ABSTRACT

Aims. FIRST is a spectro-interferometer combining, in the visible, the techniques of aperture masking and spatial filtering thanks to single-mode fibers. By turning a monolithic telescope into an interferometer, this instrument aims to deliver high contrast capabilities at spatial resolutions that are inaccessible to classical coronagraphic instruments.

Methods. The technique implemented in the FIRST instrument is called pupil remapping: the telescope pupil is divided into subpupils by a segmented deformable mirror conjugated to a micro-lens array injecting light into single-mode fibers. The fiber outputs are rearranged in a nonredundant configuration, allowing simultaneous measurement of all baseline fringe patterns. The fringes are also spectrally dispersed, increasing the coherence length and providing precious spectral information. The optical setup of the instrument has been adapted to fit onto the SCExAO platform at the Subaru Telescope.

Results. We present the first on-sky demonstration of the FIRST instrument at the Subaru telescope. We used eight subapertures of the 8.2-meter diameter pupil, each with a diameter of about 1 m. Closure phase measurements were extracted from the interference pattern to provide spatial information on the target. We tested the instrument on two types of targets : a point source (Keho'oea - α Lyrae, $m_R = 0.1$) and a binary system (Hokulei - α Aurigae, $m_R = -0.52$, and a semi-major axis = 56.4 mas). An average accuracy of 0.6° is achieved on the closure phase measurements of Keho'oea, with a statistical error of about 0.15° at best. We estimate that the instrument can be sensitive to structures down to a quarter of the telescope spatial resolution. We measured the relative positions of Hokulei Aa and Ab with an accuracy ≤ 1 mas.

Conclusions. FIRST opens new observing capabilities in the visible wavelength range at the Subaru Telescope. With SCExAO being a testing platform for high contrast imaging instrumentation for future 30-meter class telescopes, the successful demonstration and exploitation of FIRST is an important stepping stone for future interferometric instrumentation on extremely large telescopes.

1. Introduction

One of the key challenges in ground-based astronomy is the study of circumstellar environments, for example the detection and characterization of stellar companions such as exoplanets or protoplanets. This is achieved by using techniques qualified either as indirect (for example radial velocity and transit) or direct. The latter usually consists in masking the light of a star in the focal plane, using a coronagraph, to reveal its circumstellar environment. One challenge is to correct for atmospheric turbulenceas best as possible. The latter induces wavefront errors that cause stellar leakage in coronagraphs, which limits the performance of detection in terms of the inner working angle and contrast. By using adaptive optics (AO) (Rousset et al. 1990), and even extreme AO (ExAO), a large fraction of the atmospheric turbulence is corrected, and therefore it recovers the telescope native resolution power, almost down to the diffraction limit. This is critical for confining most of the starlight behind the focal plane mask, and thus increasing the achievable contrast. Indeed, exoplanets are extremely faint compared to their host star by a factor of 10^{-6} and 10^{-9} for hot Jupiters and Earth-like planets, respectively (Seager 2010). About 20 exoplanets have been imaged thanks to coronagraphs, but at distances relatively large from their host star, that is ≥ 10 astronomical units (au) (Marois et al. 2008; Lagrange et al. 2010; Currie et al. 2014). Closer-in planets, while more numerous, are harder to image due to the inner working angle (IWA) of coronagraphs being typically greater than $2\lambda/D$ with λ being the wavelength and D the telescope diameter. For an 8-meter class telescope, this corresponds to about 70 mas at 1550 nm. Indirect detections have shown that there is an abundance of massive planets around Sun-like stars at distances of about 1 to 5 au (Pascucci et al. 2019). At the distance of the Taurus group, the closest stellar formation region from Earth (140 parsecs), this corresponds to an angular separation of 7 to 40 mas. These separations are then out of reach for current 8-meter telescopes using coronagraphs, which are limited to regions >10 au for stars at about 140 pc.

One solution to probe this region is single telescope interferometry: sparse aperture masking (SAM)(Haniff et al. 1987), consists in placing a nonredundant mask delimiting several subpupils in a pupil plane of the telescope and recombining the coherent light from all of those subpupils. The nonredundancy of the mask allows for each baseline (vector defined by each pair of subpupils) to be unique. In the Fourier domain, this means that the information carried by every fringe pattern is located at a unique spatial frequency and can thus be retrieved, independently from all other fringes. SAM has been regularly used on large telescope instruments including NACO/Very Large Telescope (Lacour et al. 2011a; Lagrange et al. 2012), NIRC2/Keck (Hinkley et al. 2011), VAMPIRES/Subaru (Norris et al. 2015b), SPHERE/Very Large Telescope (Cheetham et al. 2016), or NIRISS/James Webb Space Telescope (Sivaramakrishnan et al. 2012). SAM is also planned for future extremely large telescopes (MICADO/European Extremely Large Telescope - Lacour et al. 2014). The advantage of this technique is its sensitivity to structures that extend down to $0.5\lambda/B_{max}$ (IWA), with B_{max} the interferometer's longest baseline (Lacour et al. 2011b). Considering B_{max} as the diameter of the telescope, aperture masking beats the single telescope diffraction limit by a factor of two, and brings the detection limit down to 10 mas or less on an 8-meter telescope in the visible. Moreover, it allows one to compute the closure phase (CP) self-calibrated quantity, which cancels out the AO residual and quasi-static aberrations in the instrument. The drawbacks of using aperture masking are the following: i) it can only exploit a fraction of the pupil because of the nonredundancy requirement, and ii) remaining speckle noise over each subpupil limits the achievable contrast to about 10^{-3} (Gauchet et al. 2016). A method that can make use of the aperture masking concept without its disadvantages is the pupil remapping technique. It consists in sampling the whole pupil and, with the help of singlemode fibers, recombining the different subpupils pairwise (Perrin et al. 2006). This allows one to do the following: i) exploit the light from the whole pupil, and ii) "clean" the wavefront over each subpupil, and therefore remove the speckle noise, thanks to the spatial filtering performed by the single-mode fibers; and iii) sense all spatial frequencies independently. Lacour et al. (2007) showed that such an instrument could theoretically reach a contrast of 10⁻⁶ using a classical AO system. As shown in Norris et al. (2014), the achievable contrast of pupil remapping instruments relies on the AO performance. Hence, recent advances in wavefront control (Guyon et al. 2020) are expected to benefit such instruments.

An instrument with such features, named Fibered Imager foR a Single Telescope (FIRST), was developed at the Paris Observatory (Kotani et al. 2009). FIRST is a fibered pupil remapper coupled with a spectrograph, operating in the visible (600 to 800 nm range). FIRST demonstrated its capability to resolve the binary system Hokulei (α Aurigae or Capella, V= 0.08, R=-0.52 Huby et al. 2013) and perform spectroscopic analysis at the diffraction limit on the 3-meter Lick Telescope. This success led to moving the instrument on a larger telescope: it is currently installed on the 8.2-meter Subaru Telescope as part of the Subaru Coronagraphic Extreme Adaptive Optics (SCExAO) instrument (Jovanovic et al. 2015; Vievard et al. 2020). The advantages of deploying FIRST behind an ExAO system with exquisite wavefront stability are twofold, and should significantly improve the overall performance of the instrument. First, the coupling efficiency into the single-mode fibers is increased (Jovanovic et al. 2017), hence optimizing the overall throughput. Second, interference fringes are stabilized, making long exposure times possible (up to almost one second) and increasing the instrument sensitivity to faint targets. Having a visible wavelength, single aperture remapping interferometer behind an ExAO system on an 8.2-m telescope uniquely positions FIRST to provide new observing capabilities. Specifically it could provide access to key spectral structures such as $H\alpha$.

