Abstract. The fundamental mechanism of hysteresis in the quasistatic limit of multi-stable systems is associated with transitions of the system from one local minimum of the potential energy to another. In this scenario, as system parameters are (quasistatically) varied, the transition is prompted when a saddle-node bifurcation eliminates the minimum where the system resides in. The objective of the present work is to specify this generic mechanism for systems of interacting particles assuming a natural single-well (Lennard-Jones) interaction potential for each pair of particles. We show multi-stability and present details of hysteresis scenarios with the associated bifurcations and transitions in a case study of constrained four-degrees-of-freedom four particle systems on the plane.

Keywords: Hysteresis, multi-stability, bifurcation, gradient flow, energy dissipation, quasistatic limit

MSC Subject Classification: 34C55, 70F40

1. Introduction. In this work, we revisit fundamentals of hysteresis modeling. Phenomenological models of hysteresis, which describe experimentally observed complex constitutive relations of materials and media, are ubiquitous in engineering and quite diverse. Examples include models of a stress-strain constitutive relation in elastoplastic materials (e.g. Prandtl's elastic-ideally plastic element [\[22\]](#page-20-0); Prandtl-Ishlinskii hysteresis model and its generalizations [\[6\]](#page-19-0); Moreau's sweeping process [\[10\]](#page-20-1); rate-independent yield criteria [\[7,](#page-19-1) [21\]](#page-20-2); Armstrong-Frederick [\[2\]](#page-19-2), Chaboche [\[8\]](#page-20-3), Mroz nonlinear hardening rules [\[11\]](#page-20-4)); related models of dry friction and creep-fatigue damage counting (Maxwell-slip friction model [\[1\]](#page-19-3); rainflow-counting algorithm of calculating fatigue [\[25\]](#page-20-5)); magnetizing field-magnetization constitutive laws of magnetic materials (Preisach independent domain model [\[23\]](#page-20-6); Bouc-Wen, Jiles–Atherton, Stoner–Wohlfarth models [\[4,](#page-19-4) [26,](#page-20-7) [28\]](#page-20-8); Krasnosel'skii-Pokrovskii and Mayergoyz-Friedman models [\[5,](#page-19-5) [9\]](#page-20-9)); pressure-saturation constitutive equations for flows in porous media (Parlange and Mualem hysteresis models [\[12,](#page-20-10) [13\]](#page-20-11)); coupling of mechanical, magnetoelectric and temperature variables in smart materials such as piezoelectric and magnetostrictive materials, shape-memory alloys and shape-memory polymers, to mention a few.

The aforementioned models are intrinsically meso- or macroscopic and usually are loosely related to the microstructure. From one side, it can be considered as a sort of advantage—media and systems with broad variety of the microstructures can exhibit similar hysteresis behavior and can be described by similar models. From the other side, one always encounters a problem of adequate attribution of specific parameters to the effective models. Arguably, the best way is to evaluate parameters from the "first principles", i.e. starting from the potentials of interatomic interactions, or potential energy landscape. Unfortunately, such relationships are usually far beyond the reach. The dynamic hysteretic behavior is governed by an interplay of the structural modifications and dynamic dissipation. Each of these two intrinsic components in microscopic models is not understood at the level of quantitative predictions, except possibly for very few very simple models. The goal of this work is to explore the minimal requirements to the interaction potential that warrant the hysteretic behavior. The dissipation is assumed to be overwhelming. As such, the system is considered in a quasistatic response regime. This simplification leaves aside a number of important dynamic features of the process [\[14,](#page-20-12) [15,](#page-20-13) [16,](#page-20-14) [17,](#page-20-15) [18,](#page-20-16) [19,](#page-20-17) [20\]](#page-20-18), but still leaves a hope to achieve a useful approximation to realistic dynamics.

The fundamental mechanism of hysteresis associated with multi-stability and bifurcation is revealed by the following classical example (see e.g. [\[27\]](#page-20-19)). Let us consider a one-degree-of-freedom particle in the potential well

(1.1)
$$
V(x; h) = \frac{x^4}{4} - \frac{x^2}{2} - hx,
$$

where h is the external field, which is varied quasistatically (i.e. the inertia is ignored). Assume that initially h is large, so that V has a unique minimum point $x = x_*(h)$ located on the positive semi-axis $x > 0$, and the particle sits at this minimum, see Figure [1.](#page-1-0) Suppose that h decreases. At the critical value $h_* = 2/3\sqrt{3}$, the potential acquires the double well shape by developing the second minimum on the negative semi-axis $x < 0$ through the saddle-node bifurcation, see Figure [2.](#page-2-0) At the critical value $h = -h_{*}$, the positive minimum is eliminated through the other saddle-node bifurcation, and the particle transitions to the remaining negative minimum $x =$ $-x_*(-h)$. Next, assuming that from this point h increases, the particle will be located at the negative minimum of V until this minimum is eliminated through the saddlenode bifurcation at $h = h_{*}$, at which point the particle will transition back to the positive minimum $x = x_*(h)$, closing the hysteresis loop.

Fig. 1. Particle in the double-well potential [\(1.1\)](#page-1-1).

This simple system displays important features of hysteresis. First, within the bi-stability range, $-h_* < h < h_*,$ the state of the system (the position of the particle at the positive or negative minimum of the potential) is determined both by the concurrent and past values of the input h , hence one talks about history-dependence. Second, the history-dependence with the associated hysteresis loop manifests itself in the quasistatic limit of slow variations of h (this fact is referred to as rate-independence of hysteresis $[3]$. Third, each transition of the particle from one minimum of V to another is associated with an irrecoverable energy loss.

Generalizing the above example to multi-particle systems, the energy potential of a system with many degrees of freedom can have a large number of minimum points (metastable states). Further, as input variations cause the energy landscape to change, the same bifurcation mechanism (demonstrated by the double well potential) leads to a complex pattern of transitions between the states, creating a structure of hysteresis loops of the material constitutive law at a macrolevel. As one example, the Preisach model of magnetic hysteresis considers N non-interacting particles, each in a double well potential [\(1.1\)](#page-1-1), i.e. the energy potential of the system is

$$
V(x_1,...,x_N; h) = \sum_{i=1}^N \left(\frac{x_i^4}{4} - \frac{x_i^2}{2} - (ha_i + b_i)x_i\right),
$$

Fig. 2. Transitions of the particle from one to another (local) minimum of the potential energy shown in Figure [1](#page-1-0) as the exogenous field parameter h (input) changes quasistatically. At the points $h = \pm h_*$, one minimum collides with the local maximum and disappears in a saddle-node bifurcation causing a transition to the other minimum.

where h is the input; a_i, b_i are parameters. This potential has up to 2^N minima for a particular value of h, and produces a specific structure of nested hysteresis loops (known as return-point memory), which are characterized by the so-called wiping-out and congruency properties [\[9\]](#page-20-9), see Figure [3.](#page-2-1) A hysteresis loop is an evidence that the system goes through one sequence of states as h increases and then through a different sequence of states as h decreases; or, that the system goes through the same sequence of states (in the reversed order) as h decreases, but the transitions from one state to another and the reversed transitions occur at different values of h (as in Figure [2](#page-2-0) in the case of the double well potential).

