Thermalization phenomena, while ubiquitous in quantum systems, have traditionally been viewed as obstacles to be mitigated. In this study, we demonstrate the ability, instead, to harness thermalization to dynamically engineer and stabilize structured quantum states in a mesoscopically large ensemble of spins. Specifically, we showcase the capacity to generate, control, stabilize, and read out "shell-like" spin texture with interacting 13 C nuclear spins in diamond, wherein spins are polarized oppositely on either side of a critical radius. The texture spans several nanometers and encompasses many hundred spins. We capitalize on the thermalization process to impose a quasi-equilibrium upon the generated texture; as a result, it is highly stable, immune to spin diffusion, and endures over multiple-minute long periods — over a million times longer than the intrinsic interaction scale of the spins. Additionally, the texture is created and interrogated without locally controlling or probing the nuclear spins. These features are accomplished using an electron spin as a nanoscale injector of spin polarization, and employing it as a source of spatially varying dissipation, allowing for serial readout of the emergent spin texture. Long-time stabilization is achieved via prethermalization to a Floquet-induced Hamiltonian under the electronic gradient field. Our work presents a new approach to robust nanoscale spin state engineering and paves the way for new applications in quantum simulation, quantum information science, and nanoscale imaging.

I. INTRODUCTION

Thermalization is a pervasive phenomenon in all of physics. The quest to elucidate how isolated microscopic quantum systems approach equilibrium, has spurred a thriving field at the intersection of contemporary theoretical and experimental research. This has been marked by ongoing developments in nonequilibrium dynamics, such as the Eigenstate Thermalization Hypothesis for closed quantum systems [\[1–](#page-38-0)[3\]](#page-38-1), anomalous transport and emergent hydrodynamics [\[4–](#page-38-2)[6\]](#page-38-3), or the creation of prethermal ordered states of matter [\[7](#page-38-4)[,8\]](#page-38-5).

Thermalization in quantum systems proceeds analogously to its classical counterpart: entropy grows with time, erasing traces of the system's prior history. Physically, this translates into a gradual reduction of accessible information that can be obtained from local measurements until, in thermal equilibrium, a maximum entropy state is reached. In most cases, such loss of information is irreversible, impeding the capacity to harness quantum systems. Consequently, a broad endeavor has been underway to retard, even preclude, these thermalization processes. Techniques range from physically isolating quantum systems (e.g. in vacuum) or through quantum control [\[9\]](#page-38-6), cooling them to near absolute zero temperatures [\[10\]](#page-38-7), or, in a complementary manner, exploiting theoretical paradigms of many-body localization to inhibit the onset of thermalization [\[11\]](#page-38-8).

Though the thermalization process is often depicted as leading to mundane, featureless states, in this work, we demonstrate its utility in preparing structured mesoscopic quantum states. Specifically, in a system of interacting nuclear spins at high temperature $(>100K)$, we exploit out-of-equilibrium thermalizing dynamics to controllably engineer and stabilize mesoscopic *shell-like* nuclear spin polarization textures that span several nanometers and envelope hundreds of nuclear spins (Fig. [1A](#page-1-0)). Simultaneously, we continuously observe the formation and stabilization of these textures with high temporal resolution over prolonged, multiple-minute-long periods. This spatiotemporal control, facilitated by thermalization, obviates the need for local spin manipulation or readout, intrinsically protects against control errors, and bypasses technical challenges of differentiating spins with near-identical resonance frequencies. Given these methodological advantages, our approach has direct implications for quantum memories [\[12](#page-38-9)[,13\]](#page-38-10), spintronics [\[14](#page-38-11)[,15\]](#page-38-12), and nanoscale magnetic resonance imaging [\[16](#page-38-13)[,17\]](#page-38-14).

Our experiments are in a model system of Nitrogen Vacancy (NV) center electrons in diamond surrounded by ¹³C nuclear spins (Fig. [1A](#page-1-0)) [\[18\]](#page-38-15). The sparsely distributed NVs en-compass ~10^{4 13}C nuclei, spanning a radius of ≈12 nm [\[19\]](#page-38-16). Our strategy is built upon three elements. Firstly, the optically polarizable NV electron serves as a "polarization injector" and a nanoscale "antenna". In its role as an antenna, it generates a nanoscale gradient through the hyperfine interaction, resulting in localized displacement of the nuclear spin resonance frequencies [\[20\]](#page-38-17). Under this gradient field, a time-periodic (Floquet) drive stabilizes the nuclei into a metastable state [\[21\]](#page-38-18), characterized by a shell-like polarization texture (Fig. [1B](#page-1-0)). Finally, spatially dependent dissipation from the NV is exploited to observe these textures: ¹³C nuclei in the electronic proximity relax faster, providing a means to *serially* probe spins farther away from the electron, without locally measuring them (Fig. [1B](#page-1-0)).

To demonstrate this new toolbox, we first demonstrate a simple means to produce spin textures. Here the NV is exploited to successively inject "hyperpolarization" – polarization that is orders of magnitude greater than Boltzmann levels – of alternate sign into the ¹³C nuclei. However, the resulting **State-Engineered** spin texture lacks stability: its domain boundary melts due to nuclear spin diffusion [\[22\]](#page-38-19).

Exploiting thermalization, however, offers a solution — creating polarization textures with domain boundaries protected

Fig. 1. **System and readout.** (A) *Spin-textures.* Controllable "shelllike" spin texture of positive and negative polarization (shaded red and blue, respectively) is generated in a nanoscale ensemble of 13 C nuclear spins surrounding a central NV electron (manipulated by an external laser, shown in green). The domains are separated by the critical radius r_c at the domain boundary (dashed white line). The texture encompasses $~\sim$ O(100) spins within the critical radius and remains stable for minutes. The optically-pumped electron serves as a spin injector, and produces a nanoscale magnetic field gradient B (shaded light pink) that stabilizes the spin texture in a prethermal state. (B) *Experimental schematic* showing prethermalization caused by Floquet driving at high-magnetic field (HF) $B_0 \ge 7$ T, with a train of spin-locking θ -pulses of length t_p . $\hat{\mathbf{x}}$ - $\hat{\mathbf{y}}$ spin polarization is interrogated in windows between the pulses for total readout times $t > 60s$ ($> 0.5M$ pulses). (C) ¹³C spin texture is generated and stabilized by a spatially-varying potential $\phi(r)$ created upon Floquet driving with $\theta \approx \pi$ in the presence of the NV gradient (cf. Sec. [III\)](#page-3-0).

against spin diffusion. We create an effective inhomogeneous parent Hamiltonian with spatial characteristics derived from the NV antenna field (Fig. [1C](#page-1-0)). Irrespective of the initial state [\[23\]](#page-38-20), the spin polarization naturally *prethermalizes* [\[24–](#page-38-21)[26\]](#page-38-22) to its drive-induced quasi-equilibrium state, forming spin shells with constant-in-time domain boundaries. We observe the formation of this generated **Hamiltonian-Engineered** [\[27](#page-38-23)[–29\]](#page-38-24) texture continuously with unprecedented resolution over a lifetime spanning several minutes. Numerical simulations corroborate these observations and illustrate a stable spin texture spanning several nanometers.

II. SPIN TEXTURING VIA HYPERPOLARIZATION INJECTION

State-Engineered shells are created by alternately injecting positive and negative hyperpolarization [\[32](#page-38-25)[,33\]](#page-38-26) for periods τ_{+} and τ_{-} , respectively (Fig. [2A](#page-2-0) inset). Direct ¹³C hyperpolarization occurs rapidly over a short range, with distant nuclei polarized more slowly via spin diffusion. Consequently, 13 C nuclei close to the NV center are negatively polarized, while more distant nuclei are left positively polarized, yielding the shell-like texture. Varying τ at a fixed τ provides a means to tune the shell size.

Spin diffusion is driven by internuclear dipolar interactions with the Hamiltonian

$$
\mathcal{H}_{dd} = \sum_{k < \ell} b_{k\ell} \left(3I_k^z I_\ell^z - \mathbf{I}_k \cdot \mathbf{I}_\ell \right),\tag{1}
$$

where
$$
b_{k\ell} = J_{\text{exp}}(3\cos^2(\vartheta_{k\ell}) - 1)/r_{k\ell}^3
$$
, $J_{\text{exp}} = \mu_0 \hbar \gamma_n^2/4\pi$,

 $\cos(\vartheta_{k\ell})=B_0 \cdot \mathbf{r}_{k\ell}/(|B_0|r_{k\ell}), \mathbf{r}_{k\ell}$ is the inter-spin vector, $B_0 = B_0 \hat{z}$ is the external field. The median ¹³C coupling strength is $\langle b_{kl} \rangle = J \approx 0.6$ kHz.

Fig. [2A](#page-2-0) depicts the *net* ¹³C polarization during spin injection, for $\tau_{+}=60$ s, after which the sign of the injected polarization is reversed (dashed vertical line). In the boxed region around $t_{\text{pol}} \approx 100 \text{ s } (\tau_{-} = 40 \text{ s})$, the total net polarization approaches zero. Although there is limited net polarization, the system can still exhibit locally large spin expectation at different sites. To observe this, the ¹³C nuclei are subject to a Floquet protocol at $B_0=7$ T (Fig. [2B](#page-2-0)(i) inset) involving a series of spin-locking θ -pulses of duration t_p , at Rabi frequency Ω, and separated by time interval τ . Spin-locking with $\theta \neq \pi$ yields the leading order effective Floquet Hamiltonian [\[29\]](#page-38-24) (see SI [S7 B\)](#page-21-0),

$$
\mathcal{H}_{\rm SL} = -\frac{1}{2} \sum_{k,\ell} b_{k\ell} \left(3 I_k^x I_\ell^x - \mathbf{I}_k \cdot \mathbf{I}_\ell \right). \tag{2}
$$

Here >560,000 pulses are applied over a period of $t \ge 60$ s. The drive induced dynamics (quasi-)conserves **x**ˆ-polarization as evident from the leading order effective Hamiltonian Eq. [\(2\)](#page-1-1) (see SI [S7 B\)](#page-21-0), resulting in long transverse lifetimes T_2 [\[34\]](#page-38-27).

This process can be quasi-continuously tracked in real-time. Between the pulses, rapid and non-destructive (inductive) interrogation of 13 C Larmor precession occurs at a rate of τ^{-1} ~10 kHz. We record the nuclear polarization amplitude S and phase φ_R in the $\hat{\mathbf{x}} - \hat{\mathbf{y}}$ plane in the rotating frame, where $\varphi_R = 0(\pi)$ refers to a vector along $\hat{\mathbf{x}}(-\hat{\mathbf{x}})$.

Each point in Fig. [2A](#page-2-0) can therefore be expanded into a secondary dimension (S, φ_R) , as shown in Fig. [2B](#page-2-0), considerably increasing the information content compared to previous approaches [\[35\]](#page-38-28). Consider first the point *(a)* at the top of the polar-ization buildup curve in Fig. [2A](#page-2-0) $(\tau_0=0)$. Considering normalized signal S in Fig. [2B](#page-2-0) (black dashed line), a long-lived decay bearing lifetime $T'_2 \approx 93.4$ s is evident, reflective of prethermalization to H_{SL} and the resulting $\hat{\mathbf{x}}$ (quasi-)conservation [\[34\]](#page-38-27). In comparison to this slow, featureless, decay, normalized signal profiles, the zero total net polarization region (boxed in Fig. [2A](#page-2-0)) exhibits distinct differences. For clarity, we consider first the representa-tive trace (bold orange) in Fig. [2B](#page-2-0)(i) at τ =44.8 s. Normalized S here features a sharp zero-crossing at $t=t_{zc}(\approx 11.34 \text{ s})$, accompanied by a simultaneous reversal in total net polarization sign from −**x**ˆ to +**x**ˆ (Fig. [2B](#page-2-0)(ii)). The region in the zero-crossing vicinity (1% variation) itself encompasses $\sim 10^4$ points, showcasing the rapid and non-invasive dynamics sampling — τ^{-1} > 14J in these experiments. Additionally, the data captures dynamics up to very long times, Jt >1.2×10⁶, surpassing previous experiments by several orders of magnitude [\[36–](#page-38-29)[38\]](#page-38-30).

The other colored traces in Fig. [2B](#page-2-0)(i) show corresponding signals S for different τ (see colorbar). The zero-crossing point t_{zc} shifts to the right with increasing τ_{zc} . The extracted t_{zc} values are elaborated in Fig. [2B](#page-2-0)(iii). A movie showcasing data for 151 changing values of τ is accessible at [\[30\]](#page-38-31).