In Section 2 we provide a comprehensive description and characterization of FIRST on SCExAO. As a first on-sky demonstration on the Subaru Telescope, we present the detection of the Hokulei ¹ system in Section 3.

2. The FIRST instrument at the Subaru Telescope

2.1. Principle of the FIRST instrument

FIRST aims at using a single telescope as a coherent interferometer. The instrument concept is shown in Fig. 1. Similarly to the aperture masking technique, FIRST samples portions of the pupil and recombines the corresponding beams interferometrically. The use of single-mode fibers, in which the subpupil beams are injected, allows for the remapping of the pupil from a redundant array (input pupil) to a nonredundant array (output pupil). By nature, single-mode fibers filter out high order perturbations of the wavefront over each subaperture, removing speckle noise and providing an increased fringe contrast. The nonredundant recombination of N subapertures gives access to $N \times (N-1)/2$ independent measurements, the complex coherences, present in the original pupil. Finally, a spectrometer adds spectral information to the recombined interferometric signal. Based on the analysis of the fringes as a function of wavelength, we can derive the optical path difference (OPD) between the different pairs of subpupils, as well as CPs.

2.2. A submodule of SCExAO

The Subaru Coronagraphic Extreme Adaptive Optics (SCExAO - Jovanovic et al. 2015) instrument is located on the Infra-Red (IR) Nasmyth platform of the Subaru Telescope. It is fed by AO188 (Minowa et al. 2010), an adaptive optics system featuring a 188-element curvature sensor that delivers the first stage of wavefront correction. SCExAO's primary purpose is to perform additional wavefront correction and starlight suppression

¹ This paper refers to the main targets per their Hawaiian names, in honor of Mauna Kea, the mountain from which we were most fortunate to perform our observations, and with acknowledgment of the indigenous hawaiian communities who have had and continue to have Kuleana (translated into English as "responsibility") to this land. We offer the reader some more information about these Hawaiian names in Appendix B

S. Vievard et al.: FIRST at the Subaru Telescope

Fig. 1. FIRST instrument principle: the redundant pupil of the telescope is divided into several subapertures (**A**). The selected subapertures, circled in red, are injected into single-mode fibers (**B**) and rearranged into a nonredundant pattern (**C**). The signal of each subaperture is dispersed using anamorphic optics and a prism (**D**). Coherent recombination produces the interferometric signal on the camera, delivering Optical Path Difference (OPD) information as a function of wavelength (**E**). RP = Redundant Pupil - μ L = micro-lenses - FB = Fiber Bundle - SMF = Single Mode Fibers - VG = V-groove - Cyl = Cylindrical lenses - P = Prism.

thanks to coronagraphy, in order to study circumstellar environments (Currie et al. 2018; Norris et al. 2015a; Kotani et al. 2020).

As can be seen in Fig. 2, the light reflected off the SCExAO deformable mirror (DM - 2040 actuators) is split by a dichroic beamsplitter. Visible light is reflected toward a periscope, sending the light toward the upper bench dedicated to the visible wavefront sensor and modules. At the output of the periscope, a first beamsplitter reflects part of the light toward the pyramid wavefront sensor (PyWFS - Lozi et al. 2019). We commonly use here a short-pass dichroic cutting at 800 nm, allowing the PyWFS to operate in the 800 – 950 nm band to provide a wavefront quality over 80% Strehl in H-band. The transmitted beam reaches the FIRST pickoff mirror, which is placed on a motorized stage to allow for light to be sent to either VAMPIRES or FIRST.

2.3. The FIRST setup

The FIRST optical components span two different benches corresponding to the injection part and the recombination part respectively. The previously mentioned FIRST pickoff mirror sends a f/27.3 diverging beam to the injection setup. A 120 mm focal length lens collimates the beam, which is then split by a polarizing beamsplitter cube (BSC). The reflected polarization is sent to a Quarter Wave Plate (QWP) right before being reflected at normal incidence off of a 37-element segmented mirror (vendor: Iris AO). This Micro-ElectroMechanical System technology (MEMS) is composed of hexagonal segments, each driven by three actuators allowing Piston, Tip and Tilt control. It is conjugated to the SCExAO pupil plane (see Fig. 3-left) and used to optimize the injection into the single-mode fibers. The circular polarization changes sign after the reflection on the MEMS and is then transmitted through the QWP and the polarized beamsplitter cube, such that all the flux with the s-polarization is transmitted in the instrument. An afocal system with two lenses (of focal length 85 mm and 35 mm, ensuring a magnification factor of 1/2.6) is used to match the segment size (606.2 µm diameter for the circle inscribed in each segment) to the micro-lens diameter (250 µm). The micro-lens array (MLA) is conjugated to the MEMS (see Fig. 3-right). Each of the micro-lens has a 980 µm focal length and focuses the light from the subpupils on the core

Fig. 2. SCExAO optical path from the entrance (bottom) to the FIRST injection module sitting on the visible bench (middle), and in the FIRST recombination bench (top).

of single-mode fibers, held in a bundle on a hexagonal pattern grid with a 250 μ m pitch center-to-center. The current FIRST instrument recombines the light from 9 subapertures (see Fig. 3) each with a 1.04 m on-sky diameter. The fibers of the bundle are connected to single-mode fiber extensions (polished by hand for path length matching, Huby 2013) that run to the recombination bench.

Inside the recombination bench, the outputs of the fibers are installed on a linear V-groove mount according to a nonredundant pattern (pitch of 250 μ m). The beam exiting each fiber is

Fig. 3. Configuration of the 9 subapertures in FIRST. Left: Image of FIRST's MEMS conjugated with the Subaru Telescope pupil. The subapertures are numbered after the segment index. Right: Image of the pupil plane after the micro-lens array, where each lens is conjugated to a MEMS segment: the camera detector is conjugated to both the MEMs plane and the microlens array. In green are highlighted the 9 segments used in FIRST.

collimated by a micro-lens, and can follow two different paths, that can be selected thanks to a mirror on a motorized stage: (i) toward a monitoring camera for the optimization of the coupling efficiency, or (ii) toward the spectrometer and the final science camera. The spectrometer consists of an afocal anamorphic system, comprising a set of spherical and cylindrical lenses, that stretches the beam in the dispersion direction and compresses it in the orthogonal direction. The beams are then spectrally dispersed with an equilateral SF2-prism and recombined on the science detector, a 512×512 pixel EMCCD (Andor iXon Ultra Life 897). The spectral resolution is estimated using a Neon spectral calibration light source (AvaLight-CAL-Neon-Mini). We present on Fig. 4 the acquired spectrum. The spectral resolution is calculated by computing the $\lambda/\Delta\lambda$ ratio for each spectral peak (with λ and $\Delta \lambda$ the each peak's wavelength and Full Width Half Maximum respectively). The result is presented on the graph in the same figure. We obtain a resolution of around 300 at 700 nm. FIRST's field of view, computed as the size of the diffraction spot from the largest subaperture (Guyon 2002) is about 139 mas at 700 nm.