FIG. 3. (a) A sample input $h = h(t)$ of the Preisach model. (b) Input-output diagram of the Preisach model depicting input h (magnetizing field) vs output m (magnetization) for the input shown on panel (a). The output is given by $m = \sum_{i=1}^{N} c_i \operatorname{sign}(x_i)$, where c_i are parameters (cf. [\(1.1\)](#page-1-1)). The state (x_1, \ldots, x_N) and output value m at a given time t depend both on the concurrent value of h and a sequence of past extremum values of h, which are known as running main extremum values.

As we see, in the Preisach model (and other phenomenological models of hysteresis phenomena), hysteresis of an individual particle is postulated. In this paper, we ask the following question: can hysteresis emerge in a system of particles interacting via naturally non-hysteretic potentials? To be more specific, we limit our discussion to systems of identical particles and the classical Lennard-Jones interaction.

As a starting point, we make an observation that a chain of particles with the nearest neighbor interaction does not display hysteresis if the particles are elongated along a straight line (see the next section). Therefore, we look at systems of particles on a plane. As the main result, we answer affirmatively to the above question by presenting examples of simple 4-particle (constrained) planar configurations, which exhibit hysteresis. We provide a detailed analysis of the associated bifurcation scenarios (Section [3\)](#page-4-0). The paper is concluded with a discussion of these results.

2. Preliminaries. We consider a collection of N particles in the potential field with the potential

(2.1)

$$
V(\mathbf{r};h)=V(\mathbf{r}_1,...,\mathbf{r}_N;h)=\sum_{1\leq i
$$

where r_i is the position of the *i*-th particle; h is a scalar input variable (such as the amplitude of external forcing, load, external field etc.); $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ is the Eucledian distance between the *i*-th and *j*-th particles; Φ_{ij} is the interaction potential of the pair of particles; a_i are vector-valued parameters; and, dot stays for the dot product. It is assumed that the two-particle interaction potential is the Lennard-Jones potential

(2.2)
$$
\Phi_{ij}(r) = 4\varepsilon_{ij}\Phi_1(r), \qquad \Phi_1(r) = \left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^6,
$$

see Figure [4.](#page-3-0)

FIG. 4. The Lennard – Jones interaction potential of a pair of particles for $\sigma = 1$.

We consider the quasistatic evolution of the system in response to quasistatic variation of the parameter h . This evolution has intervals of (relatively) slow and fast dynamics. During the slow evolution, the system sits in a local minimum of the potential V, say $\mathbf{r}_{*}^{-} = \mathbf{r}_{*}^{-}(h)$, until this minimum point is eliminated via a saddle-node bifurcation as h is varied. The saddle-node bifurcation is the only generic mechanism creating/eliminating minimum points of V .

At the bifurcation point $h = h_b$, the system transits to another minimum following the fast antigradient dynamics

$$
\dot{\mathbf{r}} = -\nabla_{\mathbf{r}} V(\mathbf{r}; h_b), \qquad \mathbf{r} = (\mathbf{r}_1, \dots, \mathbf{r}_N),
$$

i.e. the system follows the one-dimensional unstable manifold of the saddle-node equilibrium point $\mathbf{r}_{*}^{-}(h_b)$ of the gradient field to another local minimum point $\mathbf{r}_{*}^{+}(h_b)$ 4

of the potential. This transition is (infinitely) fast compared to the slow dynamics following a minimum of V . The antigradient transition dynamics ensures that

$$
\dot{V} = -|\nabla_{\mathbf{r}} V(\mathbf{r}; h_b)|^2,
$$

hence V decreases along the transition trajectory, and

$$
V(\mathbf{r}_*^-; h_b) - V(\mathbf{r}_*^+; h_b) > 0.
$$

This positive quantity represents an irreversible energy loss (dissipation) associated with the transition. If, after (several) transitions, h returns to its initial value and the system returns to the same minimum of V where it started from, then hysteresis is observed.

We start by showing that a one-dimensional chain of N particles with nearest neighbor interactions and an external forcing applied at the ends of the chain does not exhibit hysteresis. Namely, let us consider the potential

$$
V(x_1, ..., x_N; h) = h(x_1 - x_N) + \sum_{i=1}^{N-1} \Phi_1(x_{i+1} - x_i),
$$

where $x_1 < \cdots < x_N$ are positions of the particles on a straight line, Φ_1 is the Lennard-Jones two-particle interaction potential (cf. [\(2.2\)](#page-3-1)), and the opposite forces $-h$ and h are applied to the two particles at the ends of the chain, see Figure [5.](#page-4-1) Using the variables $q_i = x_{i+1} - x_i$, the potential reads

$$
V(q_1,\ldots,q_{N-1};h)=\sum_{i=1}^{N-1}(\Phi_1(q_i)-hq_i).
$$

This potential does not have critical points for $h > h_* = 126/169$ (in this case, the external force expanding the chain exceeds the maximal attraction force between the particles, and the chain breaks). For $0 < h < h_*$, the potential has one local minimum and one local maximum point. For $h < 0$, the minimum is global and is a unique critical point of V (the maximum disappears at infinity as h becomes negative: $h > 0$ corresponds to the expansion and $h < 0$ to the contraction of the chain by the external forces). Since V has at most one minimum, the system does not exhibit hysteresis.

FIG. 5. System of $N = 4$ particles with nearest neighbor interactions on a line. Each force (shown by an arrow) has amplitude $|h|$.