Quasi-conservation of the net **x**ˆ-polarization naively suggests constant-in-time signal curves, in contradiction to our observations. To rationalize the data in Fig. [2,](#page-2-0) recall that the NV electron is strongly coupled to a phonon bath while the 13 C spins are only weakly coupled to it. Consequently, the NV acts as a dominant local relaxation source for the 13 C nuclei. Proximal nuclei dissipate polarization ($\sim 1/r^6$) faster than more distant ones, as can be derived with the Lindblad master equation in the strong coupling limit (see Methods and Sec. [S6 B\)](#page-18-0). Measurements at

Fig. 2. **Spin textures via hyperpolarization injection (State Engineering).** (A) Net ¹³C spin polarization under positive hyperpolarization buildup (τ_{+} , red points), followed by negative hyperpolarization injection after $\tau_{+}=60$ s (τ_{-} , blue points) at room temperature. Solid lines represent a biexponential fit. Boxed region around $t_{\text{pol}} \approx 97$ s corresponds to close to zero net polarization. (B) Normalized spin-lock decays under Floquet drive with $\theta \approx \pi/2$, showing (i) signal *S* and (ii) rotating-frame phase φ_R . *Dashed black line:* spin-lock decay corresponding to τ =0 (*a* in A), displaying long lifetime $T'_2 \approx 93.4$ s. *Colored lines:* Data for different τ_- values (colorbar). For τ_- corresponding to the boxed region in (A), decay profiles exhibit a sharp zero-crossing at $t=t_{zc}$ (II) and associated phase inversion (see ii). Each trace has >0.5×10⁶ data points, with ~10⁴ points in the vicinity (1% variation) of t_{zc}. Dark orange line: τ = 44.8 s slice is emphasized for clarity. A full movie of this dataset can be viewed at [\[30\]](#page-38-31). (iii) Movement of zero-crossing zc with −, demonstrates the ability to control spin texture. (C) *Schematic representation* of spin textures with increasing experiment progression time t (arrow). Representative points (I-IV) are marked on the τ =44.8s slice in (B). NV is located at r =0. Positive (negative) polarization is shaded red (blue). Electron-driven dissipation during t is indicated by a decrease in polarization (white region) around $r=0$. Spin diffusion is indicated by growing texture size and increasing white region at the boundary between polarization layers of different sign, with dashed line as a guide to the eye for the zero polarization regime. (D) ¹³*C NMR spectrum* obtained via Fourier transforms of full data in (B). Data is shown for varying τ_{-} (vertical axis) and plotted on a logarithmic scale, comprising 91 τ_{-} slices, separated by 0.2 s. It displays a $>10⁹$ variation in intensity dynamic range (color bar). Signature of spin shell texture formation is the narrowing of the FT spectrum with τ \approx 37s, corresponding to the boxed region in (A).

longer times *t*, therefore, serially probe nuclei *further* away from the NV.

Fig. [2C](#page-2-0) schematically represents the polarization distribution during the interrogation period t , focusing on specific points (I-IV) along the bold orange trace (τ =44.8 s) in Fig. [2B](#page-2-0). For simplicity, we depict the generated texture as spherical shells, although in reality, it possesses an angular dependence inherited from the hyperfine interaction (see Fig. [5](#page-5-0) C-D). Starting from the initial texture $(t=0)$, proximal ¹³C polarization undergoes dissipation from the NV center (shown white), gradually revealing polarization at greater distances as t increases. Zerocrossing at $t=t_{\text{zc}}$ corresponds to an equal distribution of positive and negative polarization (Fig. [2C](#page-2-0) II). Further dissipation leads to a polarization sign inversion (Fig. [2C](#page-2-0) III-IV). Overall, Fig. [2](#page-2-0) illustrates the ability to discriminate spins without relying on the electronic "frozen core", constituting a departure from previous work [\[35,](#page-38-28)[39\]](#page-38-32).

The different stages in Fig. [2C](#page-2-0) exhibit distinct signatures in the ¹³C NMR spectrum. In Fig. [2D](#page-2-0) we report the ¹³C spectrum for 91 τ values, separated by 0.2 s intervals, obtained by applying a Fourier transform (FT) to the sign-corrected data in Fig. [2B](#page-2-0). The Fourier intensity is shown on a logarithmic scale spanning over nine orders of magnitude. The wide dynamic range reflects the high signal-to-noise ratio in our experiments. ${}^{13}C$ spins closer to the NV produce broader spectral lines because they experience faster relaxation, manifesting as stronger contributions to the spectral wings around 0Hz. Conversely, more distant ${}^{13}C$ nuclei are centrally located in the spectrum due to longer relaxation times. With increasing $\tau_$, depolarization initially affects the spectral wings, resulting in an apparent narrowing of the spectrum at $\tau_-\approx 37$ s. Subsequently, the inversion of the central feature, corresponding to bulk ${}^{13}C$ nuclei, follows suit.

Spin texture generated via **State Engineering** (Fig. [2\)](#page-2-0) is not intrinsically stable. Over time, any imprinted domain boundaries

Fig. 3. Melting of spin-texture due to spin diffusion (State Engineering). (A) *Experiment schematic*. Waiting period t_{wait} at high-field is introduced after successive $\{\tau_{+},\tau_{-}\}$ spin injection, and prior to application of the Floquet drive in Fig. [2.](#page-2-0) (B) Representative signal traces showing changes in decay profiles with variable t_{wait} for texture generated with $\tau_{+}=60$ s and $\tau_{-}=42$ s (bolded trace in Fig. [2B](#page-2-0)). Decrease in signal amplitude between $t_{\text{wait}}=0$ and $t_{\text{wait}}=30$ s evidences the instability of state-engineered spin texture. A full movie of this data set, with phase information, can be found at [\[31\]](#page-38-33) (C) *Schematic representation* showing the melting of spin texture during t_{wait} due to spin diffusion at the boundary between polarization layers, dashed line serves as guide to the eye for the domain wall boundary. (D) Points show movement of the zero-crossing t_{zc} position with t_{wait} for data in (B). Solid line is a linear fit. (E) Signal intensity at $t=50$ s in (B) plotted for different values of t_{wait} normalized to its value corresponding to the $t_{\text{wait}} = 0$ case. Melting of the spin texture due to diffusion manifests as a decrease in signal. Solid line is a biexponential fit. Light blue line corresponds to case without spin texture $(\tau_{+}=60s, \tau_{-}=0)$. (F-G) *Simulations* corresponding to (D-E) showing zero-crossing times and $|\min(I_x)|$ extracted from numerical time-evolution in a one-dimensional short-range model using a similar shell-like initial state (see Fig. [5](#page-5-0) and Methods). Simulations show qualitative agreement with experimental results.

begin to dissolve due to spin diffusion. Such "melting" of spin texture can be observed in experiments where a delay period t_{wait} (<30 s) is introduced before the (shell-like) **z**ˆ-polarized state is rotated into the $\hat{\mathbf{x}}$ - $\hat{\mathbf{y}}$ ⁿ plane and the Floquet driving is started (see Fig. [3A](#page-3-1)). During t_{wait}, NV-driven dissipation of the \hat{z} -polarized texture is negligible. This is due to the increased energy gap $(\gamma_n B_0)$, as opposed to Ω , see SI Sec. S2A), and is reflected in the extremely long nuclear lifetimes $T_{1n} \approx 1$ h $\gg T'_2$ under these conditions. Consequently, spin dynamics in the t_{wait} period is primarily affected by spin diffusion. Simulations based on a Lindblad master equation confirm this picture (see Methods).

Fig. $3B$ shows the signal S dependence on the delay period t_{wait} , starting from a spin texture produced with $\tau_{+}=60 \text{ s}$ and τ =42 s. Spin diffusion gradually homogenizes (flattens) the polarization distribution as t_{wait} increases (Fig. [3B](#page-3-1)). This leads to a rightward shift in the zero-crossing point t_{zc} and a decrease in signal amplitude, as evident in Fig. [3B](#page-3-1), and as schematically depicted in Fig. [3C](#page-3-1).

The spin diffusion-mediated flattening of the polarization distribution can be directly observed by considering the signal decreasing with t_{wait} for a fixed value of t. Fig. [3E](#page-3-1) shows $S(t_{\text{wait}})$ at $t=50$ s, normalized against the value at $t_{wait}=0$ to highlight changes with t_{wait} . For a homogeneously polarized state (τ_0 =0), the thus normalized signal increases slightly with increasing t_{wait} due to polarization diffusing away from the NV, and hence being subjective to lower effective relaxation from it. These observations are supported by numerical simulations (Fig. [3F](#page-3-1)-G) obtained by solving the Lindblad equation for a simplified toy model (see Fig. [5](#page-5-0) and SI [S8 A\)](#page-26-0). All qualitative features and intuition from the microscopic dynamics are well reproduced.

III. ROBUST SPIN SHELLS BY HAMILTONIAN ENGINEERING

To stabilize the generated spin texture, we introduce a second approach of **Hamiltonian Engineering**. This stems from a surprising observation: when deploying the Floquet pulse train with flip angle $\theta \approx \pi$ (Fig. [4A](#page-4-0)) and starting with ¹³C spins positively polarized (τ_+ =60 s, τ_- =0 s), we observe that over time, the signal S exhibits a sharp zero-crossing and subsequent sign inversion that can persist longer than 180 s. This is highlighted in representative traces in Fig. [4B](#page-4-0)-C, on linear (B) and logarithmic (C) scales, respectively, both with $>10^5$ points. The emergence of spin shells here is counterintuitive. Since for $\theta \approx \pi$ no conservation law shields the initial state from rapid heat-death, one would expect the interacting nuclear spin system to quickly relax to a featureless infinite-temperature state [\[22,](#page-38-19)[40\]](#page-38-34). Despite extensive use of π -trains (CPMG experiments [\[41](#page-38-35)[,42\]](#page-38-36)) in various contexts including dynamical decoupling and quantum sensing, to the best of our knowledge, this phenomenon has hitherto not been previously reported.

We attribute the emergence of the long-lived signal to Hamiltonian engineering facilitated by the simultaneous action of the nanoscale electronic field gradient dressed by the π -train Floquet drive. In particular, the NV electron spin, thermally polarized \approx 12.6 % polarized at 9.4 T and 100 K), induces a hyperfine gradient $\eta(\mathbf{r})$ on the nuclear spins. As a consequence, the direction and magnitude of the Rabi field Ω experienced by the nuclei depends on their proximity to the electron (see Fig. [1A](#page-1-0)). When

Fig. 4. **Robust spin textures by Hamiltonian engineering.** (A) *Experiment schematic*. Spins are hyperpolarized for τ +=90s and subject to a spinlocking train with $\theta \approx \pi$. (B) Measured signal S undergoes sharp zero-crossing and associated sign inversion (phase signal is analogous to Fig. [2B](#page-2-0)(ii) and not shown). Colored lines show variation with θ (see colorbar). Each trace has ≈0.5M points. Dark purple trace highlights representative data at θ/π =0.94 for clarity, with sharp zero-crossing at t_{zc} . (C) Analogous signal to bolded purple trace in (B), with small frequency offset (see SI [S5\)](#page-16-0). Signal is plotted on a logarithmic scale and extends for >150s. Dramatic signal zero-crossing is evident. (D) *Schematic representation* of formed spin texture for key points of the bolded trace in (B) (marked I-IV). Signal zero-crossing arises due to thermalization to an effective Hamiltonian H_{eff} bearing spatial texture arising from the NV-imposed gradient (Fig. [1C](#page-1-0)). Dashed black line indicates the domain boundary at r_c . Spin texture remains robust against spin diffusion with t (see Fig. [5A](#page-5-0)). (E) *Movement of zero-crossing with* θ . 2D color plot showing logarithmic scale visualization of data in (B) plotted with respect to θ (horizontal slices). Zero crossing appears as an abrupt decrease in signal (colored blue). $\theta = \pi$ slice is marked and corresponds to a rapid signal decay. t_{zc} occurs at later times for smaller θ . Point III corresponding to zero-crossing in (B) is marked. (F) *Numerical simulations* performed with LITE for the simplified short-range model show good qualitative agreement with the experimental data (see Fig. [5](#page-5-0) and SI [S8\)](#page-25-0).