Fig. 4. Neon spectrum acquired with FIRST spectrograph. We compute the spectral resolution from the lines acquired in the Neon spectrum and plot its value as a function of the wavelength on the top-right graph.

2.4. Data reduction pipeline

2.4.1. The variable of interest: The baseline complex coherence

Classical interferometry data analysis originally relied on studying the fringe pattern Power Spectral Density (Roddier & Lena

Article number, page 4 of 16

1984). This technique is well suited for instruments with large dilution (defined as the ratio between the baseline lengths and subaperture radii) since each interferometric term is well isolated. The FIRST output pupil being relatively compact, a better suited method is the fringe fitting technique (Tatulli et al. 2007). The data reduction, extensively described in Huby et al. (2012b), aims at retrieving the complex coherence terms ($\mu_{nn'}$) for each baseline (n - n') from the fringe pattern, written as:

$$\mu_{nn'} = |V_{nn'}|e^{i\psi_{nn'}}A_nA_{n'}e^{i\Delta\Phi_{nn'}},\tag{1}$$

where $|V_{nn'}|$ and $\psi_{nn'}$ are respectively the object's complex visibility modulus and phase. Furthermore, A_n , $A_{n'}$ and $\Delta \Phi_{nn'}$ are respectively the subpupils *n* and *n'* fluxes and differential piston. The differential piston contains the static optical path difference between the fibers added to any aberrations (AO residuals + other hardware related aberrations). The baseline complex coherence terms are derived following the method described in Appendix A. The following subsection explains how to retrieve the objects information from the baseline complex coherence terms.

2.4.2. Closure phase measurements for resolved object characterization

The main goal of the data reduction pipeline is to provide spatial and spectral information about resolved objects (e.g., stellar binaries or giant stars). This information is contained in the object's complex visibilities, extracted through CP measurements. It is to be noted that the visibilities cannot be calibrated in our case, and the triple amplitudes are not better suited than CPs for our target. Therefore, they are discarded. The CPs are, by definition, the phase of the bispectrum $\mu_{nn'n''}$:

$$\mu_{nn'n''} = <\mu_{nn'}\mu_{n'n''}\mu_{nn''}^* >, \tag{2}$$

where *n*, *n'* and *n''* are the subpupil indexes used to form the triangle and <> the average. The nice feature of this quantity is that it allows differential phase errors to be cancelled between subpupils since they cancel each other out according to Eq. 1:

$$CP_{nn'n''} = \arg(\mu_{nn'n''}) = \psi_{nn'} + \psi_{n'n''} - \psi_{nn''}.$$
(3)

The CP measurements are then fitted to a model to estimate the physical parameters of the observed object. In this paper, we only focus on the case of a star and a companion. In this particular case, the object complex visibility of two unresolved sources is written as:

$$V = \frac{1}{1+\rho} (1+\rho e^{-2i\pi \Delta \cdot f}),$$
(4)

with ρ the flux ratio between the two components, Δ the separation vector (α, β) between the two components, and f the spatial frequency of the considered baseline. We then perform a fit to the estimated CP with the model. To do so, we want to minimize the χ^2 function defined for each spectral channel as:

$$\chi^{2}(\rho,\alpha,\beta) = \sum_{k}^{n_{CP}} \frac{\arg(\mu_{k,estimate} * \mu_{k,model}^{*}(\rho,\alpha,\beta))^{2}}{\sigma^{k^{2}}},$$
(5)

with $\mu_{k,estimate}$ the k^{th} estimated bispectrum, $\mu_{k,model}$ the k^{th} modeled bispectrum, and σ^k the error on the k^{th} estimated CP. We can then derive the likelihood function from χ^2 as:

$$\mathcal{L}(\rho, \alpha, \beta) \propto e^{-\frac{\chi^2(\rho, \alpha, \beta)}{2}}.$$
(6)

Each parameter can then be retrieved by marginalizing $\boldsymbol{\mathcal{L}}$ over all the other parameters.

2.5. Characterization of the instrument

2.5.1. Fiber injection and field of view

A key step in the FIRST operation is the optimization of each subaperture signal injection into the single-mode fibers. We perform the injection optimization using tip-tilt actuation of the MEMS segments, each of them being conjugated with a microlens that focuses the light onto a fiber core (see Sect. 2.3). We conduct a tip-tilt scan of the nine segments and measure the flux transmitted by each fiber using the alignment camera (see Fig. 2) where the nine fiber outputs are simultaneously imaged. We then build what we name optimization maps (one per segment-fiber association), displaying the integrated flux for each segment position of the scanned grid. An optimization map example is presented in Fig. 5, acquired on-sky (during the observation of the unresolved star ρ Persei, on September 16th, 2020) for the MEMS segment 16. The tip (or tilt) applied on each segment ranges typically from -2 mrad to +2 mrad with a step of 0.5 mrad. Given the size of each subaperture on-sky (1.04 m) and the size of each segment (606.2 µm diameter for the inscribed circle), this corresponds to an on-sky tip (or tilt) range of about ±480 mas with a step of 106 mas. We fit the optimization map signal with a 2D Gaussian function to estimate the best segment position, with substep precision. The optimization map is computed on-sky for all segment-fiber associations, simultaneously. The full procedure takes a couple of minutes.

Fig. 5. On-sky optimization map on subaperture associated with the MEMS segment number 16, with an integration time of 2 ms for each of the 81 individual images acquired to derive the map. The tip-tilt range is -2 mrad to +2 mrad on the segment, with a 0.5 mrad step. This corresponds to ± 480 mas on-sky, with a step of 106 mas.

One of FIRST goals is to detect binary objects. In practice, we assume that there is an object in the center of the field of view and a second off-axis. We want to experimentally assess the flux loss in the case of an off-axis source. To do so, we optimize the fiber injection using the MEMS for a point source simulated by the internal source of SCExAO, then we move the latter in the field of view at various distances. We record the total flux on the photometric camera (from all subapertures) moving the source in 4 directions to 18 mas, 36 mas, 54 mas, 72 mas and 90 mas

from the center. We then average the 4 direction values to obtain one value per distance. The error on each value is computed as the standard deviation of the 4 values. In Fig. 6, we plot the flux ratio between the averaged off-axis flux and the on-axis flux.

Fig. 6. Flux losses as a function of the distance from the center of the field of view. Data taken on the SCExAO internal calibration source.

We see that the flux ratio decreases with the distance from the center of the field of view. We display the λ/D limit on the graph, since FIRST's main interest lies in its ability to probe regions below the telescope diffraction limit which is 20 mas at 750 nm. We see that the flux loss for a source located at a distance smaller than 20 mas is below 5 %.