3. Case study of two-dimensional structures. As a prototypical example of hysteresis in a system of particles interacting via the Lennard-Jones potential, we consider the system of four identical particles shown in Figure [6.](#page-5-0) The particles are placed on the (x, y) -plane; the coordinates of the *i*-th particle are denoted by (x_i, y_i) . Particles 1 and 3 are constrained to the vertical lines $x = 1$ and $x = -1$, respectively, while particles 2 and 4 are constrained to the horizontal lines $y = 1$ and $y = -1$, i.e. each particle has one degree of freedom. We use the notation $q_1 = y_1, q_2 = x_2$, $q_3 = y_3$, $q_4 = x_4$ for the system coordinates. Assuming the Lennard – Jones pairwise interaction between the particles, the system potential is

(3.1)
$$
V_0^{\sigma}(q_1, q_2, q_3, q_4) = \sum_{1 \leq i < j \leq 4} \Phi_1(r_{ij}) = \sum_{1 \leq i < j \leq 4} \left(\left(\frac{\sigma}{r_{ij}} \right)^{12} - \left(\frac{\sigma}{r_{ij}} \right)^{6} \right),
$$

where r_{ij} is the Eucledian distance between particles i and j.

Fig. 6. Four constrained particles with pairwise Lennard – Jones interaction under (a) rotational external forcing; (b) expansion.

We show hysteresis in this system under external forcing. Two types of forcing will be considered.

As the first example, we will assume that particles $1-4$ are acted upon by the constant forces $h, -h, -h, h$, respectively, along the lines of their motion as shown in Figure [6.](#page-5-0) In this case, the full potential of the forced system is

(3.2)
$$
V_h^{\sigma}(q_1, q_2, q_3, q_4) = h(q_1 - q_2 - q_3 + q_4) + V_0^{\sigma}(q_1, q_2, q_3, q_4).
$$

This system is discussed in Section [3.2.](#page-11-0)

Another example, in which the constant external forces acting on particles $1 - 4$ are $h, h, -h, -h$, respectively, and and the corresponding potential is

$$
(3.3) \qquad \hat{V}_h^{\sigma}(q_1, q_2, q_3, q_4) = -h(q_1 + q_2 - q_3 - q_4) + V_0^{\sigma}(q_1, q_2, q_3, q_4),
$$

is considered in Section [3.3,](#page-14-0) see Figure [6.](#page-5-0)

3.1. Unforced system. Let us first discuss the unforced system with potential [\(3.1\)](#page-5-1). We show that, for certain ranges of the parameter σ , this potential has multiple minimum points. In other words, for such σ , the system with potential [\(3.2\)](#page-5-2) (resp. (3.3)) is multi-stable when $h = 0$, i.e. the external forcing is zero.

Potential [\(3.1\)](#page-5-1) is invariant with respect to the action of the dihedral group \mathbb{D}_4 of symmetries of the square. A generating set of this group, consisting of the clockwise rotation ρ by $\pi/2$ around the origin and the reflection κ over the line $x = y$, acts on the configuration space of the system by mapping a point $\mathbf{q} = (q_1, q_2, q_3, q_4)$ to the points

$$
\rho(q_1, q_2, q_3, q_4) = (q_4, -q_1, q_2, -q_3), \qquad \kappa(q_1, q_2, q_3, q_4) = (q_2, q_1, q_4, q_3),
$$

respectively. We will use the subgroups $\mathbb{Z}_4 = \{e, \rho, \rho^2, \rho^3\}, \mathbb{Z}_2 = \{e, \kappa\}$ of \mathbb{D}_4 .

Let us consider the fully symmetric zero critical point $\mathbf{q} = 0$ of the potential V_0^{σ} . A direct calculation shows that the eigenvalues of the Hessian of the potential at zero are

$$
(3.4)
$$

$$
\lambda_1 = \lambda_2 = \frac{9\sigma^6(\sigma^6 - 2)}{8}, \quad \lambda_3 = \frac{3\sigma^6(1663\sigma^6 - 3552)}{2048}, \quad \lambda_4 = \frac{3\sigma^6(544 - 129\sigma^6)}{2048},
$$

see Figure [7.](#page-6-0) Hence, $q = 0$ is a (local) minimum point of the potential for the values of the parameter σ from the interval

(3.5)
$$
(\sigma_*, \sigma^*) = \left(\left(\frac{3552}{1663} \right)^{1/6}, \left(\frac{544}{129} \right)^{1/6} \right) = (1.13483, 1.27107).
$$

At each end of the stability interval [\(3.5\)](#page-6-1), the anti-gradient field $-\nabla V_0^{\sigma}$ undergoes a supercritical symmetry braking bifurcation at $q = 0$.

FIG. 7. Eigenvalues $\lambda_1 = \lambda_2$ (magenta), λ_3 (orange), λ_4 (green) of the Hessian of potential [\(3.1\)](#page-5-1) at zero as functions of the parameter σ . The eigenvalues are positive for $\sigma_* < \sigma < \sigma^*$.

Symmetry breaking pitchfork bifurcation at $\sigma = \sigma^*$. As σ increases across the critical value $\sigma^* = 1.27107$ where $\lambda_4(\sigma^*) = 0$, the anti-gradient field undergoes a supercritical pitchfork bifurcation producing a pair of minimum points

 (3.6) * = $(q^*, -q^*, -q^*, q^*)$, $\kappa \mathbf{q}^* = -\mathbf{q}^* = (-q^*, q^*, q^*, -q^*)$

of the potential, which bifurcate from the critical point $q = 0$ as it changes stability and becomes a saddle. The pair of critical points [\(3.6\)](#page-6-2) exists for $\sigma > \sigma^*$, they form a \mathbb{Z}_2 orbit, and each of them is \mathbb{Z}_4 -symmetric because $\rho \mathbf{q}^* = \mathbf{q}^*$. In other words, the pitchfork bifurcation at $\sigma = \sigma^*$ breaks the \mathbb{Z}_2 -symmetry of the zero critical point but preserves the \mathbb{Z}_4 -symmetry.