 $\theta \neq \pi$ (cf. **State Engineering**, Fig. [2-](#page-2-0)Fig. [3\)](#page-3-1), this merely alters the prethermalization axis $\hat{\mathbf{x}} \rightarrow \hat{\mathbf{x}}'$ (*r*) (see SI [S7 B 1\)](#page-22-0). On the other hand, when $\theta = \pi$ exactly and we ignore the NV-induced gradient field, the absence of \hat{x} -polarization conservation leads to a rapid, yet trivial, decay of the spins within T_2^* [\[34\]](#page-38-27).

However, in the presence of the NV gradient field $\eta(\mathbf{r})$, for $\theta = \pi + \epsilon$ (with $\epsilon \ll \pi$), spin dynamics is governed by the effective Floquet Hamiltonian (see SI [S7 B 2\)](#page-23-0)

$$
\mathcal{H}_{\text{eff}} = \mathcal{H}_{\text{dd}} + \sum_{\mathbf{r}} \phi_{\mathbf{r}} I_{\mathbf{r}}^{x}, \qquad (3)
$$

where $\phi_{\bf r} = \eta({\bf r}) + (\theta - \pi)/\tau$ denotes the effective spatiallyvarying on-site potential (Fig. [1C](#page-1-0)). We operate in the regime of a weak electronic field gradient $(\phi_{\bf r}$ <1 kHz), far from the frozen-core limit — a significant departure from previous experiments [\[16\]](#page-38-13). Notably, the spatial inhomogeneity induced by $\phi_{\bf r}$ separates into two regimes by a critical radius r_c , where $\phi_{\bf r}$ flips sign: $\phi_r \le 0$ for $r = ||\mathbf{r}|| \ge r_c$. The exact position of r_c is determined by the ¹³C slice for which $\phi_r=0$ (Fig. [1C](#page-1-0)). Note that here we ignore the angular ϑ dependence for simplicity and return to it in Fig. [5C](#page-5-0)-D.

Crucially, the sign change of ϕ_r on either side of r_c means that H_{eff} internally encodes spatial structure, and r_c serves as the domain boundary. Then, irrespective of the initial state, applying the Eigenstate Thermalization Hypothesis [\[1–](#page-38-0)[3\]](#page-38-1), one predicts that the spins thermalize to the quasi-equilibrium state described by the density matrix $\rho_{eq} \propto \exp(-\beta \mathcal{H}_{eff}) = 1 - \beta \mathcal{H}_{eff} + O(\beta^2)$, with an inverse temperature β set by the energy density of the initial state. The local expectation value of \hat{x} -polarization in the thermal state, $I_r^x = Tr(I_r^x \rho) \approx -\beta \phi_r / 2 + O(\beta^2)$, then attains opposite signs on either side of r_c — imprinting a spatial structure of a quasi-equilibrium shell stabilized within the prethermal plateau (Fig. [1B](#page-1-0)).

The highlighted traces in Fig. [4B](#page-4-0)-C track such shell formation. The initial polarization profile ρ_i is far from the prethermal equilibrium ρ_{eq} : it possesses a finite amount of energy with respect to H_{eff} in the thermodynamic limit, which is initially localized within the polarized region. Over time this energy diffuses through the system due to energy (quasi-)conservation (see SI [S8 B 3\)](#page-27-0). Consequently, spins in the region $r > r_c$ begin to sequentially flip, driving the system, towards a quasi-equilibrium, $\rho_i \rightarrow \rho_{eq}$ (see schematic depiction in Fig. [4D](#page-4-0)). As the negative polarization in the outer region $(r>r_c)$ surpasses the positive polarization in the inner region $(r < r_c)$ in magnitude, the total polarization along the **x**ˆ direction undergoes a sign inversion, resulting in a zero-crossing. Importantly, since the spin texture emerges through thermalization and total polarization is not conserved, the domain boundary r_c remains stable (on prethermal

Fig. 5. **Simulations of spin texture formation and evolution** using the effective model Hamiltonians for (A) **State Engineering** and (B-D) **Hamiltonian Engineering**. Panels (A,B) are obtained from *1D short-range simulations* for infinitely extended systems including effects of dissipation using the LITE algorithm (see SI [S8 A\)](#page-26-0). System extends in both directions, but only positive values are shown. Horizontal axis displays interrogation time in [−]¹ units, vertical axis displays distance from NV in arbitrary units (a.u.). (A) *Spin texture via State Engineering.* We imprint the spin texture in the initial state using 11 positively polarized spins close to the NV center at $r = 0$ followed by 18 negatively polarized spins. (i) Colors display polarization $I_r^x(t)$ (colorbar) at different sites at time t (vertical slices). Panel displays spreading dynamics with t. Formed shells melt under diffusion (see SI $S8 \text{C}$). (ii) Integrated polarization over the spin ensemble, corresponding to signal S measured in Fig. [2.](#page-2-0) Simulations reveal formation of a sharp zero-crossing in either case (zc marked), occurring at the instance of zero total net polarization. (B) *Spin texture via Hamiltonian engineering*. The initial state at *t*=0 contains 11 positively polarized spins within a background of spins in a fully mixed state. (i) Polarization $I_r^x(t)$ (colorbar) showing that spin texture forms via thermalization. Late time behavior (dashed line) follows energy diffusion $\propto \sqrt{t}$. Shell critical radius r_c (horizontal dashed line) is stabilized. (ii) Integrated ensemble polarization showing formation of zero-crossing analogous to Fig. [4.](#page-4-0) (C, D) *Formed shells in three-dimensions* via Hamiltonian Engineering, obtained from late-time dynamics of classical three-dimensional long-range simulations (see SI Fig [S28](#page-37-0) for full time traces). For the classical simulation dissipation is not considered and spins within the frozen core (white region in D) are not simulated.

timescales). This stands in contrast to **State Engineering** (see Fig. [5\)](#page-5-0). Furthermore, the signal drop observed here is orders of magnitude larger compared to **State Engineering**, since we do not operate in a regime of nearly zero total net polarization, indicating a larger spin texture gradient (Methods).

Experiments in Fig. [4B](#page-4-0)-C, therefore, uniquely enable real-time observation of spin flipping dynamics during the prethermalization process. This capability, combined with the large accessible values of $Jt > 10^6$, allows us to investigate thermalizing spin dynamics with exceptional resolution over extended time periods, surpassing the capabilities of previous experiments by many orders of magnitude [\[36](#page-38-29)[–38\]](#page-38-30).

Colored traces in Fig. [4B](#page-4-0) show similar experiments for different values of θ in the vicinity of $\theta = \pi$ (see colorbar). The zero-crossing position is observed to change with θ . A movie of this data is accessible in [\[43\]](#page-38-37). Fig. [4E](#page-4-0) recasts this movie for 120 different values of θ in a 2D plot on a logarithmic scale in intensity, where the darker blue colors highlight the zero crossing. This visualization clearly elucidates the movement of t_{zc} with θ . Additionally, a distinct slice in the plot displays rapid signal decay (indicated by the dashed line). This is attributed to bulk 13 C nuclei, which are far removed from the NV influence, corresponding for which $\theta = \pi$. The qualitative behaviour can be reproduced in numerical simulations (see Methods and Refs. [\[44,](#page-38-38)[45\]](#page-38-39)). While the exact shape of the zero-crossing arc depends on the details of the model (such as ϕ_r), the simulations capture the diverging behaviour of t_{zc} found for $\theta \to \pi^-$.

Based on data in Fig. [4,](#page-4-0) we estimate (see Methods) that the

domain spans $r_c \approx 2.7$ nm · $\sqrt[3]{|3 \cos^2 \theta - 1|}$ encompassing ≈ 150 spins for the representative line in Fig. [4B](#page-4-0) (θ =0.94 π) [\[46\]](#page-38-40). We are able to exert control over the r_c domain boundary by changing the Floquet engineered Hamiltonian [\(3\)](#page-4-1). By adjusting the kick-angle θ we can modify the effective on-site potential ϕ_r , and hence r_c , allowing us to tune the shell size between tens (\approx 50) up to mesoscopic numbers (\geq 300) of spins (see SI Sec. [S7 D\)](#page-24-0) [\[47\]](#page-38-41). We observe that the movement of t_{zc} matches the theoretical pre-diction (Fig. [4E](#page-4-0),F). Varying Rabi frequency Ω or the frequency offset can modify the Hamiltonian and allow furthur control over r_c (SI Sec. S5). Furthermore, thermalization to shell-like texture is found to be robust to lattice orientation (SI Sec[.S5 B\)](#page-17-0) or initial states employed (SI Sec[.S5 A\)](#page-17-1).

IV. NUMERICAL RESULTS

Quantum simulations here use Local-Information Time Evolution (LITE) [\[44,](#page-38-38) [45\]](#page-38-39), a recently developed algorithm suited to investigate diffusive and dissipative quantum dynamics. Numerical tractability constrains us to work with a simplified onedimensional toy-model Hamiltonian, but which captures all relevant features of H_{eff} (Methods).

Fig. [5A](#page-5-0)(i) shows simulations corresponding to **State Engineering** experiments. Time is represented on the horizontal axis in units of J^{-1} , the vertical axis represents the distance from the NV (both axes are on a logarithmic scale), and the colorbar shows the local $\hat{\mathbf{x}}$ -polarization \tilde{I}_r^x . Considering an initial shell-like texture produced by spin injection, we observe that the subsequent dynamics are characterized by melting domain walls, causing the magnetization gradient to diminish over time. Fig. [5A](#page-5-0)(ii) shows the total net polarization $S = \sum_r I_r^x$ — analogous to that measured in experiment. We observe a zero-crossing similar to Fig. [2B](#page-2-0). Notably, in **State Engineering**, we rely on dissipation to enable the observation of the sign-inversion of the total polarization: in the absence of dissipation, total \hat{x} polarization is (quasi)-conserved and thus will appear constant on prethermal timescales.

In contrast, Fig. [5B](#page-5-0) considers **Hamiltonian Engineering**, and polarization initially confined in the vicinity of the NV. Over time, by virtue of energy diffusion, the spins prethermalize to a polarization gradient under the NV-induced potential. Peripheral spins become endowed with negative polarization (blue region), and ultimately, over time, the total polarization inverts as the majority of spins feature negative polarization. Importantly, the domain r_c (dashed horizontal line) separating the local positive and negative polarization regions is solely set by the on-site potential ϕ_r present in H_{eff} and is, therefore, stationary. As the spins thermalize, the (non-conserved) polarization adapts to the *stable* gradient profile imposed by Heff. Irrespective of the initial state, the diffusion-propelled dynamics therefore induce a polarization gradient with a time-invariant domain boundary.

Considering the net polarization (Fig. $5B(ii)$ $5B(ii)$), we observe a steep zero-crossing in qualitative agreement with experiments. We note that the zero-crossing t_{zc} arises even in the absence of dissipation (see SI $S8B$), as observed in the long-time slices in Fig. [5B](#page-5-0)(i). Dissipation only serves to extinguish polarization at distances close to the NV (i.e., accelerating the inevitable diffusion-induced polarization inversion).

To demonstrate that these results hold beyond one-dimensional short-range models, we additionally perform classical simulations based on a three-dimensional long-range model comprising $\approx 10^3$ dipolar-interacting spins on a diamond lattice (Methods). In contrast to the one-dimensional quantum simulations, here the system is finite and free of dissipation so that equilibrium is reached in finite time. Notably, here, the system thermalizes to a three-dimensional spin texture which exhibits the analytically predicted ϑ -dependence of the NV gradient field with r_c spanning several nanometers (cf. Sec. [III\)](#page-3-0).

V. DISCUSSION & OUTLOOK

Our experiments introduce several novel features. The creation, stabilization, and observation of spin texture are achieved through *global* spin control and readout. Despite this, a good degree of local nuclear discrimination is shown to be attainable by utilizing an electron as a *controllable* spin injector, gradient source, and dissipator. Notably, unlike other experiments [\[16\]](#page-38-13), our approach is not confined to the constraints presented by diffusion barrier limits, enabling examination of a mesoscopically large number of nuclear spins around each electron. The injected hyperpolarization exceeds the Boltzmann polarization levels by orders of magnitude compared to previous studies [\[39\]](#page-38-32).