2.5.2. Throughput and injection efficiency

In order to assess the throughput efficiency of the instrument, we measured the optical power of the beam using the SCExAO calibration source using a power meter (calibrated for 635 nm) at different locations in the setup. Table 1 presents the throughput results.

 Table 1. Measured throughput efficiency of the main optical elements in the injection setup.

Optical element	Measured throughput
Collimation lens	95%
Polarizing BSC + QWP	
(double path)	42%
Microlens array	92%

The transmission of 42% obtained after the double passage through the BSC + QWP accounts for the selection of one of the two polarizations, since the p-polarization is necessarily dropped. Polarization separation is anyway required at some point in the setup, to avoid the loss of contrast due to the differential optical path difference between the polarizations, induced by birefringence of the polarization maintaining fibers. The 8% difference between the expected 50% for a single polarization and the 42% measured is a loss due to optics surface transmission and quality (cube and QWP). In the near future, we will improve the setup by replacing the BSC+QWP with a D-mirror and quasi-normal incidence on the MEMs, thus reducing the number of optical surfaces. Furthermore, the polarization separation could be performed with a Wollaston prism in the recombination setup.

In order to determine the injection efficiency, the amount of flux incident on each fiber input has been estimated based on an image of the focal plane of the MLA (see Fig. 3-right). The total flux was measured by the power meter, while the image was used to estimate the fraction of the total flux falling on each individual fiber by integrating the signal in a selected area around the focal

Fig. 7. Optical path difference between 3 subapertures, displayed over the 500 frames of 50 ms each. We compute the closure phase for consistency check. The bias in the CP is of instrumental origin. Data taken on the SCExAO internal calibration source.

point of each microlens. The flux at the output of each fiber of the bundle is then measured with the power meter to evaluate the injection efficiency per segment/fiber. The results are reported in Table 2.

Table 2. Estimated injection efficiency in each of the 9 single-mode fibers, obtained on the SCExAO internal calibration source.

Segment #	Flux fraction	Injection efficiency
15	1.7%	25%
16	1.8%	41%
17	2.0%	69%
19	2.1%	56%
20	1.7%	46%
24	1.5%	37%
29	1.1%	62%
33	1.6%	68%
37	1.8%	52%

Fractions of a few percent were expected, since each microlens focuses the light from an area corresponding to less than 1/37 of the whole pupil area, leading to a maximal fraction of 2.6%. Lower fractions were measured, due to possible vignetting by the edges of the pupil or spiders, and to diffraction effects. It is to be noted that segment #15 is nonfunctioning, hence the injection could not be optimized. Therefore, we dismiss this segment in the following and only consider the remaining eight. The coupling efficiency measured for segment #24 is significantly lower than expected since it is not very close to the edge or near a spider - this could be due to damages on the single-mode fiber itself.

2.5.3. Phase stability

We described in Section 2.4 the data reduction pipeline, aiming at estimating each baseline's complex coherence to compute the CP, useful to retrieve spatial information of the observed object. In the case of a point source, the objects complex visibility modulus is 1, and its phase is 0, and Eq. 1 becomes:

$$\mu_{nn'} = A_n A_{n'} e^{i\Delta\Phi_{nn'}} \quad \text{with} \quad \Delta\Phi_{nn'} = 2\pi\sigma\delta_{nn'} [2\pi], \tag{7}$$

Article number, page 6 of 16

where σ is the wavenumber in nm⁻¹ and $\delta_{nn'}$ is the OPD in nanometers. We focus here on the characterization of $\delta_{nn'}$. To do so, we acquire data on the SCExAO internal calibration source. We obtain 500 frames of 50 ms exposure each. Using the data reduction pipeline, we extract the phase from the baseline complex coherences. In order to extract the OPD value, we first need to unwrap the phase, fit a linear polynomial, and extract the slope of the latter following:

$$\frac{\partial \Delta \Phi_{nn'}}{\partial \sigma} = 2\pi \delta_{nn'}.$$
(8)

This operation is done for every baseline, and every frame. Figure 7 shows the evolution of the OPD for three different baselines formed by subapertures 37 - 24 - 33, over the 500 frames. For each baseline, the OPD varies around an average value that is plotted with a solid black line. These variations are caused by turbulence on the SCExAO bench plus thermal/mechanical instabilities. We assume that these variations average to zero over the 500 frames. This allows us to state that the OPD average value corresponds to the static path length mismatch between the fibers. The measured standard deviation for the [37, 24], [37, 29] and [24, 29] baselines are respectively 0.3, 0.4 and 0.3 µm. The average OPD variations due to bench turbulence and fiber thermal/mechanical instabilities are contained within 0.4 µm RMS. We confirm that the computation of the CP (in red on the graph) cancels out all the perturbations: the average value of the CP is 0.4 μ m and the standard deviation is 0.1 μ m.

From the OPD measurements, we can compute a piston value per fiber. We present these values in Fig. 8. In the future, we will incorporate optical delay lines to reduce these piston values. It is also interesting to highlight that one could extract each subaperture piston value and use it to monitor the wavefront. Such interferometric wavefront sensing process could for example be useful to help correct for the island effect (Vievard et al. 2021). The island effect is due to the pupil fragmentation and induces differential piston values in the pupil fragments, to which classic wavefront sensors like the Shack-Hartman or the PyWFS are not sensitive.

Fig. 8. Piston value per fiber, corresponding to the path length mismatch between the fibers.

3. First On-sky demonstration on the Subaru Telescope

We present in this section the first on-sky tests performed with FIRST on the Subaru Telescope. Two observation programs were conducted: the first one on a point source target, to test and validate our instrument and data reduction process, the second one on a binary star, to demonstrate FIRST's capability to measure relative positioning of the two binary components. A log of all the data acquired for these studies is presented in Table 3.

Table 3. Observation log. NA = Not Applicable.

3.1. Observation of a point source

3.1.1. Observation of Keho'oea

As described in Sect. 2.4, the best end product of the FIRST interferometric data reduction are the CP measurements. For an unresolved point source, the CP signal should be zero, for all triangles. However, this is usually not the case in practice, as instrumental biases remain and need to be calibrated. This is why the observation of calibrator stars before and/or after the target of interest is required. The calibrator data allows one to compute CP measurements that are subtracted to the target of interest CP measurements thus removing the instrument bias and producing a CP signal originating solely from the target of interest.

We acquired data on Keho'oea (α Lyrae or Vega, $m_V = 1.25$, $m_R = 0.1$), during an Engineering night on the 13th of July 2020 UTC at the Subaru Telescope (Proposal ID: S20A-EN13, PI: Olivier Guyon, Support Astronomer: Sebastien Vievard, Telescope Operator: Andrew Neugarten). The data were acquired be-

tween 6:50 a.m. and 7:39 a.m. UTC. The conditions reported by the Canada France Hawaii Telescope Weather Tower² showed a seeing measurement of 0.6 arcsec (measured @500 nm). The SCExAO PyWFS pickoff was set to 850 nm Short Pass Filter, meaning that FIRST received light from about 650 nm to about 800 nm (since the PyWFS pickoff is at an angle, the transmitted wavelength cut-off is lower than 850 nm). Because of limited time to perform our tests, we were not able to acquire data on another unresolved target during that night. In order to calibrate our Keho'oea data, we decided to take, during the slewing of the telescope, data on the SCExAO internal calibration source. Although it does not include bias that could be induced by the telescope and AO188, we can at least calibrate the bias originating from SCExAO.