It is important to observe that the one-dimensional subspace

(3.7)
$$
L = \{ \mathbf{q} = (q, -q, -q, q), q \in \mathbb{R} \}
$$

FIG. 8. Square shaped formations of the particles on the (x, y) -plane corresponding to minima [\(3.6\)](#page-6-2) of potential [\(3.1\)](#page-5-1) (red and blue) and the the square formation corresponding to the zero critical point (magenta).

of points fixed by the symmetry group \mathbb{Z}_4 in the configuration space of the system is invariant for the anti-gradient flow, i.e. $-\nabla V_0^{\sigma}(\mathbf{q}) \in L$ for $\mathbf{q} \in L$. Each point of L in the configuration space corresponds to positioning of the particles in the corners of a square. In particular, the two squares corresponding to the minimum points $\pm \mathbf{q}^*$ of the potential are symmetric to each other with respect to the bisector line $x = y$, see Figure [8.](#page-7-0) Since L contains the critical points $\pm q^*$ given by [\(3.6\)](#page-6-2), these points can be found as minimum points of the restriction of V_0^{σ} to L, which is given by

$$
v_0^{\sigma}(q) = V_0^{\sigma}(q, -q, -q, q) = \frac{129\sigma^{12} - 1088\sigma^6(1+q^2)^3}{2048(1+q^2)^6}
$$

,

see Figure [9.](#page-8-0) In this way, one obtains

$$
q^* = \sqrt{\left(\frac{\sigma}{\sigma^*}\right)^2 - 1}
$$

for the minimum points $\pm q^*$ of the function v_0^{σ} and for the components of minimum points [\(3.6\)](#page-6-2) of the potential V_0^{σ} . Further, by direct calculation, the eigenvectors of the Hessian at any point of L are

(3.8) $(1, 1, 1, 1), (1, -1, 1, -1), (-1, -1, 1, 1), (1, -1, -1, 1).$

Moreover, the corresponding eigenvalues at the critical points $\pm \mathbf{q}^* \in L$ of the potential equal

$$
\mu_1 = \mu_2 = \frac{1287(\sigma^*)^{14}}{2176 \sigma^2}, \quad \mu_3 = \frac{3(\sigma^*)^{14}(7373(\sigma^*)^2 - 397\sigma^2)}{17408 \sigma^4},
$$

$$
\mu_4 = \frac{1161(\sigma^*)^{14}(\sigma^2 - (\sigma^*)^2)}{1024 \sigma^4}.
$$

Hence [\(3.6\)](#page-6-2) are minimum points of the potential for

(3.9)
$$
\sigma^* < \sigma < \sigma^{**} = \sqrt{7373/397} \sigma^* = 5.47766.
$$

At the point $\sigma = \sigma^{**}$, the minima $\pm \mathbf{q}^*$ destabilize in the direction $(-1, -1, 1, 1)$, which is perpendicular to L , and become saddles.

FIG. 9. The restriction $v_0^{\sigma}(q)$ of the potential $V_0^{\sigma} = V_0^{\sigma}(q)$ to the one-dimensional subspace $L = \{q = (q, -q, -q, q), q \in \mathbb{R}\}\$ of the configuration space for $\sigma = 1.4 > \sigma^*$. The subspace L is invariant for the anti-gradient field and the action of the symmetry group \mathbb{Z}_4 .

In Section [3.2,](#page-11-0) we will consider the system with rotational forcing (potential [\(3.2\)](#page-5-2)) for $\sigma > \sigma^*$ and show hysteresis between the square shaped configurations of particles as the external forcing parameter h is varied.

Symmetry breaking pitchfork bifurcation at $\sigma = \sigma_*$. Now, let us consider the other bifurcation point, $\sigma = \sigma_* = 1.13483$, where the zero $\mathbf{q} = 0$ of the anti-gradient field loses stability. At this supercritical pitchfork bifurcation point, the additional (non-zero) critical points of V^σ_0 appear in a different anti-gradient flow invariant onedimensional subspace, namely

$$
M = \{ \mathbf{q} = (q, q, -q, -q), q \in \mathbb{R} \}
$$

(cf. [\(3.7\)](#page-6-3)). More precisely, when the eigenvalue $\lambda_3(\sigma)$ (cf. [\(3.4\)](#page-6-4)) crosses zero at $\sigma = \sigma_*$ as σ decreases, see Figure [7](#page-6-0) (the orange line), the point $q = 0$ becomes a saddle, and a pair of minimum points of V_0^{σ} forming a \mathbb{Z}_2 -orbit is created in M. These points

$$
(3.10) \t\mathbf{q}_{*} = (q_{*}, q_{*}, -q_{*}, -q_{*}), \t\rho \mathbf{q}_{*} = -\mathbf{q}_{*} = (-q_{*}, -q_{*}, q_{*}, q_{*})
$$

are $\mathbb{Z}_2 \times \mathbb{Z}_2$ -symmetric because the points of M are fixed by the subgroup $\mathbb{Z}_2 \times$ $\mathbb{Z}_2 = \{e, \rho^2, \kappa, \kappa \rho^2\}$ of \mathbb{D}_4 , i.e. the pitchfork bifurcation at $\sigma = \sigma_*$ preserves the $\mathbb{Z}_2 \times \mathbb{Z}_2$ -symmetry of critical points. Each point of M in the configuration space corresponds to positioning of the particles in the corners of a rectangle. The two rectangles corresponding to critical points $\pm \mathbf{q}_*$ of the potential are mapped to each other by the rotation by $\pi/2$, see Figure [10.](#page-9-0)

The components of critical points [\(3.10\)](#page-8-1) can be obtained by finding minimum points $\pm q_*$ of the restriction of V_0^{σ} to M:

$$
\hat{v}_0^{\sigma}(q) = V_0^{\sigma}(q, q, -q, -q) = \frac{\sigma^6}{64} \left(-\frac{16}{(q-1)^6} - \frac{16}{(1+q)^6} - \frac{2}{(1+q^2)^3} + \sigma^6 \left(\frac{2}{(q-1)^{12}} + \frac{2}{(1+q)^{12}} + \frac{1}{(32(1+q^2)^6)} \right) \right),
$$

FIG. 10. (a) Rectangular formations of the particles on the (x, y) -plane corresponding to minima [\(3.10\)](#page-8-1) of the potential V_0^{σ} . (b) Trapezoid shaped configurations of particles corresponding to minima $(3.11).$ $(3.11).$

see Figure [11.](#page-9-1) Figure [11](#page-9-1) shows the dependence of q_* on σ obtained by numerical minimization (in Wolfram Mathematica). The eigenvectors of the Hessian on the subspace M are the same as on L and are given by (3.8) . The corresponding eigenvalues of the Hessian on M can be obtained explicitly, they are given by rational expressions in q and σ . Figure [12](#page-10-1) presents the eigenvalues of the Hessian evaluated at the critical points $\pm \mathbf{q}_*(\sigma)$. At the bifurcation value of the parameter, $\sigma = \sigma_*$, they merge with eigenvalues [\(3.4\)](#page-6-4) evaluated at the critical point $q = 0$.