Our method of continuous interrogation in the rotating frame, as opposed to point-by-point probes in the lab-frame [\[39\]](#page-38-32), offer a distinct methodological advantage. It facilitates a rapidly sampled $(J\tau<0.07)$ visualization of polarization dynamics while reaching into the very-long-time regime $(Jt > 1.2 \times 10^6)$. The latter is orders of magnitude beyond previous experiments [\[36](#page-38-29)[–38\]](#page-38-30), permitting direct observation of emergent stabilization. The dynamics observed complement recent experiments with cold atoms [\[5,](#page-38-42)[48–](#page-38-43)[51\]](#page-39-0), but occur in a distinct and novel context: at the nanoscale, in the solid-state, and in the limit of strongly interacting dipolar-coupled spins (for which $JT_2^* \approx 1$).

Our dynamical stabilization protocol operates distinctly out of equilibrium. The dynamics is governed by an emergent quasiconservation of energy and explicitly breaks polarization conservation, allowing us to inhibit diffusion in the spin polarization channel. In conjunction with the electronic hyperfine field, this protocol stabilizes localized, shell-like spin textures at a finite energy density, even in the absence of local control. Note that no obvious static protocol could yield similar outcomes in our system. The underlying physics of this dynamical stabilization deviates from traditional state engineering approaches, is versatile, and can encompass a variety of models (short- or long-range, clean or weakly-disordered interacting systems, quantum or classical models), across different dimensions.

The elucidated **Hamiltonian Engineering** protocol, therefore, highlights the untapped capabilities of nonequilibrium control techniques in manipulating quantum matter. For example, our approach can be utilized within quantum simulators to induce a magnetization domain wall in a close to infinite-temperature state – the starting point to investigate sub/superdiffusive spin dynamics [\[5](#page-38-42)[,52](#page-39-1)[,53\]](#page-39-2). Depending on the structure of the effective Hamiltonian and the initial state, one can also stabilize and investigate spin textures at negative-temperature [\[54\]](#page-39-3). Our work, therefore, presents a first instance of a far-reaching idea that demonstrates the applicability of concepts from the emerging field of nonequilibrium quantum dynamics, to engineer stable many-body states with tailored attributes [\[55\]](#page-39-4).

Lastly, the manipulation and control of the orientation of spin polarization at sub-nanometer length scales itself, opens up several promising future directions. The use of ubiquitously occurring nuclear spins, as elucidated in this work, broadens the application of spin texturing to diverse systems, moving beyond previously considered magnetic materials [\[12,](#page-38-9)[14,](#page-38-11)[15,](#page-38-12)[56–](#page-39-5) [58\]](#page-39-6). This suggests applications in quantum memories [\[12,](#page-38-9)[13\]](#page-38-10), spintronics [\[14,](#page-38-11) [15\]](#page-38-12), and spatiotemporal quantum sensing harnessing hyperpolarized nuclei as sensors [\[59\]](#page-39-7). Controllable spin textures may also be applied to non-invasive nanoscale chemical imaging in materials science and biology. We envision employing targeted electron spin labels to map the radial spin densities of different nuclei (e.g., 1 H and 13 C) within molecules.

VI. ACKNOWLEDGEMENTS

We thank J. H. Bardarson, T. Klein Kvorning, R. Moessner, C. Ramanathan, J. Reimer, D. Suter for insightful discussions, and J. Mercade (Tabor Electronics) for technical assistance. This work was supported by ONR (N00014-20-1-2806), AFOSR YIP (FA9550-23-1-0106), AFOSR DURIP (FA9550-22-1-0156), a Google Faculty Research Award and the CIFAR Azrieli Foundation (GS23-013). CF and CA acknowledge funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (Grant Agreement No. 101001902). The computations with the LITE algorithm were enabled by resources provided by the National Academic Infrastructure for Supercomputing in Sweden (NAISS) and the Swedish National Infrastructure for Computing (SNIC) at Tetralith partially funded by the Swedish Research Council through grant agreements no. 2022-06725 and no. 2018-05973.

Classical simulations were performed on the MPI PKS HPC cluster.

VII. AUTHOR CONTRIBUTIONS

KH, CF, ND, PMS and DM contributed equally to this work. Order in which these authors are listed was decided by dice roll.

DM, KH, ND, MM and ED built the experimental apparatus. ND, DM, KH, SB and AA collected data and performed data analysis. KH, ND and DM conceived of experimental design for Hamiltonian Engineering, and QRF, WB, XL and AA conceived of experimental design for State Engineering. UB, AP, ND, KH and AN made data visualizations.

PMS and CF developed the Floquet analysis. PMS did the numerically exact quantum simulations and the classical simulations. CF did the approximate quantum simulations using LITE and the diffusion analysis. CA performed the open quantum systems analysis and contributed to LITE simulations. MB supervised the theory work. PMS, CF, CA, and MB helped interpreting and analyzing the numerical and experimental data. AA, MB, PMS, CF, CA, ND and KH wrote the paper.

VIII. METHODS

EXPERIMENT

A. Sample

Experiments here employ a single-crystal diamond sample $(3x3x0.3mm)$ from Element6. It contains 13 C spins at natural abundance (1.1 %), and ≈1 ppm NV⁻ concentration, corresponding to inter-NV spacing of ∼25 nm, and each NV center has 10^{413} C surrounding it. The sample also hosts ≥ 20 ppm of substitutional nitrogen impurities (P1 centers). For experiments in Fig. [2-](#page-2-0)Fig. [4,](#page-4-0) the sample is oriented such that its [100] face is approximately parallel to B_0 . However, as elucidated in SI, Sec. [S5 B,](#page-17-0) these results are qualitatively independent of the sample orientation.

B. Experimental Apparatus

State Engineering experiments (Fig. [2-](#page-2-0)Fig. [3\)](#page-3-1), carried out at room temperature, employ an apparatus described before in [\[60\]](#page-39-8). For Hamiltonian Engineering (Fig. [4\)](#page-4-0), on the other hand, we introduce a novel instrument (Fig. 6) for ¹³C hyperpolarization and interrogation at cryogenic temperatures. Low temperatures allow access to higher Boltzmann electronic polarization, consequently stronger electronic gradient fields, and slower electronic relaxation rates. The instrument supplies for the first time (to our knowledge) a method for *"cryogenic field cycling"* for dynamic nuclear polarization (DNP), allowing simultaneous operation at variable fields (1mT-9.4T), and controllable cryogenic temperatures down to 4K (although we restrict ourselves to 77K in this work).

The device utilizes an Oxford SpectrostatNMR cryostat under continuous flow cryogenic cooling, which is mechanically moved ("shuttled") from lower (few mT) fields into a $B_0=9.4$ T NMR magnet (Oxford). The low-field position situated 640mm above the magnet center $(\mathbf{B}_{pol}=36 \text{ mT})$ is employed for hyperpolarization; the cryostat is then shuttled to high-field (9.4 T) where the 13 C nuclei are interrogated. Shuttling occurs via a Motor/Actuato

NMR Probe

Shuttling

Track

Cryostat

Fig. 6. **Novel instrumentation for cyrogenic DNP.** (A) *Device construction.* CAD model showing instrument and highlighting main components. It consists of a 9.4 T superconducting magnet, surrounded by an aluminum frame to which a 4K cryostat is mounted on a belt-driven actuator, bearing a high-torque motor. Laser illuminates sample from the bottom. (B) Photograph showing key features of the instrument. Cryostat is shown at low-field position \mathbf{B}_{pol} ; actuator truck and mounts are visible.

belt-driven actuator (Parker) powered by a motor (ACS) fitted with a high-torque gearbox for enhanced load-bearing capacity for the heavy (25lb) cryostat. The actuator carries a movable stage to which two custom-designed clamps secure the cryostat. A 1.6 m flexible transfer line allows for continuous cooling during shuttling and operation over >1 week. Shuttling occurs at 7 mm/s and takes ≈90 s. Long ¹³C T_1 lifetimes (>1hr) at fields exceeding 0.1T, mean that there is minimal loss of polarization during shuttling. We note that room temperature experiments $(Fig. 2-Fig. 3)$ $(Fig. 2-Fig. 3)$ $(Fig. 2-Fig. 3)$ $(Fig. 2-Fig. 3)$, in contrast, involve shuttling in <1s.

The diamond sample is secured at the bottom portion of the cryostat in a custom-built NMR/DNP probe (Fig. [7\)](#page-8-0). The probe is top-mounted in the cryostat and includes two coils: a loop through which microwaves (MWs) are applied for DNP, and a saddle coil for NMR detection. A novel arrangement employing O-rings at the probe top allows the NMR coil to be frequencytuned and impedance matched without breaking vacuum.

For optical DNP at \mathbf{B}_{pol} , an optical window at the cryostat bottom permits illumination by a laser $(\lambda=532$ nm, Coherent) directed into the bore using a 45◦ mirror. A pair of piezo-driven Zaber mirrors ensure optimal alignment into the cryostat center, aided by a camera mounted with a 637nm long-pass filter at the top of the cryostat. A TTL-triggered mechanical shutter controls illumination timing to within 1μ s.

Hyperpolarization employs MW chirps applied across the NV EPR spectrum. MWs are generated by a Tabor Proteus arbitrary waveform transceiver (AWT) and gated by a Mini-Circuits ZASWA-2-50DR+ switch. MWs are amplified in two stages by ZHL 2W-63-S+ and ZHL-100W-63+ amplifiers. A Varian VNMRS console generates the RF pulses at the ¹³C Larmor frequency (\approx 100MHz), while the NMR signal is detected in windows between the pulses, filtered, and amplified by a Varian preamplifier, and digitized by the AWT. We apply >0.5M pulses, yielding a continuously interrogated NMR signal for up to $t=180s$ that is non-destructive since spins are only weakly

Fig. 7. **Probe for** ¹³**C hyperpolarization and readout** (A) CAD model showing the schematic of the NMR/DNP probe. It fits snugly within the cryostat, providing additional RF shielding. >3ft long tuning rods extend through the top of the probe and allow for RF cavity tuning and impedance matching, even under vacuum and cryogenic conditions. (B) *Photograph* of constructed probe. A close-up of coil arrangement is shown, highlighting the RF saddle coil and centrally placed microwave loop employed for hyperpolarization. Aperture at probe base enables optical access to the sample.

coupled to the RF coil. Timing of all events — lasers, MW application, mechanical shuttling, triggering NMR detection, and signal digitization — is synchronized by the Swabian pattern generator, controlled by MATLAB.

C. Hyperpolarization Methodology

Hyperpolarization follows [\[33\]](#page-38-26). Application of a continuouswave 532nm green laser (5W) induces polarization in the NV electrons to the m_s =0 state at **B**_{pol}. This is transferred to ¹³C nuclei through successive traversals of rotating frame Landau-Zener level anti-crossings. Practically, this is accomplished by utilizing MW chirps generated by a Tabor Proteus AWT, sweeping across the NV center EPR spectral bandwidth (25 MHz) at a rate of 200 Hz.

D. Data Acquisition and Processing

Induced 13 C Larmor precession signal into the RF saddle coil is captured by a Tabor Proteus AWT, and digitized every 1ns in t_{acq} windows between the pulses. It is decimated to preserve memory and improve acquisition and processing speed (here 64 fold). A Fast Fourier Transform (FFT) is applied to extract signal amplitude S and phase φ in each t_{acq} window. Phase signals in each window are linearly offset by the phase accrued during t_p pulse periods, a phase unwrapping algorithm is used to unfold this trivial phase development, yielding phase φ_R of the spins in the rotating frame. (S, φ_R) forms the basis for the experimental

Fig. 8. **Estimation of flip angle** θ . (A) Schematic of spin-locking Rabi experiment, consisting of a train of $\pi/2$ pulses, where the angle of the first pulse θ_{init} , is varied. (B) Typical signals in case of $\theta_{\text{init}} = \pi/2$ and $\theta_{\text{init}} = \pi$, with total measurement time of $t = 70$ s, corresponding to $> 0.5M$ pulses. (C) Variation of integrated signal S_{int} with length of the first pulse. Solid line represents sinusoidal fit. Slight off-resonance in the pulses leads to a finite signal even at θ_{init} =0.

Fig. 9. **Comparison of State and Hamiltonian Engineering signals**. Comparison of signal S for State Engineering data in main text Fig. [2](#page-2-0) (taken at room temperature) and Hamiltonian Engineering data from main text Fig. [4](#page-4-0) (taken at 100 K) for comparable zero crossing times $t_{zc} \approx 31$ s. Data is shown on a logarithmic scale for clarity. Measured signal is over an order of magnitude greater in the Hamiltonian Engineering method.

data in this work.