3.1.2. Data analysis: from the fringes to the closure phase

Figure 9-left shows a typical Keho'oea image of the dispersed interferometric pattern during this test. The exposure time was 100 ms, and the camera EM gain was set to 50. We acquired a total of 50 cubes of 100 images each. The raw images typically present a curvature caused by astigmatism induced by the dispersing prism (Huby et al. 2012a). This curvature is estimated and corrected thanks to our wavelength calibration data (using the AvaLight-CAL-Neon-Mini Spectral Calibration Light Source). The source is injected in one of the FIRST fibers, and the spectral lines are imaged on the detector. Once the curvature is corrected on each frame, we can compute the Power Spectral Density (PSD). Figure 9-right shows the PSD computed from stacking 30 cubes of the acquired data. From this image, we fit the V-groove step by fitting the peaks for several spectral line. The white dots show the result of the peak fitting. 28 peaks are present, for each spectral channel fitted, since 8 subapertures were actually used during the observations, due to a broken segment on the MEMS.

Fig. 9. Images delivered by FIRST. Left: Exposure of 100 ms and 50 EMgain of Keho'oea, corrected from curvature. The vertical dark line around wavelength channel 50 corresponds to the telluric oxygen A band absorption line around 760 to 765 nm. Right: Power spectral density computed from 30 cubes of 100 acquisitions with 100 ms exposure and 50 EMgain. The white dots show the PSD peak fitting for some selected spectral lines.

Fig. 10. CP measurements for the 56 triangles as a function of the wavelength. The Keho'oea data is displayed in blue, with an offset of $+50^{\circ}$. The SCExAO internal calibration source data is displayed in orange, with an offset of -50° . The triangles are numbered from 1 to 56, with the corresponding subapertures.

Fig. 11. CP computed from the Keho'oea observation, averaged over the wavelength dimension for each triangle. The red diamonds and blue circles respectively correspond to the averaged value before and after calibration using the SCExAO internal calibration source.

The last required ingredient for the data reduction is referred to as flat fields. They correspond to the transmission (flux for each spectral channel) of each fiber alone, or what we denoted as E_n with *n* the fiber index (see Sect. 2.4). To acquire these data we move all segments but one in order to "switch off" the fiber signals except for one. This process is repeated eight times to get the eight flat fields. We acquire these on each target that we observe. We compute our estimates following Eq. A4, to reconstruct the 28 baseline complex coherences from the 8 subapertures. Finally, following Eqs. 2 and 3, we build our 56 CPs. We average the bispectra extracted from the 50×100 images. We also compute 56 CP from the data acquired on the SCExAO internal calibration source (20 cubes of 100 images each, with an exposure time of 100 ms and an EM gain of 20). Because these two sources are unresolved, their CP values should be 0°. For visualization purposes, we plot the CP measurements from each target on the same graph, but each with a different offset on Fig. 10. The CP measurements obtained on Keho'oea are displayed in blue, with an offset of $+50^{\circ}$ (materialized by a solid black line). The CP measurements obtained on the SCExAO internal source are displayed in orange, with an offset of -50° (materialized by

a solid black line). Each of the 56 graphs shows the CP values as a function of the wavelength.

As expected, some CP values are nonzero, due to the instrumental bias. Indeed, the series of blue and orange dots (the CP measurements) do not overlap exactly on the solid black lines (materializing the introduced offset) in all of the 56 graphs. For example, on graph number 1, both CP values are a few degrees above 0. However, for the graph number 49, the bias is very small. We can qualitatively confirm that the bias amplitude for both targets is the same in a first approximation. We note on the Keho'oea data that for some triangles, there is a small "bump" centered around 765 nm. This is probably due to a decrease of the fringe contrast at this wavelength, induced by the telluric oxygen A band absorption line around 760 to 765 nm. We do not see this bump in the SCExAO calibration source data. Finally, the calibration source data show a disrupted signal on several triangles (2, 7, 12, 13, 14,15) appearing as high frequency (in the wavelength dimension) oscillations. It is a periodic signal, as the function of the wavelength, that we have noticed several times on the SCExAO internal source, but which origin is still uncertain (and under investigations).

To push the analysis further we compute the average, over the spectral dimension, of the Keho'oea CP signal before and after calibration with the SCExAO internal source. We also compute the associated statistical error, as the standard deviation over the spectral dimension divided by the square root of the number of spectral channels minus 1. Results are presented in Fig. 11: the graph shows the averaged CP value for each triangle following the numbering of Fig. 10. The error bars illustrating the statistical errors are too small to be seen, so we present them in the form of histograms on Fig. 12. Before calibration, the average CP spans about $\pm 30^{\circ}$. After calibration, the average CP values are confined within the $\pm 5^{\circ}$ range. The averaged value of all CP measurements after calibration is -0.6° , with a standard deviation of the averaged values of 0.3°. Four reasons can lead to a nonzero value here: i) on-sky CPs are calibrated using SCExAO's internal source which does not take into account biases that could originate from the telescope, AO188 and/or turbulence residuals; ii) instrumental systematic errors (which could be related to the observed CP oscillations); iii) Scattered light from the Keho'oea surrounding debris disk can also induce a signal in the CP; iv) Our error bars might be underestimated. Nevertheless, we confirm thanks to this example that our data reduction pipeline is valid.

Finally, we wish to compare the instrument performance between this observation and the one performed at the Lick Observatory on the same target (Huby et al. 2012b), where uncal-

Fig. 12. Histograms of the closure phase error bar estimates, averaged over the spectral dimension. Top and bottom graphs show the histograms of the averaged error bars for the raw CP data and calibrated CP data respectively.

ibrated and calibrated CP data showed a statistical error of 0.3° and 0.5° respectively, at best. At the time, closure phase were averaged over 133 spectral channels and the effective integration time was 1000 s (prior to selection of the best frames). Only 5 closure phase over 56 were exploitable. Figure 12 shows the histograms of the statistical errors obtained for the present observation. Uncalibrated and calibrated CP measurements have statistical errors, at best, of about 0.15° and 0.2° respectively. This corresponds to an improvement in performance by a factor of about 2. FIRST at Subaru also offers several notable enhancements: i) The acquisition procedure has undergone improvements, making it significantly faster. In our current implementation, the process took less than 10 minutes for an effective integration time of 500 seconds. This represents an upgrade from the previous setup, which required approximately 1.5 hours for an effective integration time of 1000 seconds. ii) Unlike before, there was no need here for frame selection thus optimizing the efficiency of the instrument. iii) Furthermore, all 56 closure phase measurements were fully exploitable here. This achievement ensures that every single measurement is valuable and contributes to the overall analysis, significantly enhancing the quality of the results.