FIG. 11. (a) The restriction of potential [\(3.1\)](#page-5-1) to the subspace M for $\sigma = 1$. (b) Minimum point q_* of the potential shown in panel (a) as a function of σ .

One can see that on the interval $(\sigma_{\star}, \sigma_{\star}) = (1.13431, 1.13483)$, all the eigenvalues at the critical points $\pm \mathbf{q}_*(\sigma)$ are positive, hence $\pm \mathbf{q}_*(\sigma)$ are minima of the potential V_0^{σ} . However, at the point σ_{\star} , one eigenvalue crosses zero, see Figure [12,](#page-10-1) and these minima destabilize, one in the direction of the eigenvector $(1, -1, 1, -1)$, the other in the direction of the eigenvector $(1, 1, 1, 1)$ (both directions perpendicular to M), hence the critical points $\pm \mathbf{q}_*(\sigma)$ become saddles for $\sigma < \sigma_*$. The corresponding two simultaneous pitchfork bifurcations at the points $\pm \mathbf{q}_*(\sigma_*)$ give rise to a \mathbb{Z}_4 -orbit of critical points of the potential,

(3.11)
$$
\mathbf{q}_{\star}, \qquad \mathbf{q}^{\star} = \rho \mathbf{q}_{\star}, \qquad -\mathbf{q}_{\star} = \rho^2 \mathbf{q}_{\star}, \qquad -\mathbf{q}^{\star} = \rho^3 \mathbf{q}_{\star},
$$

of which $\pm q_{\star}$ belong to the two-dimensional subspace of points fixed by the group $\mathbb{Z}_2 = \{e, \kappa\},\$

(3.12)
$$
N_0 = \{ \mathbf{q} = (q, q, p, p), (q, p) \in \mathbb{R}^2 \},
$$

and $\pm \mathbf{q}^*$ belong to the two-dimensional subspace of points fixed by the group \mathbb{Z}_2 = ${e, \rho^2 \kappa},$

(3.13)
$$
N_1 = \{ \mathbf{q} = (-q, p, -p, q), (q, p) \in \mathbb{R}^2 \}.
$$

A point of N_0 corresponds to a configuration of particles forming an isosceles trapezoid, which is symmetric with respect to the line $x = y$; a point of N_1 corresponds to the particles forming a trapezoid, which is symmetric with respect to the line $x = -y$; and, \mathbb{Z}_4 -orbit [\(3.11\)](#page-10-0) corresponds to rotations of an isosceles trapezoid by multiples of $\pi/2$, see Figure [10.](#page-9-0) Both N_0 and N_1 are anti-gradient flow invariant.

Minimizing V_0^{σ} on N_0 provides the branch of critical points $\mathbf{q}_{\star}(\sigma)$. We restrict our attention to the segment of this branch shown in Figure [13a](#page-11-1) with σ ranging over the interval (.95, 1.145), which contains the bifurcation point σ_{\star} . The eigenvalues of the Hessian are positive on this segment (see Figure [14\)](#page-11-2), hence $\mathbf{q}_{\star}(\sigma)$ is a minimum point of the potential, and so are all four points of \mathbb{Z}_4 -orbit [\(3.11\)](#page-10-0). The branch containing this segment connects to the the branch of rectangular configurations [\(3.10\)](#page-8-1) via the fold bifurcation at $\sigma = 1.148$, see Figure [15](#page-12-0) and the subcritical bifurcation at the point σ_{\star} , see Figure ??.

Fig. 12. Eigenvalues of the Hessian of potential [\(3.1\)](#page-5-1) at its critical points [\(3.10\)](#page-8-1) as functions of $\sigma < \sigma_*$ (black lines). They merge with the eigenvalues at zero (colored lines) at the bifurcation point $\sigma = \sigma_*$. The colors match those in Figure [7.](#page-6-0)

It is worth noting that on the parameter interval $1.1384 < \sigma < 1.145$ the minimum at zero co-exists with four minimum points (3.11) creating muli-stability for $h = 0$.

Branches of minima [\(3.11\)](#page-10-0) shown in Figure [13a](#page-11-1) correspond to isosceles trapezoidal configurations of particles located within the square $-1 \leq x, y \leq 1$ (equivalently, $-1 \leq q, p \leq 1$). In addition, the potential V_0^{σ} has a \mathbb{Z}_4 -orbit of critical points which also belong to the subspaces N_0 , N_1 but correspond to isosceles trapezoidal configurations with two particles located outside the square $-1 \leq q, p \leq 1$, see Figure [13.](#page-11-1) These are saddle points with one unstable direction which is perpendicular to the subspace N_0 (resp., N_1) where the critical point is located, see Figure [16.](#page-12-1) There

FIG. 13. (a) Components $q_{\star} = q_{\star}(\sigma)$ (orange), $p_{\star} = p_{\star}(\sigma)$ (blue) of a minimum point $q_{\star} =$ $\mathbf{q}_\star(\sigma)=(q_\star,q_\star,p_\star,p_\star)$ of V_0^σ corresponding to an isosceles trapezoidal configuration of particles (red nodes on Figure [10\)](#page-9-0). The parameter σ ranges over the interval (.85, 1.145) containing the bifurcation point σ_{\star} . (b) Components $q_{\star}(\sigma), p_{\star}(\sigma)$ of a critical point corresponding to an isosceles trapezoidal configuration of particles with two particles lying outside the square $-1 \leq x, y \leq 1$. The range of the parameter σ overlaps with that of the branch shown on panel (a).

Fig. 14. (a) Positive eigenvalues of the Hessian for the branch of minimum points shown in Figure [13a.](#page-11-1) (b) Zoom into the two smaller eigenvalues from panel (a).

is an interval of the parameter σ within which these critical points co-exist with the minimum points shown in Figure [13a.](#page-11-1) We notice that the restriction of the potential to the subspace N_0 ,

$$
V_0^{\sigma}(q,q,p,p) = \frac{\sigma^6}{64} \left(-\frac{8}{(q-1)^6} - \frac{128}{(4+(q-p)^2)^3} - \frac{128}{((1+q)^2+(p-1)^2)^3} - \frac{8}{(1+p)^6} + \sigma^6 \left(\frac{1}{(q-1)^{12}} + \frac{128}{(4+(q-p)^2)^6} + \frac{128}{((1+q)^2+(p-1)^2)^6} + \frac{1}{(1+p)^{12}} \right) \right),
$$

has a singularity on the lines $q = 1$, $p = -1$ and at the point $(q, p) = (-1, 1)$. The restriction of this potential to the subspace N_1 has singuarities at the same locations.