E. Estimation of Kick Angle

To estimate kick angle θ , important in Fig. [4,](#page-4-0) we conduct ¹³C Rabi experiments and fit the obtained nutation to a sinusoidal curve. A spin-locking train of \sim $\pi/2$ pulses and continuous readout (see Fig. $8B$) for $t=70$ s is employed to enhance measurement SNR. The pulse length of the initial pulse θ_{init} is varied, and the integrated signal is measured, as shown in Fig. [8C](#page-8-1). High SNR yields a high-precision estimate of θ , with an error of within 1 %.

F. Comparison of Signals in State and Hamiltonian Engineering

For clarity, we contrast in Fig. [9](#page-8-2) the measured signal S amplitude for experiments of State engineering (Fig. [2-](#page-2-0)Fig. [3\)](#page-3-1) and Hamiltonian engineering (Fig. [4\)](#page-4-0). Spin texture created by State Engineering starts from a regime of *low* net polarization (Fig. [2A](#page-2-0)), and sign inversion (characterized by the t_{z} zerocrossing), occurs due to electronic dissipation. On the other hand, Hamiltonian engineering starts with large net polarization, and sign inversion occurs on account of thermalization into the imposed potential. As a result, the measured signal, and the magnitude of the zero-crossing drop in the Hamiltonian engineering method is over one order of magnitude larger than State engineering (see Fig. [9\)](#page-8-2). The strong signal and robustness of the domain boundaries highlight the advantages of Hamiltonian engineering for stable spin texture generation and readout.

G. Additional Results on Hamiltonian Engineering

To further validate the physical picture in Fig. [4](#page-4-0) and Fig. [5B](#page-5-0) for Hamiltonian engineering, additional studies are conducted to probe the thermalization process. A summary of these findings is provided here, with further details available in the SI. First, to confirm that the zero-crossing observed in Fig. [4B](#page-4-0) does not arise from spins tipping towards the **z**ˆ-axis where they are unobservable, we interrupted the Floquet drive with a $\pi/2$ pulse at $t=t_{zc}$. The data (SI Sec. [S4\)](#page-15-0) reveal no generation of \hat{z} during , supporting the thermalization model above. Next, we investigated the relative roles of diffusion and dissipation leading up to t_{zc} by studying profiles similar to Fig. [4B](#page-4-0) with varying temperatures (Sec. $S_5 C$). Temperature serves as a control parameter for relaxation, as it strongly lengthens $(\gtrsim 50\text{-}$ fold) the electronic T_{1e} while only linearly changing the strength of the electronic gradient. Decreasing the temperature results in a rightward shift of t_{zc} due to the slower rate of electron dissipation, consistent with theoretical expectations (Fig. [5B](#page-5-0)).

THEORY

H. Effective Hamiltonians for State and Hamiltonian Engineering protocols

As explained in the main text, the experimental system is subject to a Floquet drive which consists of a periodic train of **x**ˆ-pulses. When the period of switching is small compared to the energy scales of the physical system, this driving induces prethermalization wherein the dynamics is governed by an effective Hamiltonian [\[21\]](#page-38-18), before the system eventually heats up to a featureless infinite-temperature state.

In the SI (Sec. [S7\)](#page-20-0), we provide a detailed derivation of the approximate effective Hamiltonians H_{SL} , Eq. [\(2\)](#page-1-1), and H_{eff} , Eq. [\(3\)](#page-4-1), that govern the dynamics of the nuclear spin system for the State and Hamiltonian Engineering approaches, respectively. In particular, using exact simulations on system sizes up to $N=16$ quantum spins, we obtain an excellent agreement between the dynamics generated by the effective Hamiltonian and the exact Floquet system in all temporal regimes of interest (see SI, Sec. [S7\)](#page-20-0). Therefore, for the theoretical analysis in the main text, we work with static effective Hamiltonians. We emphasize that their applicability is limited to the duration of the prethermal plateau.

I. Dissipation induced by the NV center

In the strong coupling limit between the NV center and ^{13}C spins, the dissipation induced by the NV-center can be rigorously derived from the Hamiltonian of the full system in three dimensions (see Sec. $S6B$). Unlike previous works [\[61\]](#page-39-9), we integrate out the phonon bath and the NV electron obtaining a Markovian master equation for the ${}^{13}C$ spins only. Such a Markovian master equation involves on-site Lindblad jump operators with coupling constants decaying as $\sim 1/r^6$ as a function of the distance r from the NV center (which is effectively short-ranged). Thus, as a simplification, in our approximate one-dimensional quantum simulations, we approximately solve the Lindblad equation with local jump operators L acting only on the site with index $r = 0$ (representing the location of the NV) with isotropic coupling constants,

$$
L_{+} = \frac{1}{2} \left(I_0^x + iI_0^y \right), \quad L_{-} = \frac{1}{2} \left(I_0^x - iI_0^y \right), \quad L_{z} = I_0^z. \tag{4}
$$

Such operators generate both dephasing and dissipation in the system. Both effects are produced by the jump operators derived in Sec. [S6 B](#page-18-0) for the Hamiltonian of the full system in three dimensions.

J. Numerical simulations

1. Quantum simulations

We use the novel algorithm LITE (local-information time evo-lution, see Refs. [\[44,](#page-38-38)[45\]](#page-38-39)) to simulate the dynamics of the 13 Cspins with respect to the effective Hamiltonians subject to dissipation. LITE is designed to investigate the out-of-equilibrium dynamics of quantum systems, including open systems governed by the Lindblad equation. Its adaptive system size allows us to effectively simulate infinite systems. Motivated by the experimental setup, the system is initialized in a spatially inhomogeneous partially polarized state, where a relatively small number of spins in proximity to the NV center $(r=0)$ carry a finite partial \hat{x} -polarization, while spins located far from $r=0$ are fully mixed $\rho_{r\gg a}$ =1₂/2.

To use the LITE toolbox effectively, we investigate numerically tractable one-dimensional short-range toy models akin to the effective (three-dimensional) Hamiltonians of the coupled 13 C system

$$
\mathcal{H}_{\pi/2} = -\frac{1}{2} \sum_{r} J_r (3I_r^x I_{r+a}^x - \mathbf{I}_r \cdot \mathbf{I}_{r+a}),
$$

$$
\mathcal{H}_{\pi} = \sum_{r} J_r (3I_r^z I_{r+a}^z - \mathbf{I}_r \cdot \mathbf{I}_{r+a}) + \phi_r I_r^x.
$$
 (5)

The subscripts indicate the corresponding partner Hamiltonian in the actual system: $\pi/2$ refers to the system kicked with $\theta = \pi/2$ resulting in the effective Hamiltonian $H_{\rm SL}$; likewise, subscript π refers to a kick angle $\theta \approx \pi$ with the associated Hamiltonian \mathcal{H}_{eff} . In the simulations, $J_r = J_0 + W$ is taken weakly disordered with W drawn uniformly at random from the interval $[-0.3|J_0|, 0.3|J_0|]$ and with lattice constant a. The on-site potential follows $\phi_r \sim \frac{1}{r^3}$ – $\delta\theta$ with $r = 0$ corresponding to the location of the NV center, and $\delta\theta$ is the deviation in the kick angle from π (see SI [S7 B 2\)](#page-23-0). For the simulations in Fig. [5](#page-5-0) we use $a = 0.2/\sqrt[3]{\pi}$, $\delta\theta = 0.05\pi$, $J_0 = -0.025$, and $\gamma=0.1|J_0|$

While these toy models may appear simplistic compared to the actual experimental system, as they lack the complexity of higher dimensions and long-range spin-spin couplings, they capture the

Fig. 10. **Zero crossing radius for State Engineering.** Zoom-in to Jt < 200 region in Fig. [5A](#page-5-0)(i) with adjusted color map scale to reveal polarization dynamics close to NV $(r = 0)$. The dynamics of positive polarization close to NV are dominated by dissipation such that it decays to zero before the crossing radius can move outwards due to diffusion.

essential physics of diffusion (and dissipation), since they obey the same conservation laws compared to their three-dimensional counterparts. Therefore, the conclusions drawn from our numerical results can be qualitatively extended to the experimental system.

2. Classical simulations

In addition, we also performed classical simulations analyzing the dynamics of the system with hundreds of dipolar-interacting spins of the full three-dimensional long-range interacting model. Spins are placed randomly on the vertices of a 3D diamond lattice of a finite extent, with lattice constant $a=0.356$ nm, and the classical evolution, generated under the effective Hamiltonian H_{eff} [\(3\)](#page-4-1), is studied. In the classical limit, the evolution of the spins I_k is described by (see SI, Sec. [S10 A\)](#page-36-0)

$$
\frac{\mathrm{d}}{\mathrm{d}t} \boldsymbol{I}_k(t) = \boldsymbol{I}_k(t) \times \boldsymbol{\nabla}_{\boldsymbol{I}_k} \mathcal{H}_{\mathrm{eff}}(\boldsymbol{I}_k(t)). \tag{6}
$$

In particular, for the classical simulation we are only considering closed system dynamics, i.e. we do not include dissipation as is done in the LITE simulations. However, as we also comment on later dissipation is not an essential ingredient for Hamiltonian Engineering.

As in the experiment, we average the simulation data over many (here 100) different lattice configurations. For each lattice configuration, we consider an ensemble of 150 partially polarized initial states drawn from a spatially inhomogeneously polarized distribution, where all spins within a radius $r < 7$ nm are polarized and all others unpolarized, without correlations between the spins. We then evolve this ensemble using the classical Hamilton equations (Eq. [\(6\)](#page-10-0)), and compute the ensemble-averaged polarization, see Sec. [S10.](#page-36-1)

K. Details on the Theoretical Results for State Engineering

1. Zero crossing radius for State Engineering

In Fig. [5A](#page-5-0)(i) the polarization dynamics close to the NV center seem to show an abrupt sign inversion from positive to negative polarization. However, this is only an artefact originating from the logarithmic time scale. In Fig. [10](#page-10-1) we show the region close to $r=0$ and around the potential sign inversion on a linear scale. Here, it becomes clear that the strong dissipation close to the NV leads to a quick decay of positive polarization. Therefore, the positive polarization cannot diffuse outwards. In fact, the negative polarization diffuses symmetrically in both directions filling the polarization hole left by the decayed positive polarization. Thus, the positive polarization does not abruptly invert; rather it is absorbed by the NV and the negative polarization can freely diffuse into what initially was a positively polarized regime. In the absence of dissipation, both positive and negative polarization would diffuse outwards leading to an increase in crossing radius (see SI Fig. [S27\)](#page-35-0).

2. Waiting time analysis

Typically, the dissipation strength is indirectly controlled by tuning the temperature of the sample. Here, the peculiar form of the dissipation obtained in the singular coupling limit (see SI, Sec. [S6 B\)](#page-18-0), where jump operators are only the spin operators along the **z**ˆ-axis, opens up another possibility. While the strength of the dissipation itself remains immutable, the effect of the Lindblad jump operators on the system strongly depends on the direction of polarization: spins polarized along \hat{z} experience only dephasing, whereas spins polarized in any other direction undergo both dephasing and dissipation. Experimentally, this is reflected in the extremely long T_1 lifetimes of \hat{z} -polarized states; during this period, the system still evolves under diffusion and any initial domain wall starts to melt over time (cf. SI, Fig. [S25\)](#page-33-0). Since dissipation does not affect the spins uniformly, different signals are expected to emerge depending on the waiting time wait after which the system is finally rotated out of the **z**ˆ-axis.

To simulate this effect we initialize the system in domain wall states akin to Fig. [S25](#page-33-0) and evolve it with $\mathcal{H}_{\pi/2}$ up to times t_{wait} after which we switch on dissipation. The results are displayed in Fig. [11.](#page-11-0) As the waiting time increases, the zero-crossing time grows accordingly. This is expected since the system diffuses polarization away from $r = 0$ during t_{wait} and becomes less sensitive to dissipation (here acting only at $r = 0$). A less obvious observation is the decrease of the absolute value of the minimally reached total net polarization $|\min(I_x)|$ as a function of the waiting time (Fig. [11](#page-11-0) (c)). A possible explanation is that with increasing waiting time, diffusion causes domain walls to melt, flattening the polarization profiles; hence, the net amount of polarization left at large distances (i.e., probed at long times) is reduced with increasing waiting time. This is also supported by simulations performed with a uniformly polarized (within a small region around the NV) initial state where no such decay appears as a function of waiting time. In fact, in this scenario, even a slight increase can be observed. Intuitively, this is expected as for increased t_{wait} more polarization is able to diffuse away from the dissipation-active region around the NV. All these results are qualitatively consistent with experimental observations.

