at about -40.6 meV (Figure 1(e)).

The TSSs induced by the band inversion in the chalcogen *p*-orbital manifold are observed in the spinpolarized ARPES measurements across the E_F along $\overline{\Gamma} - \overline{M}$ direction (Figure 1(f)), whereas the bulk Dirac cone is about 0.1 eV above the $E_F^{19,21}$. Therefore, we attribute the emerging LL peaks in the applied magnetic field to the quantization of the TSS near the E_F instead of the type-II bulk Dirac cones at around 0.1 eV and other surface states far away from the E_F . The Dirac cone of TSS near the Γ point shows hole-like dispersion, which is inconsistent with the STM observations. In addition, the zero-value Berry phase enclosed by the Landau orbits further excludes that the Landau quantization of Dirac cone at Γ point where the Berry phase should be nonzero. On the other hand, the fitted dispersions and band minimum value are consistent with the electron-like subbands of TSS near E_F (highlighted by the light purple shades in Figure 1(f)). Therefore, we conclude that the Landau quantization of electron-like subbands of TSSs along the $\overline{M} - \overline{\Gamma} - \overline{M}$ direction near E_F gives rise to the single-group LLs in density of states (DOS) (Figure 1(f)).

We note that only parts (n=4, ... 10) of the LL sequence are observable in the energy range from -10 mV to 10 mV around the E_F. Moreover, the static peaks, namely the Landau levels with index n = 0, are absent in the B_z -dependent dI/dV spectra (Figure 1(d)). We attribute the absence of the other LLs to the overlap of the surface states with the bulk band^{12,29} outside this energy range. In addition, at the 0 T, the dI/dV maps of the NiTe₂ surface at low energy clearly show the standing-wave patterns originated from the intervalley scattering of surface state (Figure S6). The energy range for observing the standing-wave patterns is around -10 mV to 10 mV (Figure S6(b),(c)), coinciding with the energy range of the observed LLs.

To further investigate the effects of strain^{30,31} on the LLs, we measure the Landau-level spectroscopy at strained surfaces. In the strained region, the height distribution is not uniform (Figure 2(a)) and the lattice shows distortion (Figure S2(e-h)). Strikingly different from the single-series of LLs in graphene and topological insulators^{12,32}, there are two groups of LLs (labeled as *na* and *nb*, *n*=0,1,2...), indicating two different origins of the Landau-quantized states (Figure 2(b)). The two groups of LLs (highlighted by azure and orange shades in Figure 2(b)) show energy shifts with increasing *B_z*. At *B_z* = 11 T, the *dI/dV* spectra obtained along a relatively long distance in the region of Figure 2(a) show that the two groups of LLs are spatially homogeneous over the strain region, excluding the local effects that may cause multiple LLs at specific locations (Figure 2(e)). Furthermore, the Landau-level spectroscopy at B_z= -11 T is almost the same as the one at B_z= 11 T (Figure 2(c)), excluding the Zeeman splitting of degenerate LLs. Following the procedure used to extract the one group of LLs, we similarly label the first two peaks with the index *n* = 4 and adopt the phase factor γ =1/2 (Figure S4). Remarkably, the two groups of peaks converge into two TSS band dispersions (Figure 2(d)). In the energy range from -8 meV to 8 meV, the Fermi velocity of two dispersions remains about 1.4×10⁵ m/s with band bottom at about - 41.6 meV for band *a* and -42.1 meV for band *b*.

The multiple LLs is sensitive to the type of surface strain. In a region with strains different from those depicted in Figure 2 (Figure 3(a) and Figure S2(i-l)), three groups of LLs which are labeled as na, nb and nc (n=0,1,2...) are observed in B_z -dependent dI/dV spectra (Figure 3(b)) and Landau fan diagram (Figure 3(c)). Following the procedure before, we similarly label the first three peaks with the index n = 4 and adopt the phase factor $\gamma=1/2$ (Figure S5). Similarly, the three groups of peaks converge into three TSS band dispersions (Figure 3(d)). In the energy range from -8 meV to 8 meV, the Fermi velocity of three dispersions remains about 1.4×10^5 m/s, but the fitting band bottom are -41.0 meV for band a, -41.9 meV for band b and -42.6 meV for band c. The three groups of LLs are homogeneous over the strained region (Fig. 3(e)).