In Section [3.3,](#page-14-0) we will consider the system under expansion (potential [\(3.3\)](#page-5-3)) for $\sigma < \sigma_*$ and show hysteresis between isosceles trapezoidal configurations of particles as the external forcing parameter h is varied.

3.2. System under rotational forcing. Let us consider potential [\(3.2\)](#page-5-2) with rotational external forcing for $\sigma^* < \sigma < \sigma^{**}$ (cf. [\(3.9\)](#page-8-2)). As shown in the previous

FIG. 15. The branch of trapezoidal configurations shown in Figure [13a](#page-11-1) folds at $\sigma = 1.485$ (panel (b)) and connects to the branch of rectangular configurations shown in Figure [11](#page-9-1) at $\sigma = \sigma_{\star} = 1.1343$ (panel (a)). Solid and dashed segments of the branches correspond to a minimum and a saddle of the potential, respectively.

Fig. 16. (a) Eigenvalues of the Hessian for the branch of critical points shown in Figure [13.](#page-11-1) Panel (b) zooms into the two smaller eigenvalues from panel (a). One eigenvalue is negative, i.e. the critical points are saddles.

subsection, when the forcing is zero $(h = 0)$, the potential has two minimum points [\(3.6\)](#page-6-2) corresponding to square-shaped configurations of particles shown in Figure [8.](#page-7-0)

Potential (3.2) is invariant with respect to the action of the group \mathbb{Z}_4 but not invariant with respect to the action of the group \mathbb{Z}_2 . However, we observe that

$$
V_h^{\sigma}(\mathbf{q})=V_{-h}^{\sigma}(\kappa\mathbf{q}).
$$

In particular, if q is a local minimum point of the potential for some h, then κq is a local minimum point for the value $-h$ of the forcing parameter.

As in the case without forcing, subspace (3.7) of \mathbb{Z}_4 -symmetric points is invariant for the anti-gradient flow of potential (3.2) . Restricting the potential to L , we obtain the scalar function

$$
v_h^{\sigma}(q) = 4hq + v_0^{\sigma}(q) = 4hq + \frac{129\sigma^{12} - 1088\sigma^6(1+q^2)^3}{2048(1+q^2)^6}
$$

13

,

whose critical points q^* define \mathbb{Z}_4 -symmetric critical points $\mathbf{q}^* = (q^*, -q^*, -q^*, q^*)$ of the potential V_h^{σ} . Hence, we consider zeros of the derivative

$$
-\frac{(v_h^{\sigma})'(q)}{4} = -\frac{(v_0^{\sigma})'(q)}{4} - h = \frac{3s^6q(129s^6 - 544(1+q^2)^3)}{2048(1+q^2)^7} - h.
$$

The graph of the odd function $-(v_0^{\sigma})^{\prime}/4$ has four extremum points for $\sigma > \sigma^*$, see Figure [17.](#page-14-1) In particular, on the positive semi-axis the local maximum and minimum points satisfy

$$
(3.14) \quad 0 < q_{max} < q_{min}, \quad h_{max} := -\frac{(v_0^{\sigma})'(q_{max})}{4} > 0 > -\frac{(v_0^{\sigma})'(q_{min})}{4} =: h_{min}.
$$

Therefore, hysteresis occurs if the following conditions are satisfied:

• The local extremum values of the function $-(v_0^{\sigma})^2/4$ satisfy $h_{max} < -h_{min}$, see the blue plot in Figure [17](#page-14-1) (the orange plot violates this condition). From this condition, it follows that there is a unique point q_0 satisfying

$$
(3.15) \tq_{max} < q_0 < q_{min}, \t-\frac{(v_0^{\sigma})'(q_0)}{4} = -\frac{(v_0^{\sigma})'(-q_{max})}{4} = -h_{max},
$$

see Figure [18.](#page-15-0)

- Assuming that the external forcing parameter h oscillates between $-h_0$ and h_0 , the amplitude h_0 satisfies $h_{max} < h_0 < -h_{min}$.
- The segment of the straight line [\(3.7\)](#page-6-3) between the points $\pm (q_0, -q_0, -q_0, q_0)$ is transversally stable. In other words, the eigenvalues

(3.16)
$$
\lambda_1 = \lambda_2 = \frac{9\sigma^6(\sigma^6 - 2(1+q^2)^3)}{8(1+q^2)^7},
$$

$$
(3.17) \qquad \lambda_3 = -\frac{3\sigma^6 \left(-96(1+q^2)^3(-37+3q^2)+\sigma^6(-1663+115q^2)\right)}{2048(1+q^2)^8}
$$

of the Hessian, which correspond to the eigenvectors $(0, 1, 0, 1)$, $(1, 0, 1, 0)$, $(-1, -1, 1, 1)$ orthogonal to L (see [\(3.8\)](#page-7-1)), are positive on the segment $-q_0 \le$ $q \leq q_0$. We note that the eigenvalue

$$
\lambda_4 = \frac{3\sigma^6 \left(-544 (1+q^2)^3 (-1+7q^2)+129 \sigma^6 (-1+13q^2)\right)}{2048 (1+q^2)^8} = \frac{(v_F^{\sigma})''(q)}{4}
$$

corresponding to the eigenvector $(1, -1, -1, 1)$ in the direction of L is negative on the interval $(-q_{max}, q_{max})$ and positive on each of the intervals $(-q_{min}, -q_{max})$ and (q_{max}, q_{min}) which include the points $-q_0$ and q_0 , respectively.

Under these conditions, the system with potential [\(3.2\)](#page-5-2) exhibits hysteresis as shown in Figure [18.](#page-15-0)

The first of the above three conditions is satisfied for the values of σ from the interval (σ^*, σ^*) = (1.27107, 1.375), see Figure [19](#page-16-0) which shows the dependence of h_{max} and $-h_{min}$ on σ . The second condition is satisfied for every pair (σ, h_0) in the region bounded above by the graph of $-h_{min}(\sigma)$ (red line) and below by the graph of $h_{max}(\sigma)$ (blue line) on the same figure.

FIG. 17. Plot of the function $-(v_0^{\sigma})'(q)/4$ for $\sigma = 1.33$ (blue) and $\sigma = 1.4$ (orange). Intersections of the graph with a horizontal line $y = h$ define critical points $q^*(h)$ of the function $v_h^{\sigma}(q)$.