Fig. 11. **Waiting time simulations (a)** Time-evolution curves of the total $\hat{\mathbf{x}}$ -polarization for different waiting times. After t_{wait} the dissipation acting on the site with $r = r_{\text{NV}}$ is switched on. For increased waiting time, the corresponding zero-crossing time increases since polarization spreads diffusively during t_{wait} diminishing the effect of dissipation which acts most strongly at the position of the NV ($r_{\text{NV}} = 0$). We use an initial domain wall state with a total of $N_{+}+N_{-}=31$ initially polarized spins where the $N_+ = 13$ (panel (i), blue) and $N_+ = 11$ (panel (ii), orange) spins closest to r_{NV} have $p_r = 0.6$ and the remaining $N = 31 - N_+$ spins have $p_r = -0.2$ (here, $\rho_n \propto 1 + p_r I_r^x$). The dissipation parameters are $\gamma_z = \gamma_+ = \gamma_- = 0.5J$, and the other simulation parameters as in SI Fig. $S15$. (b) The zero-crossing time t_{zc} of the curves in (a) measured from t_{wait} as a function of t_{wait} . **(c)** The absolute value of the minimum attained value of the total **x**ˆ-polarization of the curves in (a) as a function of the waiting time, normalized with respect to $t_{\text{wait}} = 0$. In addition to the domain wall initial states, we also perform a simulation with a uniformly polarized initial state with $N = 0$ $(N_{+} = 31)$ (red curve, (iii)).

The numerical simulations shown in Fig. [3F](#page-3-1)-G have been performed by means of the LITE algorithm. During the waiting time Jt_{wait} , the system evolves under the one-dimensional shortrange version of H_{dd} and is subject to spin diffusion. When the readout protocol is activated, dissipation comes into play (see above). Therefore, we initialize the system with a different number of positively polarized spins and activate dissipation after J_t _{wait}. To plot Fig. [3F](#page-3-1) we measure the zero-crossing point t_{zc} , while for Fig. [3G](#page-3-1) we compute the minimum of the total net polarization.

L. Details on the Theoretical Results for Hamiltonian Engineering

1. Energy vs. Polarization diffusion

In the Hamiltonian Engineering simulations, we find that the √ variance of the energy distribution grows as \sim √t during the latetime dynamics $(Jt>10)$, as expected for diffusive processes (see SI $S8 B 3$). Since the energy operator has a large overlap with the **x**ˆ-polarization at long times, the diffusive scaling becomes visible in the spreading of the polarizing front (dashed tilted line, Fig. [5B](#page-5-0)); however, we stress that in Hamiltonian Engineering, proper diffusion of polarization is absent due to a lack of **x**ˆ- polarization conservation.

2. Effect of Dissipation

Let us emphasize that in contrast to State Engineering, the t_{zc} zero-crossing for Hamiltonian Engineering arises even in the absence of dissipation (see SI $S8B$). As observed in the long-time slices in Fig. [5B](#page-5-0), dissipation only serves to extinguish polarization close to the NV (i.e., accelerating the inevitable diffusion-induced polarization inversion).

3. Critical radius

In the main text, we argued that the polarization zero-crossing radius is given by the zeroes, $\phi(r_c) = 0$, of the effective on-site potential ϕ . To leading order, this on-site potential is determined solely from the microscopic gradient field induced by the NV together with the details of the kick sequence (see SI [S7 B\)](#page-21-0). Thus, assuming that we have full knowledge about the gradient field, we can estimate the crossing radius for the experimental data, see Fig. [4C](#page-4-0)-D.

In particular, we assume that the gradient field induced by the NV electron follows the dipole-dipole form $B =$ $2PK_{\rm exp}(3\cos^2\theta-1)/r^3$ with $K_{\rm exp} = \mu_0\hbar\gamma_n\gamma_e/4\pi$ and electron spin polarization of $P(\approx 10\%)$. Then, using the experimental parameters from Fig. [4,](#page-4-0) i.e., $\Omega \approx 50$ kHz, $t_{\text{acq}} = 51 \,\mu s$ and, e.g., $\vartheta = 0.94 \pi$ (t_p = 95 μ s), we can estimate the crossing radius $r_c \approx 2.7 \text{ nm} \times \sqrt[3]{|3 \cos^2 \theta - 1|}$. For more details see SI, Sec. S7D.

CONTENTS

[S1. Summary](#page-12-0) 1

S1. SUMMARY

Given the length of this Supplementary Information, as an aid to the reader, we present a summary of the main results here. Sec. S₂, summarizes sources of nuclear relaxation, with a focus on dissipation stemming from the central electron. Sec. [S2 A](#page-14-0) discusses the dephasing time (T_2^*) , longitudinal relaxation time (T_1) , and transverse relaxation under spin-lock under Floquet driving (T_2') in our system. Sec. [S2 B](#page-14-2) elucidates indirect experimental signatures of NV-driven transverse relaxation of the ¹³C spins.

Section S₃ describes spin-lock decays for a wide range of flip angles $\theta \in [0, 1.5\pi]$, showing slow featureless decays in all regions away from $\theta \approx \pi$, and sharp zero-crossings in the latter due to the formation of Hamiltonian engineering driven spin textures.

Section [S4](#page-15-0) elucidates complementary experimental studies focused on the Hamiltonian engineering method. In Sec. [S4,](#page-15-0) we describe experiments that confirm that the loss of signal during the zero-crossing is not due to the spin vector being trivially tilted onto the \hat{z} axis. This was demonstrated by inserting a $\pi/2$ pulse perpendicular to those in the train of pulses. If the spin vector were in the \hat{z} axis, this sequence would immediately create observable polarization.

Section $S5$ examines changes in t_{zc} to probe the sensitivity of formed spin texture to experimental parameters. Increasing hyperpolarization time in Fig. [S7](#page-17-5) does not significantly change the location of t_{zc} , showcasing the robustness of Hamiltonian Engineering to different initial states.

Decreasing the temperature in Fig. [S9](#page-18-1) diminishes the effect of electron dissipation to the system, preserving the generated spin texture for longer and moving t_{zc} to later times in the experimental data. In Fig. [S5,](#page-16-1) changing the effective Floquet drive Rabi frequency, by changing the pulse duty cycle while fixing θ , leads to a movement in t_{zc} as anticipated from theory.

Changing sample orientation creates composite behavior at kick angle π qualitatively identical to other Hamiltonian Engi-neering experiments (compare Fig. [S8A](#page-18-2)iii and Biii). The multidip behavior seen in Fig. [S8B](#page-18-2)ii is consistent with domain boundaries forming from NV centers inequivalently aligned with respect to the applied magnetic field. Lastly, changing the pulse transmit offset frequency (TOF) shifts the Rabi curve of the system by a finite phase, yet zero crossing behavior can appear before or after the bulk π value for a given TOF (Fig. [S6\)](#page-16-2).

Section $S6$ details the theory model for dipolar-coupled ${}^{13}C$ nuclear spins and nitrogen-vacancy (NV) center electrons. The system is described as a closed system with a hierarchical energy scale separation, allowing for independent manipulation of the 13 C nuclei and NV electrons. The Hamiltonian captures the couplings between spins and the external magnetic field. Additionally, the open system nature of the experimental setup is discussed in Sec. [S6 B,](#page-18-0) where spins and NV centers couple to a phonon bath, resulting in decoherence and dissipation. An effective Lindblad master equation is derived, considering the singular coupling limit, which describes the dissipative dynamics of the spins only. The dissipative terms in the Lindblad equation account for dephasing and dissipation effects operational in experiments.

In Sec. [S7,](#page-20-0) we investigate in more detail the dynamics of the 13 C spin system coupled to the NV center. By considering the fast dynamics of the NV spin, we replace the NV operators with their expectation values. This leads to an effective on-site potential for the 13 C spins. We analyze the system's evolution under a kick sequence and derive the effective Hamiltonian using Floquet's theorem. We consider two cases: spin locking with a kick angle different from π and near π . In the former case, the effective Hamiltonian conserves the \hat{x} -polarization, while it is not conserved in the latter case, and the strong NV-induced potential leads to a spatially inhomogeneous effective Hamiltonian. Exact numerical simulations confirm the validity of the derived effective Hamiltonians. In Sec. [S7 C,](#page-23-1) we discuss the dynamics of the 13 C system within the Eigenstate Thermalization Hypothesis (ETH). The system is expected to (ultimately) thermalize to an infinite temperature state due to the absence of energy conservation. However, at high driving frequencies, a pre-thermal plateau emerges before full thermalization. We find that in the $\theta = \pi$ case, the local polarization follows the local on-site potentials induced by the NV center, which can lead to a sign-inversion of the local polarization, and hence also of the integrated polarization. In Sec. $S7D$, we estimate the r_c domain boundary where the local polarization changes sign. Finally, in Sec. [S7 E,](#page-25-1) we present two simplified, effective Hamiltonians for $\theta \neq \pi$ and $\theta \approx \pi$ that aid in a qualitative understanding of the dynamics.

Section [S8](#page-25-0) first introduces the approximate time-evolution algorithm used to perform the quantum dynamics of the simplified one-dimensional toy models used in the rest of this Section. In particular, Sec. [S8 A](#page-26-0) summarizes the main features of the local-information time-evolution (LITE) algorithm. LITE is designed to investigate the out-of-equilibrium transport of short-range systems. In contrast to similar algorithms [REF:], it preserves local constants of motion. LITE decomposes the system into subsystems and solves the von Neumann equation for each subsystem in parallel. Importantly, it can also simulate open quantum systems described by the Lindblad master equation. In Sec. [S8 B,](#page-27-1) we apply LITE to simulate an effective one-dimensional short-range toy model for the case $\theta = \pi$. Such a toy model is derived from the experimental three-dimensional long-range model within the approximation of sparse density of spins. Thus, the one-dimensional model retains only the dominant nearest-neighbor mutual coupling and the space-dependent on-site potential generated by the NV center. For $\theta \approx \pi$, the energy diffusion and the behavior of the total **x**ˆ-polarization are analyzed, showing a sign inversion of polarization in the presence of a space-dependent potential. The diffusion of energy in the inhomogeneous systems is explored, revealing a slowing down of energy spread that can be explained in terms of a spatially dependent diffusion constant. Dissipation effects are then introduced. It is shown that dissipation favors energy diffusion, inducing the emergence of Gaussian-like energy distributions. The presence of dissipation does not alter the possibility of observing sign inversion in the total \hat{x} -polarization. In Sec. [S8 C,](#page-32-0) the dynamics of the one-dimensional spin system obtained for a kick angle around $\pi/2$ is investigated. Unlike the case of a kick angle close to π , the total (net) $\hat{\mathbf{x}}$ -polarization is conserved in addition to energy. This leads to the diffusion of polarization throughout the system, making it impossible to detect polarization gradients using global measurements. Only by introducing dissipation can a sign inversion of the integrated polarization be induced. The effects are demonstrated using numerical simulations obtained within the LITE algorithm. In Secs. [S8 D](#page-33-4) and [S8 E,](#page-34-0) we highlight the main differences between the two kick angles analyzed and summarize the results.

In Sec. [S9,](#page-34-1) we discuss the role of dimensionality and interaction range in the simplified one-dimensional versions of the long-range three-dimensional quantum system used in the experiments. We argue that, although our simplified models may not capture all the details of the out-of-equilibrium dynamics, we expect them to provide qualitative insights into the threedimensional system. We discuss the effects of dimensionality on Floquet prethermalization and equilibration dynamics within the prethermal plateau. We also consider the possible effects of many-body localization and the impact of spin-spin couplings and angular dependence.

In Sec. [S10,](#page-36-1) we perform classical simulations on a threedimensional diamond lattice to complement the previous analysis. The classical simulation allows us to study larger systems and reach longer time scales, although quantum correlations are neglected. We analyze the spin locking regime near $\theta \approx \pi$ and observe the formation of a spatially inhomogeneous local polarization profile. The classical simulation confirms the predictions from the analytical and numerical results obtained for one-dimensional toy models. The simulations show that the local polarization at late times follows the applied local potential up to an overall constant, which is related to the inverse temperature. The classical simulation results provide further support for the formation of a robust spatially inhomogeneous local polarization

profile in the experimental system.