To investigate the origin of the multiple LLs, we systematically study the strain effects based on DFT calculations and summarize our results in Figure 4. We firstly calculate the band structure of NiTe₂ (Figure S7(a)) and then track the evolution of the energy band belong to TSSs near E_F under different types of strain. Based on the Fermi surfaces detected by the ARPES measurements¹⁹, the TSSs bands form three pairs of electron pockets which are located at approximately midway site along three equivalent $\overline{\Gamma} - \overline{M}$ directions $(\overline{\Gamma} - \overline{M}_1, \overline{\Gamma} - \overline{M}_2 \text{ and } \overline{\Gamma} - \overline{M}_3)$, respectively (Figure 4(b)). In the region with uniform topographic height and without strain (Figure 4(a)), the electron-like subbands of TSS along the three directions are equivalent due to the crystalline symmetry, which results in one group of LLs (Figure 1(f) and Figure 4(b)). However, in the strained surface region, the crystalline symmetry is broken and the valley degeneration is lifted^{30,31,33}, which leads to the cascade of multiple groups of LLs. Under the uniaxial strain, such as strain along the crystalline zigzag (Figure 4(c)) or armchair direction (Figure 4(e)), there is an relative energy shift for one of the three subbands (Figure S7(c)). For example, when a strain up to 1% along the zigzag direction is applied, the TSS subband along the $\overline{\Gamma} - \overline{M}_3$ direction shifts -2.5 meV away from those along $\overline{\Gamma} - \overline{M}_1$ and $\overline{\Gamma} - \overline{M}_2$ directions (Figure 4(d)). Similarly, a strain of 1% along the armchair direction induces an energy shift of 1.8 meV between the subband along the $\overline{\Gamma} - \overline{M}_3$ direction (Figure 4(f)) and the other two directions. Accordingly, the valleys of the band under uniaxial strain produces two groups of LLs (right panel of Figure 4(d) and Figure 4(f)). The lattice distortion, two groups of LLs and their spectrum weights observed in the surface region of Figure 2 are consistent with the armchair strain case. Intriguingly, under the in-plane shear strain (Figure 4(g)), the 3-fold symmetry is fully broken and the valley degeneration along the three directions is completely lifted (Figure 4(h)). As a result, the minima of the three pairs of subbands are significantly different, inducing three sequences of LLs (right panel of Figure 4(h)). The lattice distortion, three groups of LLs

and their spectrum weights observed in the surface region of Figure 3 are consistent with the shear strain case.

When considering the same energy splitting, the strain value in the FFT analysis (Figure S2) appears to be relatively larger than the calculated value (Figure 4). It is possibly caused by the inhomogeneous strain distribution present in the bulk NiTe₂. Specifically, the lattice distortions observed in the STM measurements correspond only to the top layer of bulk NiTe₂, whereas the DFT calculations assume a homogeneous distribution of strain in all layers of NiTe₂. It is therefore reasonable that the local lattice distortion at the surface of the top layer is larger than the calculated value due to the presence of inhomogeneities or large-sized surface wrinkles in the as-cleaved NiTe₂ sample in experiments. Nevertheless, the DFT calculations still qualitatively agree with the STM observations that multiple groups of LLs are indeed controlled by the types of strains (uniaxial or shear).

These findings reveal that the valley degeneracy of the TSSs can be effectively tuned by the different type of strain. However, it should be noted that STM is a local probe that can only detect the local strain present in the top layer of the NiTe₂ crystal. As such, it is difficult for us to experimentally estimate the magnitude of strain needed to obtain a given energy separation achievable with the state-of-the-art tunable strain apparatus. The quantitative relationship between the global strain and the separation of the TSSs remains for future investigations. The discovery of valley polarized TSSs in NiTe₂ reveals its potential for realizing a highly helicity-polarized⁶, Josephson diode effect²⁴ and valley-polarized surface-isolated transport³⁴. Since the formation of bulk Dirac cones and TSSs from a single orbital manifold is ubiquitous in TMDs¹⁸, the lifting of the degenerate degrees of freedom via rotation symmetry breaking and the emergence of multigroup LLs can be extended to other TMDs such as PdTe₂²³, PtSe₂³⁵ and WS₂³⁶. In addition, the monolayer NiTe₂³⁷ and doped NiTe₂^{38,39} have been predicted to host superconducting ground state. Therefore, our findings will inspire further studies on the formation of superconducting TSSs^{8,40} and topological superconductivity in the homojunctions/heterojunctions based on the TMDs thin films.