The third condition involves the interval $(-q_0, q_0)$ where q_0 is defined non-locally by equation [\(3.15\)](#page-13-0) (see Figure [18\)](#page-15-0). Figure [19](#page-16-0) shows the dependence of q_0 on σ on the interval of interest, (σ^*, σ^*) . As confirmed by Figure [20,](#page-16-1) the eigenvalues $\lambda_1 = \lambda_2$, λ_3 (see [\(3.16\)](#page-13-1), [\(3.17\)](#page-13-2)) evaluated at $q = q_0(\sigma)$ are positive for the values of σ from this interval. These eigenvalues are even functions of q, the eigenvalues $\lambda_1 = \lambda_2$ decrease with q for $q \ge 0$, and the eigenvalue λ_3 also decreases with q in the domain of interest, i.e. in

(3.18)
$$
\{(\sigma,q): \sigma^* < \sigma < \sigma^*, \ 0 \le q \le q_0(\sigma)\}.
$$

Hence, Figure [20](#page-16-1) ensures that all the transversal eigenvalues are positive on the segment $-q_0(\sigma) \le q \le q_0(\sigma)$ for each σ from the interval (σ^*, σ^*) , i.e. the third condition is also satisfied on this interval.

Hence, we conclude that the system with potential [\(3.2\)](#page-5-2) exhibits hysteresis if the parameter σ of the potential satisfies $\sigma^* < \sigma < \sigma^*$. It is the same type of hysteresis associated with bi-stability as shown in Figure [2.](#page-2-0)

Clearly, the symmetric range of h can be replaced by any asymmetric range $h_1 \leq h \leq h_2$ provided that $h_{max} < -h_1, h_2 < -h_{min}$.

3.3. System under expansion. In this section, we consider potential [\(3.3\)](#page-5-3) for the fixed $\sigma = 1.12 < \sigma_*$ and vary the force parameter h. This potential is invariant with respect to the action of the subgroup $\mathbb{Z}_2 \times \mathbb{Z}_2 = \{e, \rho^2, \kappa, \kappa \rho^2\}$ of \mathbb{D}_4 and satisfies

$$
\hat{V}_h^{\sigma}(\mathbf{q}) = \hat{V}_{-h}^{\sigma}(\rho \mathbf{q}).
$$

Therefore, the planes N_0, N_1 defined by $(3.12), (3.13)$ $(3.12), (3.13)$ (which correspond to isosceles trapezoidal formations of particles, see Figure [10\)](#page-9-0) are invariant for the gradient field in the configuration space.

Figure [21](#page-17-0) presents two branches of critical points located in the plane N_0 . Eigenvalues along the yellow branch are shown in Figure [22.](#page-17-1) This critical point is a minimum for $h = 0$. As h decreases, the smallest eigenvalue becomes negative at $h = h_* = -0.122$. The corresponding saddle-node critical point is

$$
(q_1, q_2, q_3, q_4) = (-0.430867, -0.430867, -0.110452, -0.110452).
$$

Fig. 18. Hysteresis loop for potential [\(3.2\)](#page-5-2) with external forcing h. The system moves along the straight line L of \mathbb{Z}_4 -symmetric states, hence the position in the configuration space is described by one scalar parameter q. The blue curve is the graph of the function $-(v_0^{\sigma})'(q)/4$, see the blue curve in Figure [17.](#page-14-1) Solid parts of the curve correspond to minimum points of the potential. As h increases from the minimal value $-h_0$, the point $(q^*(h), h)$ follows the solid part on the right branch of the curve moving upwards left in the direction of the local maximum of the curve. In the configuration space, the system sits at the (moving) local minimum point $\mathbf{q}^*(h) = (q^*(h), -q^*(h), -q^*(h), q^*(h))$ of the potential. Once the point $(q^*(h), h)$ reaches the maximum point of the curve at $h = h_{max}$, it transits horizontally along the dashed arrow to the left branch of the curve, which corresponds to the local minimum point $-q^*(-h) = \kappa q^*(-h)$ of the potential. In the configuration space, this event corresponds to the local minimum $\mathbf{q}^*(h)$ disappearing in the saddle-node bifurcation at $h = h_{max}$, and the system transitioning to the remaining minimum point $-q^*(-h)$ along the line L. Now, as h increases further, the point $(q^*(h), h)$ follows the solid segment on the left branch of the curve until it reaches the highest point at $h = h_0$. Similarly, as h decreases from the maximum value h_0 , the point $(q^*(h), h)$ follows the left branch of the curve downwards right, transits along the horizontal dashed arrow to the right branch of the curve at the point $h = -h_{max}$, and continues along the right branch until it reaches the rightmost lowest point at $h = -h_0$. In the configuration space, the system sits in the local minimum point $-q^*(-h)$ until this minimum disappears in the saddle-node bifurcation at $h = -h_{max}$, at which point the system transitions to the local minimum $\mathbf{q}^*(h)$ along the line L, and then remains at $\mathbf{q}^*(h)$ until h reaches the value $-h_0$.

Figure [23](#page-18-0) shows the transition from the above critical point to the minimum point

$$
(q_1, q_2, q_3, q_4) = (-1.69683, -1.69683, -0.0720405, -0.0720405)
$$

on the blue branch resulting from a small perturbation in a direction perpendicular to the subspace N_0 of isosceles trapezoidal configurations.

Eigenvalues along the blue branch are shown in Figure [24.](#page-18-1) As h increases from the value h_* , the smallest eigenvalue becomes negative at $h = h^* = -0.0135$. The corresponding critical point is

$$
(q_1, q_2, q_3, q_4) = (-1.58907, -1.58907, -0.110771, -0.110771).
$$

Figure [23](#page-18-0) shows the backward transition from this saddle-node critical point to the minimum point

$$
(q_1, q_2, q_3, q_4) = (-0.355008, -0.355008, -0.0969899, -0.0969899)
$$

on the yellow branch resulting from a small perturbation in a direction perpendicular to the subspace of isosceles trapezoidal configurations N_0 . Thus, varying h over an

FIG. 19. (a) Dependence of the the extremum values h_{max} (blue) and $-h_{min}$ (red) of the function $-(v_0^{\sigma})^2/4$ on σ . The value of σ at the intersection point is $\sigma^* = 1.375$. (b) Dependence of q₀ on σ on the interval (σ^*, σ^*) .