S2. DISSIPATION SOURCES IN THE EXPERIMENT

A. Nuclear relaxation in transverse and longitudinal directions

In this discussion, we elucidate the mechanisms for ${}^{13}C$ nuclear relaxation for different initial states. Let us begin by examining Fig. [S1A](#page-14-4), which illustrates the ${}^{13}C$ dephasing when prepared in a superposition state, αI_x . In the absence of the applied Floquet drive, the measured signal rapidly decays in $T_2^* \sim 1.5$ ms. This is primarily attributable to interspin interactions, specifically, the formation of many-body spin states invisible under inductive readout. The magnitude of the internuclear dipolar coupling can be estimated from this decay as $\langle J \rangle$ =660 Hz.

Moving on to Fig. [S1B](#page-14-4), we consider the spins prepared in the $\rho_z \propto I_z$ state. In this case, the corresponding (T_1) relaxation is found to be remarkably long, with T_1 <1hr even at room temperature. Relaxation arises from spin-flipping noise perpendicular to **z**ˆ, stemming from the spectral density component that matches the nuclear Larmor frequency ($\omega_L = \gamma_n B_0$). Phononic contributions likely play a dominant role in these decay channels; their inherently weak nature results in the long T_1 . Conversely, to assess the contribution of electronic dissipation to this relaxation, it is worth noting that the corresponding spectral density is centered at $(T_{1e})^{-1}$, which is orders of magnitude separated from ω_L . Hence, this contribution can be considered to be extremely weak. This is supported by experiments in Fig. [3](#page-3-1) of the main paper.

Lastly, we direct our attention to T'_2 relaxation, as shown in Fig. [S1C](#page-14-4). Here spins are prepared in a superposition state $\rho_I \propto I_x$ and subjected to Floquet driving, which preserves them along **x**ˆ. However, this effective Hamiltonian is only accurate to leading order in a Magnus expansion, and higher-order terms can induce heating to infinite temperature. Relaxation additionally arises from **z**ˆ-oriented noise spectral matched to the energy gap in the rotating frame, $\Omega_{\text{eff}} = \Omega(t_p/\tau)$, where the latter factor is the pulsing duty cycle. In our experiments, $(T_{1e})^{-1}$ ~100kHz and exhibits a significant contribution at Ω_{eff} . Consequently, the electron can play a role as a *"dissipator"* for the spins.

Note that while the lattice contains both NV and P1 center electrons, the NV center is present at the same location $r=0$ for every ¹³C ensemble considered while the P1s are randomly positioned. Thus, upon ensemble averaging, the P1s contribute to only a background rate of T'_2 relaxation, while the NV-driven relaxation is discernible in a spatially dependent manner.

B. Indirect evidence for electron dissipation on the ¹³**C nuclear spins**

In previous work, we presented preliminary evidence supporting the role of the electron spin as a nanoscale dissipator for neighboring nuclear spins [\[62\]](#page-39-10). Here, we provide a concise summary of these findings. Specifically, we observed that the relaxation profiles of ¹³C spins in the T'_2 regime appear to lengthen when a greater degree of hyperpolarization (achieved by employing longer τ_{+} durations) is injected into the spins. This is shown in Fig. S_2 , where the colorbar represents τ_+ . We interpreted this

Fig. S1. **Nuclear dephasing and relaxation**. (A) Panel illustrates T_2^* Let $\frac{13}{2}$ dephasing of ¹³C spins during free induction decay at room temperature. The fast decay observed, $T_2^* \approx 1.5$ ms, is attributed to internuclear interactions. Reproduced from [\[34\]](#page-38-27) (B) Panel presents T_1 decay at room temperature, lasting over twenty-five minutes at 7T. Reproduced from [\[62\]](#page-39-10).

Fig. S2. **Indirect evidence for electron dissipation**. Normalized spin lock curves plotted against increasing polarization time τ_{+} , reproduced from [\[62\]](#page-39-10). Data demonstrates that T'_2 values increase with τ_+ , indicating that $13C$ nuclei located further away are less affected by relaxation from the NV, while proximal spins experience faster NV relaxation. This indirect evidence is further supported by the formation of shells, as depicted in Fig. [2.](#page-2-0)

behavior by considering that, with longer τ_{+} durations, the polarization has more time to diffuse within the lattice, thus reaching nuclei less affected by relaxation originating from the NV center. Instead, the observation of sharp zero-crossings in Fig. [2](#page-2-0) of the paper provides more *direct* evidence for this, and allows it to be exploited for the readout of spin texture.

S3. PRETHERMAL SIGNAL DECAYS AT A WIDE RANGE OF FLIP ANGLES

We present here an analysis of spin-lock decay behavior for a wide range of flip angles, $[0, 1.5\pi]$, as a comparison to the results in the main text which focused on the proximity of $\theta = \pi$ (Fig. [4\)](#page-4-0) and $\theta = \pi/2$ (Fig. [2\)](#page-2-0). Experiments here (Fig. [S3\)](#page-15-1) were conducted at 115K, similar to conditions in Fig. [4.](#page-4-0) Fig. [S3A](#page-15-1) shows the integrated signal S_{int} for the range of angles, and Fig. [S3B](#page-15-1)-D shows representative slices of signal S at specific values of θ in three ranges (shaded). A full movie of the dataset is available in

4

Fig. S3. Data for a wide range of spin-locking angles, $\theta \in [0, 1.5\pi]$. (A) Integrated signal S_{int} over the first 60 s of experiment time Shaded regions show representative regions centered at $\theta = 0.1\pi$, π , and 1.3 π , respectively. (B-D) Corresponding decay profiles for the shaded regions in (A) are shown, with θ values indicated by the colorbar. Prethermal decays are featureless and follow stretched exponential decays on either side away from $\theta = \pi$. Near π , however, there is a significant change in the signal profile, associated with the formation of shell-like spin textures. Full movie corresponding to this dataset is available at Ref. [\[63\]](#page-39-11)

the Youtube link at Ref. [\[63\]](#page-39-11).

Data in Fig. [S3B](#page-15-1),D illustrates that far from π , the spin-lock profiles 'exhibit slow decays at T'_2 that follow stretched exponential behavior. In the regime away from π , there is no inversion of the spin signal with changing θ . However, as observed in Fig. [S3C](#page-15-1) (also Fig. [4\)](#page-4-0), in the proximity of π , there are sharp zero crossings corresponding to the formation of spin-shell texture. Overall, these results demonstrate unexpected sign inversions for the case of CPMG pulse trains, which to our knowledge, has not been reported previously.

S4. EXPERIMENTS PROBING z POLARIZATION ˆ

In the experiments describing shell formation through Hamiltonian Engineering (Fig. [4](#page-4-0) of the main paper), we observed an apparent change in the polarization direction from **x**ˆ to −**x**ˆ, which was attributed to the thermalization of spins under the electron gradient induced potential. In this section, we aim to provide additional evidence to support this. Specifically, we conducted measurements probing the **z**ˆ component of the spin vector at various time points t along experimental traces in Fig. [4B](#page-4-0). This allows us to examine whether the observed zero-crossings in Fig. [4](#page-4-0) are trivially a result of the spin vector tilting towards the \hat{z} axis, where the spins become unobservable.

To further investigate this, we performed additional experiments as depicted in Fig. [S4A](#page-16-3). The spins are subject to the Floquet drive as before, but it is interrupted at time $t=t_c$ with $\pi/2$ pulses applied in either the $\hat{\mathbf{x}}$ direction (Fig. [S4A](#page-16-3)) or the **y**ˆ direction (Fig. [S4B](#page-16-3)). These pulses reorganize the spin populations from the $\hat{\mathbf{y}}$ - $\hat{\mathbf{z}}$ or $\hat{\mathbf{x}}$ − $\hat{\mathbf{z}}$ planes into the $\hat{\mathbf{x}}$ - $\hat{\mathbf{y}}$ plane at t_c . Setting $t_c = t_{zc}$, we can precisely probe the \hat{z} component at the zero-crossing point. Moreover, by varying t_c , we can track the \hat{z} component throughout the observed dynamics in Fig. [S4A](#page-16-3)-B.

Specifically, Fig. [S4A](#page-16-3)(i) and Fig. [S4B](#page-16-3)(i) display data obtained at $t_c = t_{zc}$ slices for both cases. Notably, no significant \hat{z} signal was observed, with the residual signal primarily attributed to the frequency offset of the pulses employed in these experiments. To further support this observation, the inset Fig. [S4B](#page-16-3)(ii) illustrates the variation of the \hat{z} amplitude as a function of t_c . It reveals that the \hat{z} component undergoes negligible change with . Consequently, Fig. [S4](#page-16-3) provides compelling evidence that the zero-crossing observed in Fig. [4](#page-4-0) arises from the thermalization dynamics of the spins, rather than from the polarization vector deviating away from the **x**ˆ-**y**ˆ plane.

Fig. S4. **"Interrupted" Floquet driving experiments** investigating if zero-crossing observed in Fig. [4](#page-4-0) is caused by polarization tipping to the **z**ˆ axis. (A) i) *Schematic* of the experiment shown in the inset, consisting of a spin-locking train interrupted by an orthogonal $\pi/2$ pulse of phase x or y at $t = t_{int}$ that reorganizes population from the \hat{z} axis to the \hat{x} - \hat{y} plane. (A-B) i) Signal at $t_{int} = t_{zc}$ for case of $\pi/2|_x$ in (A) or $\pi/2|_y$ in (B) interrupt pulses. The measured \hat{z} amplitude for $\pi/2|_x$ pulses does not significantly change, indicating that zero-crossing in Fig. [4](#page-4-0) does not result from spins tipping out of the $\hat{\mathbf{x}}$ - $\hat{\mathbf{y}}$ ⁿ plane. Residual $\hat{\mathbf{z}}$ -component can be attributed to slight off-resonance in the pulses. (A-B) ii) Signal decays for the interrupted Floquet driving experiments where $t_{int} \neq t_{zc}$. In (A), the $\pi/2|_x$ pulse caused minimal disruption to the signal decays. However, in (B) the $\pi/2|_v$ pulse reorganized the population of spins from the **x**ˆ axis to the unobservable **z**ˆ axis, causing an abrupt loss of signal.

S5. HAMILTONIAN ENGINEERING: VARIATION OF zc WITH EXPERIMENTAL PARAMETERS

Accurately estimating the domain boundary of the generated spin texture based solely on the zero-crossing position t_{zc} poses a significant challenge. t_{zc} relies on the complex interplay between electron dissipation and spin diffusion, making it inadequate for providing an accurate measurement of the critical radius r_c associated with this boundary. However, by considering the variations in experimental parameters, it is possible to anticipate the trends in the movement of r_c (and, consequently, t_{zc}), which can then be validated through experimental investigations.

Consider first the influence of the nuclear Rabi frequency Ω_{eff} . Since the effective flip angle θ is determined as an interplay between the electronic gradient field and the strength of the **x**ˆ Rabi field, changing Ω_{eff} would directly affect r_c . We anticipate from theory that decreasing Ω_{eff} should result in a leftward shift in t_{zc} . In experiments (see Fig. [S5\)](#page-16-1), we manipulate Ω_{eff} by modifying the duty cycle of the Floquet drive, as schematically denoted in the inset of Fig. [S5.](#page-16-1) Experimental data in Fig. [S5](#page-16-1) then confirms

Fig. S5. **Variation of spin-lock profiles with pulse duty cycle**. Spinlock profiles for different effective Rabi frequencies (see colorbar) applied to the nuclear spins and $\theta \sim \pi$, similar to Fig. [4](#page-4-0) of the main text. Ω_{eff} is controlled here by varying the pulse duty cycle, while maintaining a fixed flip angle θ . Inset shows pulse sequence schematic, with definition of the duty cycle being the total time between the start of one pulse and the next.

Fig. S6. **Variation of spin-lock profiles with frequency offset**. (A) Spin-lock profiles at different frequency offset values for the Floquet drive (see colorbar). (B) Movement of zero-crossing with offset. The 2D color plot shows offset data from (A) plotted on a logarithmic scale. Zero crossing appears as an abrupt decrease in signal (colored blue). There is a wide range of offsets (∼2 kHz) for which a zero crossing is observed.