3.1.3. Detection limits

We now use the data previously analyzed to assess FIRST dynamic range detection limit. It consists in estimating, for given positions around Keho'oea, the lowest flux ratio at which a potential companion could have been detected. We used the method derived in Absil et al. (2011) and Le Bouquin & Absil (2012), making use of CP computed on a point source to generate sensitivity maps. We fit the Keho'oea CP measurements to binary models, as described in Section 2.4, and derive the χ^2 associated for each set of parameters (ρ, α, β). We then normalize the $\chi^2(\rho, \alpha, \beta)$ values by dividing them by the χ^2 for $\rho = 0$. This allowed us to convert the normalized χ^2 into a probability following:

$$P(\rho, \alpha, \beta) = 1 - CDF_{\nu} \left(\frac{\nu \chi^2(\rho, \alpha, \beta)}{\chi^2(\rho = 0)} \right),$$
(9)

where CDF_{γ} is the χ^2 cumulative probability distribution function with ν degrees of freedom. In our case, the number of degrees of freedom is given by the number of independent CP triangles (21) multiplied by the number of spectral channels (77) minus 1 (total: 1616 degrees of freedom). The tested data set can allow the model with no companion ($\rho = 0$) to be rejected if P is below a certain threshold. If this threshold is set at a probability of 0.27%, then this ensures a 3- σ detection according to Le Bouquin & Absil (2012). For each companion position probed (α, β) , the sensitivity limit is derived by the lower flux ratio ρ that is not compatible with the single star model ($\rho = 0$), meaning that P<0.27%. The resulting sensitivity map is shown on Fig. 13-left for the ± 30 mas window around the central star. Companions as faint as 8×10^{-3} times the central star flux can be detected in some area of the field of view. The central part of the map, in white, contains 0-values - meaning that no companion can be detected. From this map, we compute the radial average, leading to Fig. 13-right, where the average sensitivity curve as a function of the separation to the central star is plotted. This performance study shows that a companion could be detected at a the separation of 5 mas, or $\lambda/4D$. The achievable contrast decreases rapidly from around 0.16 to 0.02 between 5 mas and 15 mas. As expected with interferometric techniques, the con-

Fig. 13. Left: Map of $3-\sigma$ sensitivity around Keho'oea for the detection of companions, with a total integration time of 500 s (50 cubes) on target (not including the integration time of a calibrator). Right: Computation of the left map radial value (excluding 0-values).

trast limit then reaches a plateau around 0.02 between 15 mas and 40 mas.

3.1.4. Magnitude limit

We extrapolate the previous detection limit results obtained on Keho'oea to estimate the instrument performance for stars with different magnitudes. Similarly to Huby et al. (2012b), we can assess the effective integration time τ , that would be required to obtain the same performance as on Keho'oea ($R_{mag,0} = 0.1$ observed with an integration time τ_0) using:

$$R_{mag} = R_{mag,0} + 2.5 \log\left(\frac{\tau}{\tau_0}\right),\tag{10}$$

This extrapolation is valid under the assumptions of 1- similar observation conditions, and 2- photon noise limited regime. As presented in the previous section, the contrast limit for a total effective integration time of $\tau_0 = 500 \ s$ (50 cubes with 100 images of 100 *ms* each) reaches 0.02 for separations greater than λ/D . This limit corresponding to $R_{mag,0} = 0.1$ is plotted in Figure 14, and the sensitivity limit is extrapolated to give R_{mag} as a function of the effective integration time τ required to reach the same contrast performance.

This study allows us to convey that FIRST can, at this stage, reach contrasts of about 0.02, around magnitude 3 stars, with an effective exposure time of about 2 hours.

3.2. Observation of a binary

3.2.1. Observation of Hokulei

After validation of the data reduction pipeline on a point source, we were able to study the case of a binary system: Hokulei (α Aurigae or Capella, $m_V = 0.08$, $m_R = -0.52$). The goal was to measure the separation and position angle (PA) of the two binary components. Hokulei is a binary that is well resolved by the Subaru Telescope in the visible, with a 56.4 mas semi-major axis and a period of about 104 days (Torres et al. 2015). Although this target is not the most scientifically significant for FIRST (since we ultimately aim at targets below the diffraction limit of the telescope), it is an easy engineering target (bright magnitude in the visible and low contrast) to test and validate the CP fitting

Fig. 14. Extrapolation of the detection performance for different star magnitude as a function of the effective integration time.

technique described in Sect. 2.4.

We observed Hokulei during the engineering observing nights on the 16th and 17th of September 2020 UTC (Proposal ID: S20B-EN13, PI: Olivier Guyon, Support Astronomer: Sebastien Vievard, Telescope Operator: Andrew Neugarten) as summarized in Table 3. We acquired data with FIRST between 2:43 p.m. and 3:00 p.m. UTC on Sept. 16th 2020, while seeing as reported by the CFHTWT was about 0.6 arcsec. On Sept. 17th, we acquired data between 3:07 p.m. and 3:36 p.m. UTC, with an average seeing of 0.6 arcsec as well. The SCExAO PyWFS pickoff was set to 850 nm Short Pass. During the first night, we used ρ Persei ($m_V = 3.39, m_R = 1.59$) as a calibrator. We did not have enough on-sky time during the second night to acquire data on a calibrator. Therefore, we used SCExAO internal calibration source right after observations to calibrate the CP bias. The Hokulei expected separation and PA were computed thanks to the Binary Analysis Tools (BATs ³). BATs uses Hokulei orbit

³ https://github.com/scexao-org/Binary_analysis

parameters from Torres et al. (2015) to estimate the companion position at a given date (see Fig. 17).

3.2.2. Calibration of the field rotation

On September 16th 2020, we acquired 19 cubes of 500 frames each on Hokulei. The exposure time was 30 ms and the EM gain was 300. For calibration purposes, we acquired 20 cubes of 500 frames each on ρ Persei. The exposure time was 40 ms and the EM gain was 300. Following the same procedure explained in Sect. 3.1 we extracted the 28 baseline complex coherences from the 8 subapertures, and computed the 56 CPs. We show on Fig. 15 the signal of the 56 CPs (in blue on the graphs) extracted from one of the Hokulei data cubes, and calibrated with the ρ Persei calibrator measurements. We can differentiate two categories in these CP plots. 1- the triangles which do not detect the companion. These triangles are formed by baselines whose on-sky projected spatial frequency do not overlap with the spatial frequency of the binary. It is the case, for example, of triangle #3 where we can see that the CP is 0° (similarly to the Keho'oea CP measurements) over the spectral bandwidth. 2- the triangles which detect the companion. In this case, the on-sky projected spatial frequency overlaps with the binary spatial frequency, creating a nonzero phase of the object visibility. It is the case of, for example, triangle #49.

We use Eq. 4 to model CP measurements for different flux ratios and angular separations between the two components of the binary. We then compare the generated models to the CPs obtained on-sky using Eqs. 5 and 6. This allows us to build χ^2 and likelihood maps - one per spectral channel - to estimate the best (α, β) position of the binary companion. We show an example of χ^2 maps on Fig. 16, providing an estimate of the companion position. We display three maps compiled from three different cubes of 500 images each (cubes number 2, 10 and 19). The best CP fit (computed from cube number 2) is also displayed on the graphs of Fig. 15, where we can see that the model is very similar to the on-sky measurements.