FIG. 20. Transversal eigenvalues $\lambda_1 = \lambda_2$ (red) and λ_3 (blue) evaluated at the point $q_0(\sigma)$ as functions of σ on the interval (σ^*, σ^*) .

interval $[h_0, h^0]$ which satisfies $[h_*, h^*] \subset [h_0, h^0] \subset [-0.15, 0]$ results in a hysteresis loop. Bifurcations at the points $h = h_*, h^*$ are subcritical pitchfork bifurcations associated with \mathbb{Z}_2 -symmetry breaking of the isosceles trapezoidal solutions, see Figure [25.](#page-19-7)

4. Conclusions. A particle in a quasistatically varied double-well potential is a canonical example of hysteresis associated with bi-stability and elimination of a minimum of the potential energy via a saddle-node bifurcation. We explored similar scenarios in systems of particles assuming a natural single-well (Lennard-Jones) interaction potential for each pair of particles. In this setting, if N identical particles are constrained to a straight line, each particle interacts with its nearest neighbors, and a quasistatically varied external forcing is applied at the ends of the chain, then the potential energy has at most one minimum, hence the system doesn't exhibit hysteresis. Therefore, we considered particles on the plane. Two hysteresis scenarios were shown in a simple (constrained) four-particle system with four degrees of freedom. The first scenario is equivalent to a one-degree-of-freedom particle in a double-well potential because the evolution in the configuration space is restricted to a one-dimensional in-

FIG. 21. Components q, p for two branches of isosceles trapezoidal critical points $(q, q, p, p) \in$ N₀. For the yellow branch, the formation of particles belongs to the square $-1 \le x, y \le 1$; for the blue branch, two particles are located outside this square; $-0.15 < h < 0$; $\sigma = 1.12$.

Fig. 22. (a) Eigenvalues for the yellow branch of critical points shown in Figure [21.](#page-17-0) (b) The smallest eigenvalue corresponding to a direction perpendicular to N_0 .

variant attracting manifold (straight line) of symmetric square-shaped configurations. In the second scenario, critical points of the potential which are restricted to an invariant plane of isosceles trapezoidal configurations are destabilized by a symmetry breaking bifurcation in a transversal direction, hence the ensuing transient dynamics towards a minimum occurs outside the plane where the minima are located.

Important phenomenological models of hysteresis (such as models of constitutive relations of materials and media) combine, or admit decomposition into, many bi-stable elements. As such, they exhibit specific types of hysteresis, which can be identified by properties of hysteresis loops. For example, hysteresis loops of the Ising, Preisach and Prandtl-Ishlinskii models close after one period (the so-called return point memory property); additionally, all hysteresis loops of the Preisach model corresponding to the same periodic input are congruent to each other; all the loops of the Prandtl-Ishlinskii model are centrally symmetric. It would be interesting to characterize hysteresis of multi-particle systems, in which particles interact via the Lennard-Jones potential (as in (2.1) – (2.2)), and compare it to the types of hysteresis exhibited

FIG. 23. (a) Transition from the yellow branch to the blue branch at the bifurcation point $h = -0.122$. (b) The backward transition at the bifurcation point $h = -0.0135$. Each panel shows the time plots of the coordinates q_i of q during the corresponding transition, which follows the antigradient dynamics $\dot{\mathbf{q}} = -\nabla \hat{V}_h^{\sigma}(\mathbf{q}).$

Fig. 24. (a) Eigenvalues for the blue branch of critical points shown in Figure [21.](#page-17-0) (b) The smallest eigenvalue corresponding to a direction perpendicular to N_0 .

by standard phenomenological models. One particular example of such multi-particle systems are amorphous media, specifically low-molecular and polymer glasses. Plastic phenomena in these systems are closely related to the succession of bifurcations of their complicated multi-dimensional potential landscape [\[29,](#page-20-20) [30\]](#page-20-21). Numeric simulations, both in athermal quasistatic regime and with molecular dynamics, demonstrate clear hysteretic behavior, in complete agreement with physical intuitive apprehension of plasticity. Still, a direct relationship between this hysteresis and the particularities of interatomic interactions remains mysterious. However, these questions are beyond the scope of this work. It would be also interesting to replace transitions along the anti-gradient field with inertial transition dynamics $m\ddot{\mathbf{q}} + \gamma \dot{\mathbf{q}} + \nabla V(\mathbf{q};h) = 0$. The anti-gradient transitions correspond to the limit of large friction forces. In the opposite frictionless limit (i.e., $m\ddot{\mathbf{q}} + \nabla V(\mathbf{q};h) = 0$), transitions are initiated by saddle-center bifurcations and end at oscillating regimes.

It is worth noting that any type of hysteresis is possible in a two-degrees-offreedom system if the class of potentials is not restricted. To make this statement precise, an edge-labeled directed graph Γ was associated in [\[24\]](#page-20-22) with any N-degree-offreedom potential energy $V_h(\mathbf{q})$ as follows. With each energy minimum (state) that

FIG. 25. Subcritical \mathbb{Z}_2 -symmetry breaking pitchfork bifurcations at the points (a) $h_* = -0.122$ and (b) $h^* = -0.0135$, which limit the bi-stability range of the \mathbb{Z}_2 -symmetric trapezoidal solutions.

exists on an input interval

(4.1) h − ^j < h < h⁺ j

(where h_j^{\pm} are saddle-node bifurcation points), one associates a graph vertex v_j . Every vertex has two outgoing directed edges. One edge, labeled h_j^- , corresponds to the transition from the state labeled v_j to another state as a decreasing input h reaches the bifurcation value h_j^- ; the other edge, labeled h_j^+ , corresponds to the transition, which occurs when an increasing input reaches the bifurcation value h_j^+ . Since the graph Γ encodes all the transitions between states in response to quasistatic variations of the input, it is called a hysteresis map for V_h . By design, for any vertex v_j , the labels h of all the incoming edges satisfy (4.1) . As shown in [\[24\]](#page-20-22), any edge-labeled directed graph Γ which, at each vertex, has exactly two outgoing edges, with the incoming edge labels h and outgoing edge labels h_j^{\pm} satisfying [\(4.1\)](#page-19-8), is a hysteresis map for some two-degrees-of-freedom potential $V_h(q_1, q_2)$. It would be interesting to determine what hysteresis maps correspond to multi-particle potentials [\(2.1\)](#page-3-2) with Lennard-Jones interactions.