EXPERIMENTAL METHOD

Single crystal growth and characterization of NiTe₂ sample. Single crystals of NiTe₂ are synthesized *via* the self-flux method. The as-grown NiTe₂ single crystals were characterized by optical microscope (Olympus BX51-SC30). XRD pattern was collected using a Rigaku SmartLab SE X-ray diffractometer with Cu K α radiation (λ =0.15418 nm) at room temperature. The rocking curve was achieved on BRUKER D8 VENTURE diffractometer with Mo K α radiation (λ =0.71073 Å). The Raman spectrum was obtained by using Labram HR EV0, equipped with a diode laser emitting at 532 nm at a nominal power of 12 mW. The samples used in the TEM measurements were transferred onto a lacey support film after ground. The HRTEM image and SAED patterns were obtained by JEOL JEM-2100Plus microscope, operated at 200 kV.

Scanning tunneling microscopy/spectroscopy. The samples used in the STM/S experiments are cleaved at low temperature (78 K) and immediately transferred to an STM chamber. Experiments were performed in an ultrahigh vacuum $(1 \times 10^{-10} \text{ mbar})$ ultra-low temperature STM system equipped with 11 T magnetic field. All the scanning parameters (setpoint voltage and current) of the STM topographic images are listed in the figure captions. The electronic temperature in the low-temperature STS is 620 mK, calibrated using a standard superconductor, Nb crystal (Figure S8). Unless otherwise noted, the dI/dV spectra were acquired by a standard lock-in amplifier at a modulation frequency of 973.1 Hz. Non-superconducting tungsten tips were fabricated via electrochemical etching and calibrated on a clean Au(111) surface prepared by repeated cycles of sputtering with argon ions and annealing at 500 °C.

Strain analysis and data fitting. We analyze the strain distortions by comparing the length of three pairs of Bragg peaks in the Fourier transform of atomically-resolved STM images in strained regions (Figure S2)⁴¹.

We assign the LL index *n* based on the semi-classical Lifshitz-Onsager relation. The extremal area S_n in the reciprocal space of the *n*th Landau level at energy E_n is given by $S_n = 2\pi e(n + \gamma)B/\hbar$, where γ is the phase factor. In the reciprocal space, we have $S_n = \pi k_n^2$, where k_n is the geometric mean of the quantized orbital radius of S_n .

To obtain the accurate energy of the Landau peaks, we firstly substrate the Landau level spectroscopy by the spectrum with zero magnetic field. Then we use Lorentzian function:

$$y = y_0 + \frac{2A}{\pi} \frac{w}{4(x - x_c)^2 + w^2}$$

to fit the Landau peaks and extract the peak center x_c . Our fitting results match the original data very well (Figure S9) which makes the peak energy we get accurate.

DFT calculations. The structural optimizations and the electronic properties of layered NiTe₂ thin film were calculated in terms of the density functional theory $(DFT)^{42,43}$, with the projector augmented wave (PAW) potentials⁴⁴ as implemented in the Vienna Ab initio Simulation Package (VASP)⁴⁵. The Perdew-Burke-Enzerhof approximation to the generalized-gradient approximation (GGA)⁴⁶ is adopted. Our computational slab model consists of ten NiTe₂ unit-cell layers, and a vacuum layer with thickness of 18 Å. For structural optimization calculations, we use a $14 \times 14 \times 1$ Gamma-center k-point mesh and an energy cutoff 550 eV for convergence. The lattice constants are relaxed by minimizing the total energies to an accuracy of 0.001 meV per primitive unit cell, and the ion positions are relaxed with an accuracy of 0.001 eV/Å. The scalar relativistic approximation is used to treat the relativistic effects. The spin-orbit coupling is also included in calculating the band structures of this compounds.