One interesting thing to highlight is the evolution of the estimated position on the likelihood maps. We can see that it starts at a position around (-34, -27) mas, and ends around (-38, -24) mas. This is due to field rotation, since the imaging mode on SCExAO is with a fixed pupil. This variation should be calibrated by the derotation step of the data reduction. In order to retrieve the absolute on-sky position angle of the companion, we have to subtract offset angles due to the fixed pupil imaging mode, and different optics in the AO188 and SCExAO instruments. Using the Hokulei data sets provides an opportunity to validate this calibration. First, we compute the parallactic angle, which is corrected by an image rotator in AO188 to keep the pupil in fixed position. To do so, we use the BATs package, allowing one to compute the parallactic angle (noted PAD, see Table C.1) from the pointing status of the Subaru Telescope: the Azimuth and Elevation coordinates of the target (Az,El). We then found the static offset between the FIRST baselines and the pupil by comparing the averaged PA estimate from the September 16th 2020 data (after subtracting the parallactic angle) to the theoretical position angle of the binary, given in Table 4. The static offset computed is 138.2°. We use the following equation to derotate the FIRST estimated position angle PA_{FIRST} using the static offset and the parallactic angle:

$$PA_{onsky} = -1 \times (PA_{FIRST} - (138.2 + PAD)). \tag{11}$$

We apply this equation to every FIRST estimated position angle (see Table C.1) in order to get a de-rotated estimate. We note that this offset should be the same to apply for all future data sets, assuming the alignment of the pupil stays the same.

3.2.3. Errors on the estimate

We now discuss how we compute error bars for the estimated separation and position angle. Each cube *i* yields an estimated 2D position (α_i, β_i) of the binary companion, which is then converted into separation and position angle (Sep_i, PA_i) ; *i* being here the cube identification. The final random error is computed as the standard deviation of the cubes averaged estimates divided by $\sqrt{(N-1)}$, with N the number of cubes. These errors are the ones presented in Table 4. We also need to take into account a systematic error on the plate scale. It is proportional to the baseline length divided by the wavelength. We estimate the wavelength uncertainty to be 0.5nm, so around 0.1%. However, most of the systematic error on the separation comes from the baseline length. We estimated the subaperture diameter to be about 1.04 meters from the instrument design, but we have no independent way to verify this value. Reducing this systematic error will come, in the future, with calibrating the baseline lengths using well known binaries. We discuss the amplitude of the systematic errors in our data analysis.

3.2.4. Relative measurements of Hokulei components

For the 16th of September 2020 data, we find an estimated separation of 44.3 ± 0.1 mas, with a PA of $274.7^{\circ}\pm0.1^{\circ}$ (after applying Eq. 11 to each PA_{FIRST} estimates, as seen in Table C.1). When comparing with the 45.1 mas expected separation, we see that our measurement is off by about 1 mas. This would correspond to a systematic error of about 3% on the subaperture size. We show on Fig. 17 our results with and without considering the separation systematic error of 1 mas for the error bars. On September 17th, we acquired 19 cubes of 500 frames each on Hokulei. The exposure time was 10 ms and the EM gain was 300. For calibration purposes, we acquired 20 cubes of 100 frames each on the SCExAO calibration source right after closing the telescope. The exposure time was 10 ms with no EM gain. Using the same procedure as for the 16th September 2020, we compute the CP and perform the model fitting. We find an estimated separation of 46.4 ± 0.1 mas with a PA of $270.6\pm0.2^\circ$, from the data cubes analysis. As we can see in the Table 4, this compares well with the expected separation and PA, respectively of 46 mas and 270.7°, taking into account the systematic error.

We plot on Fig. 17 the orbit of Hokulei Ab, and show the expected and estimated position of the Ab binary component for both dates of observation. Two error bars are drawn: error bars that only take into account the random errors, and error bars that only take into account systematic errors. The random error bars are drawn along the principal axes of the error ellipse derived from the covariance matrix (see Table 4). The systematics error bars represents the 1 mas error over the separation, and are oriented toward the central star. We can see how well our estimate of the companion position compares to the expected position when taking into account the systematic errors. We can also see that even though we used the SCExAO calibration source to calibrate the CP obtained on Hokulei on September 17th and not a reference star, the estimation of the position compares well with the expected position. Most of the CP bias is well calibrated by the sole SCExAO internal source. Our tests did not allow us

Fig. 15. CP fit after calibration, for one cube of data obtained on Hokulei. The blue curves are the 56 CPs measured by FIRST, the red curves are the fitting results.

Fig. 16. Estimation of the Hokulei binary companion position delivered by χ^2 maps, for 3 cubes of data during our sequence. Time increases from left to right. We can notice that the position estimate evolves with time due to the field rotation.

to provide an absolute estimation of the Ab binary component, since we used (Torres et al. 2015) to de-rotate the data from September 16th 2020, and used this reference for the September 17th 2020 data reduction. However, observing Hokulei at two different epochs allows us to compute the differential PA of the Ab binary component. (Torres et al. 2015) informs us that the differential PA between the two epochs is 4.0° . FIRST provides a differential PA of $3.9^{\circ} \pm 0.3^{\circ}$, which compares well with the expected value. In the course of about 24 hours, we were able to track the movement of the companion along its orbit.

4. Conclusion

We presented the integration, characterization and on-sky demonstration of the FIRST spectro-interferometer on the 8.2-m Subaru Telescope. FIRST interferes simultaneously multiple parts of the telescope pupil to extract information from astronomical objects, with a sensitivity to structure that extends down to at least 10 mas and a spectral resolution of about 300 at 700 nm. FIRST's optimal field of view is up to 40 mas, over which the fiber injection losses are less than 5 %. Using 8 samples of the Subaru Telescope pupil, each with a projected di-

Table 4. Summary of the results: expected (from Torres et al. (2015)) and estimated position of the Hokulei binary companion on both days of observation from the collected data. The errors presented here are computed as the standard deviation of the averaged estimates provided by each cubes, hence the standard deviation of the cube estimates divided by $\sqrt{(N-1)}$ (with *N* the number of cubes).

Fig. 17. Orbit of Hokulei Ab binary component. In blue and brown are respectively the expected and estimated positions of the Ab component on both observation days. Brown colored error bars only take into account the random errors. Salmon colored error bars are a quadratic sum of random and systematic errors.

ameter of about 1 m, we demonstrated FIRST's ability to provide CP measurements both on a point source - Keho'oea - and on a binary star: Hokulei. The Keho'oea observation allowed to highlight several improvements of the instrument compared to the previous setup installed on the 3-meter Lick Telescope. The instrument now shows better efficiency in terms of acquisition procedure and better stability allowing the exploitation of all data and measurements thus increasing the overall quality of the results. The Keho'oea data showed an average accuracy of 0.6° from the CP measurements, and statistical error of 0.15° at best on uncalibrated data. We also evaluated FIRST detection capabilities. Analysis showed ability to sense companions separated from their host star with a separation as little as a quarter of the telescope theoretical diffraction limit. Moreover, we assessed that the instrument can enable detection with a contrast down to 0.02 at λ/D separation. The observation of Hokulei demonstrated FIRST's capability to detect and track the position of the binary companion along its orbit using observations about 24 hours apart. The best random error on the separation and PA were respectively 0.1 mas and 0.1°. Systematic errors on the separation, due to an uncertainty on the subaperture projected diameter, were estimated to be about 1 mas. Acquiring more data on well known binary systems will be essential to calibrate systematic errors. With these new capabilities, and the demonstration of the instrument to perform measurements below the diffraction limit of the telescope, we will be able to fully commission FIRST

at the Subaru telescope and offer it to the scientific community for open use.

The success of demonstrating/commissioning such instrument on SCExAO is an important stepping stone for future interferometric instrumentation on extremely large telescopes. Their large collecting area and small diffraction limit (about 4 mas in the optical wavelengths), coupled with spectral dispersion capabilities, would offer unique high contrast and high resolution capabilities with high sensitivity for Earth-like exoplanet research and characterization.

Appendix A: Reconstruction of the baseline complex coherences

Considering N fibers providing N interfering beams, the fringe intensity can be written and developed, for each wavelength, as:

$$I(\mathbf{x}) = \left(\sum_{n < N} A_n E_n(\mathbf{x})\right)^2$$

= $\sum_{n < N} A_n^2 E_n^2(\mathbf{x})$
+ $2 \operatorname{Re}\left[\sum_{n < n' < N} A_n E_n(\mathbf{x}) A_{n'} E_{n'}(\mathbf{x}) e^{i(2\pi f_{nn'}\mathbf{x} + \Delta\Phi_{nn'})}\right]$
= $\sum_{n < N} A_n^2 E_n^2(\mathbf{x})$ (A1)
+ $2 \sum_{n < n' < N} A_n E_n(\mathbf{x}) A_{n'} E_{n'}(\mathbf{x}) \cos(2\pi f_{nn'}\mathbf{x} + \Delta\Phi_{nn'})$

with x the spatial variable (pixel index), E_n the normalized envelope of each beam and $f_{nn'}$ the nn' baseline frequency. By taking into account the object's complex visibility and rearranging Eq. A1, it is possible to obtain a linear relationship between the interferogram I(x) and the complex coherence (Eq. 1):

$$I(\mathbf{x}) = \mu_0 E_g(\mathbf{x})$$

$$+ \sum_{n < n' < N} \mathcal{R}\{\mu_{nn'}\} C_{nn'}(\mathbf{x})$$

$$+ \sum_{n < n' < N} I\{\mu_{nn'}\} S_{nn'}(\mathbf{x})$$
(A2)

with μ_0 the total flux, $Eg(\mathbf{x})$ the normalized global envelope function and

$$\begin{cases} C_{nn'}(\mathbf{x}) = 2E_n(\mathbf{x})E_{n'}(\mathbf{x})\cos(2\pi f_{nn'}\mathbf{x})\\ S_{nn'}(\mathbf{x}) = -2E_n(\mathbf{x})E_{n'}(\mathbf{x})\sin(2\pi f_{nn'}\mathbf{x}) \end{cases}$$

 $\{E_g(\mathbf{x}); C_{nn'}(\mathbf{x}); S_{nn'}(\mathbf{x})\}$ form a base on which the $I(\mathbf{x})$ interferogram can be decomposed. This base depends on the instrument setup. Let us define x_k the pixel index with $k \in \{1, ..., n_p\}$ with n_p the number of pixels. We also concatenate indexes nn' into $\{1, ..., n_B\}$ with n_B the number of baseline pairs. Finally the unknowns (μ_{n_B}) can then be regrouped in a vector **P** and Eq. (A2) can be written as the matrix product:

$$\mathbf{I} = \begin{bmatrix} I_{x_1} \\ \vdots \\ I_{x_{np}} \end{bmatrix} = \mathbf{V}\mathbf{2}\mathbf{P}\mathbf{M} \cdot \begin{bmatrix} \mathcal{R}\{\mu_1\} \\ \vdots \\ \mathcal{R}\{\mu_{n_B}\} \\ I\{\mu_1\} \\ \vdots \\ I\{\mu_{n_B}\} \\ \mu_0 \end{bmatrix} = \mathbf{V}\mathbf{2}\mathbf{P}\mathbf{M} \cdot \mathbf{P}$$
(A3)

with V2PM =

$$\begin{bmatrix} C_1(x_1) & \dots & C_{n_B}(x_1) & S_1(x_1) & \dots & S_{n_B}(x_1) & E_g(x_1) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ C_1(x_{n_p}) & \dots & C_{n_B}(x_{n_p}) & S_1(x_{n_p}) & \dots & S_{n_B}(x_{n_p}) & E_g(x_{n_p}) \end{bmatrix}$$

According to the formalism introduced by Millour et al. (2004), the V2PM is the Visibility-To-Pixel matrix with a size of $(2n_B + 1) \times n_p$. This matrix is rectangular hence it cannot be inverted. However, because the recombination on FIRST is nonredundant, each baseline frequency is unique hence the V2PM modes are orthogonal one to another. In this case, we can compute V2PM[†], the partial generalized inverse of V2PM matrix computed from the Singular Value Decomposition of V2PM. We can then compute the estimates $\widehat{\mathbf{P}}$ according to:

$$\widehat{\mathbf{P}} = \mathbf{V} 2\mathbf{P} \mathbf{M}^{\dagger} \cdot \mathbf{I},\tag{A4}$$

which allowed us) to reconstruct the baselines complex coherences.

Appendix B: Hawaiian naming of stars

The following knowledge was gathered from Kumu Leilehua Yuen, a cultural practitioner and traditional knowledge holder on Hawai'i island and from Johnson & Mahelona (1975). The intention of sharing this knowledge is to grow our understanding of these main targets and astronomy as a whole through a lense of heritage and knowledge specific to where these observations are made, Hawai'i. In Native Hawaiian culture⁴, celestial objects can change in name depending on their position in the sky and their use. For example, Keho'oea is also named Kahō'eoa, Kaho'ea or Keoe. The name Keho'oea appears in chant fourteen (Ka Wa Umikumamaha) of the Kumulipo, line 1859 (Beckwith 2000). The Kumulipo is a genealogical chant and the most well known origin story of Native Hawaiian culture. Like other important cultural knowledge, the Kumulipo was transmitted orally for generations by highly trained specialists. It was documented in writing during the time of King Kalākaua. One of the most important translations into English was by Hawai'i's last monarch, Queen Lili'uokalani during her unjust imprisonment within her own palace and the illegal occupation of the Kingdom of Hawai'i during a coup by American businessmen.

In literal translation from 'ōlelo hawaii (Hawaiian language), Hokulei is a compound word: "hōkū" / "star" and "lei" / "garland" or "to rise like a cloud." Some practitioners translate the name as "star garland." Yuen was taught the translation "star/constellation that rises like a cloud," in reference to the fact that Hokulei is the brightest star of its constellation, Aurigae.

Appendix C: FIRST raw data

We present in the following Tables the output of the FIRST data reduction, for every cube taken during the two epochs.

⁴ A distinction is made between the indigenous Native Hawaiian culture and the multicultural "local" practices which have evolved since the in-migration of peoples from around the world.