Similarly, changing pulse frequency offset at fixed Ω should result in a shift of the 13 C spin layer that has a flip angle matching π , thereby changing r_c and t_{zc} . In the rotating frame of the Floquet drive, changing offset refers to applying a global \hat{z} oriented field to the 13 C nuclei. Since this field can either enhance or counteract the local field from the NV center gradient, the precise magnitude of the shift to r_c is challenging to predict. However, qualitative trends in these shifts are easily observable. For instance, Fig. [S6A](#page-16-2) demonstrates the effect of changing the offset at a fixed length t_p of the applied pulses. A change in t_{zc} is observed, and for large offsets, the zero-crossing no longer

Fig. S7. **Effect of hyperpolarization injection** τ_{+} on spin-shell tex**ture.** (A) Schematic of the experiment sequence, where injection time τ_{+} is varied. After shuttling time t_s =90s the sample is subjected to a spin-locking train with $\theta \sim \pi$ for readout, identical to main text Fig. [4A](#page-4-0). (B) Normalized signal decays for different values of τ_{+} , as indicated by the colorbar. (C) Analysis of the zero-crossing times t_{ZC} with τ_{+} . Solid line is a spline guide to the eye.

appears in the 70s experiment time. This is consistent with effectively shifting the position of the 13 C slice corresponding to r_c . We find that the $\theta = \pi$ slice occurs *after* the parabola-like t_{zc} curve observed in Fig. [4C](#page-4-0) for off-resonant pulses. This again points to shifting r_c via the resonance offset field. Nevertheless, the physics underlying the formation and thermalization of the spinning shell remains unchanged in this case.

A. Experiments with changing hyperpolarization time

We examine the relationship between results displayed in Fig. [4](#page-4-0) of the main paper and the amount of hyperpolarization injected into the ¹³C nuclear spins. Specifically Fig. [S7](#page-17-5) describes experiments varying the amount of time τ_{+} for which hyperpolarization is injected. Temperature is maintained consistent at 115K, flip angle here is 160°, and shuttling time t_s =90 s.

The amplitude signal obtained in these experiments (Fig. [S7B](#page-17-5)) shows the expected zero crossing and subsequent phase inversion. The zero crossing time t_{zc} does not significantly change with increased hyperpolarization time τ_{+} . This stands in contrast to the movement of the zero crossing with variations in the flip angle (Fig. [4\)](#page-4-0) or temperature (Fig. [S9\)](#page-18-1). These results support the fact that spin texture engineered via **Hamiltonian Engineering** is qualitatively independent of the initial state of nuclear spins.

B. Experiments with different orientations

Here we examine the effect of changing the diamond sample orientation to results described in Fig. [4](#page-4-0) of the main paper. We compare two different sample orientations, where the NV center families have different directions relative to B_0 . Fig. [S8A](#page-18-2)-B shows the DNP-measured EPR spectra of the NV centers in both cases. For experiments similar to Fig. [4B](#page-4-0), we find qualitatively identical development of spin-shell texture and zero-crossings in both cases, as described in the colorplots in Fig. [S8A](#page-18-2)iii,Biii. The physics underlying Fig. [4](#page-4-0) can therefore be considered independent of the exact sample orientation.

C. Temperature dependence of spin texture

We now consider the effect of changing temperature on the observed spin texture signal via **Hamiltonian Engineering** (Fig. [4](#page-4-0) of the main paper). A key advance enabled by the instrumentation (Fig. [6\)](#page-7-0) introduced in this paper is the ability to study the role of temperature (in 77K-RT range), which previously has been shown to have a strong effect on rates of electronic relaxation T_{1e} (of both NV and P1 centers).

Fig. [S9](#page-18-1) presents experiments conducted at six representative temperatures. To ensure consistency, we maintain the same nuclear Rabi frequency for all experiments. Results indicate that the time at which the zero-crossing occurs (t_{zc}) increases as the temperature decreases. This can be seen as a direct reflection of the increase in the NV center T_{1e} , which in turn decreases the strength of the dissipation acting on the 13 C nuclear spins (see also Sec[.S6 B\)](#page-18-0). We note that Ref. [\[64](#page-39-12)[,65\]](#page-39-13) found that for samples with comparable NV center densities as the one employed here, T_{1e} increases sharply close to 100K and can exceed T_{1e} > 1s under these conditions.

S6. THEORY MODEL

A. Closed system

As outlined in the main text, the system of interest is given by dipolar coupled 13 C nuclear spins with the (rotating-frame) Hamiltonian

$$
\mathcal{H}_{\text{dd}} = \sum_{k < \ell} b_{k\ell} \left(3I_k^z I_\ell^z - \mathbf{I}_k \cdot \mathbf{I}_\ell \right),\tag{S.1}
$$

where $I_k = \left(I_k^x, I_k^y, I_k^z\right)^T$, the spin-1/2 operators I_k^{η} $\frac{\eta}{k} = \sigma_k^{\eta}$ $\frac{\eta}{k}/2$ describes the nuclear spins, and σ^{η} ($\eta \in \{x, y, z\}$) are the Pauli matrices. The couplings between different 13 C spins strongly depends on their distance and the angle with the \hat{z} axis via $b_{k\ell} = J_{\text{exp}}(3\cos^2(\theta_{k\ell})-1)/r_{k\ell}^3$ where $\cos(\theta_{k\ell})=B$. $\mathbf{r}_{k\ell}/(|B||\mathbf{r}_{k\ell}|)$; $\mathbf{r}_{k\ell}$ is the inter-spin vector and $B = (0, 0, B)^T$ is the externally applied magnetic field and $J_{\text{exp}} = \mu_0 \hbar \gamma_n^2 / 4\pi$, with the gyromagnetic ratio of the neutron γ_n and the vacuum permeability μ_0 . The ¹³C-spins relevant for the experiment are randomly placed on a diamond lattice in the proximity of NVcenters. The NV-centers are approximately described by an electronic two-level system, which is itself coupled to all 13 C nuclear spins via dipole-dipole interactions:

$$
\mathcal{H}_{NV} = \epsilon_{NV} S^z, \qquad (S.2)
$$

$$
\mathcal{H}_{NV^{-13}C} = \sum_{j} K_j \Big(3S^z I_j^z - S \cdot I_j \Big). \tag{S 3}
$$

Here $S^{\eta} = \sigma^{\eta}/2$ with $\alpha \in \{x, y, z\}$ are (pseudo-)spin-1/2 operators describing the two-level system of the NV-center. $\overline{K}_j = K_{\text{exp}}(3\cos^2(\vartheta_j)-1)/r_j^3$ with the vector **r**_j between the NV center and the j -th ¹³C nuclear spin and the corresponding angle

Fig. S8. **Spin-texture for two different sample orientations.** (A-B)i *EPR spectra.* Indirectly obtained EPR spectrum via ¹³C DNP, produced by sweeping MWs in narrow 25MHz windows. The integrated signal of resulting NMR decay curves is plotted as a function of the center frequency of the swept MWs. Solid line is a spline guide to the eye. (A-B)ii Representative signal decays in the proximity of $\theta = \pi$ showing zero crossings. (A-B)iii Color plots showing full data similar to Fig. [4E](#page-4-0) of the main paper, highlighting the movement of the zero crossings with θ for the two orientations. Panels (A-B)iii indicate physics underlying Hamiltonian Engineering (Fig. [4\)](#page-4-0) is qualitatively independent of sample orientation.

Fig. S9. **Variation of spin-shell profiles with temperature.** (A) Representative spin-lock decays with the temperature (see colorbar). Experiments are performed at a fixed flip angle ($\theta \sim \pi$), and identical Rabi frequency. (C) Variation of zero-crossing time $t_{\rm ZC}$ with temperature.

 $cos(\vartheta_i) = \mathbf{B} \cdot \mathbf{r}_i / (|\mathbf{B}||\mathbf{r}_i|)$ between \mathbf{r}_i and the external magnetic field B, and $K_{\text{exp}} = \mu_0 \hbar \gamma_n \gamma_e / 4\pi$, where γ_e is the gyromagnetic ratio of the electron.

Note that the system obeys the hierarchy of energy scales $\epsilon_{\rm NV} \gg K \gg J$, where J and K are characteristic energy scales associated with the Hamiltonians of Eq. (S_1) and (S_3) . The separation of energy scales is important as it allows to independently kick (i.e., apply strong short pulses to) the 13 C spins while leaving the NV two-level system unaffected. Moreover, it allows us to consider the singular-coupling limit in order to derive an effective Lindblad master equation for the ${}^{13}C$ spins coupled to the NV center (see below). The kick Hamiltonian of interest, created from an external microwave field at resonant Larmorfrequency of the external magnetic field, is given in the rotating frame by

$$
\mathcal{H}_x(t) = \begin{cases} \Omega \sum_j I_j^x & n\tau < t < n\tau + t_p, \quad n \in \mathbb{N} \\ 0 & \text{otherwise} \end{cases}
$$
 (S.4)

with the driving period τ and pulse width duration t_p .

For the combined system of NV and 13 C nuclear spins, it is useful to perform an interaction-picture transformation with $\mathcal{H}_{dd} + \mathcal{H}_{NV^{-13}C}$ as the interaction Hamiltonian. Using the rotatingwave approximation, we readily obtain

$$
\widetilde{\mathcal{H}}_{\text{tot}} = \mathcal{H}_{\text{dd}} + \sum_{j} 2K_{j} S^{z} I_{j}^{z}, \qquad (S.5)
$$

in the rotating frame with respect to $\exp(-it\mathcal{H}_{NV})$.

B. Open system

In the experimental platform, both the NV center and the 13 C spins are not completely isolated. They are coupled to a bath of phonons generated by the diamond lattice; such a bath causes decoherence and dissipation. Thus, a comprehensive theory of the system should take these effects into consideration.

Following the rotating-wave approximation, Eq. $(S₅)$, the microscopic Hamiltonian of the total system composed of the NV center and the 13 C spins reads

$$
\mathcal{H}_{\text{tot}} = \mathcal{H}_{\text{dd}} + \mathcal{H}_{\text{NV}} + \sum_{i} 2K_{j} S^{z} I_{j}^{z}
$$
 (S 6)

$$
= \sum_{j < k} I_{jk} \left(3I_j^z J_k^z - \mathbf{I}_j \cdot \mathbf{I}_k \right) + \epsilon_{\text{NV}} S^z + \sum_j 2K_j S^z I_j^z, \quad (S.7)
$$

in the lab frame. The first term represents the Hamiltonian of the $13¹³C$ spins, the second is the Hamiltonian of the NV center, and the last is the effective interaction between the two. As mentioned, the total system obeys the following hierarchy of energy scales:

$$
\epsilon_{\rm NV} \gg K \gg J,\tag{S 8}
$$

which implies that the timescale intrinsic to the NV center is much shorter than any other timescale of the problem. This allows us to assume that the NV center is strongly coupled to the thermal phonon bath while the 13 C spins are only weakly coupled to it. Therefore, we also assume that the NV center is always in thermal equilibrium with the phonons. For simplicity, we consider the NV at infinite temperature: $\rho_{\text{NV}}(t) = \frac{1}{2} \mathbb{1}_{\text{NV}}$, for all times t ; however, our results can be easily generalized to any temperature.

The thermal-equilibrium assumption for the NV allows us to derive an effective quantum master equation for the reduced system of the 13 C spins by tracing out the NV center (and, indirectly, the phonons to which it is coupled) in the form of a Lindblad master equation. The latter is the most general Markovian master equation. It describes the equation of motion of a reduced system in contact with a thermal bath which is memoryless, i.e., whose timescale is much shorter than any other timescale in the problem, as the NV center in our system. Moreover, the hierarchy of energy scales $(S 8)$ indicates the validity of the so-called *singular coupling limit*, that enormously simplifies the microscopic derivation of the Lindblad equation [\[66](#page-39-14)[–68\]](#page-39-15). Notice that previous works [\[61\]](#page-39-9) have investigated the opposite scenario in which one is interested in integrating out the nuclear spins to derive a master equation for the NV electron only. From Eq. $(S 8)$, it is clear that this opposite scenario generates a highly non-Markovian master equation for the NV electron.

The derivation of the Lindblad equation for the 13 C spins proceeds as follows. Let us rewrite the total system Hamiltonian (S_6) in the more general form as [\[69\]](#page-39-16)

$$
\mathcal{H}_{\text{tot}} = \mathcal{H}_{\text{13}}{}_{\text{C}} \otimes \mathbb{1}_{\text{NV}} + \alpha^{-2} \mathbb{1}_{\text{13}}{}_{\text{C}} \otimes \mathcal{H}'_{\text{NV}} + \alpha^{-1} V', \qquad (S \, 9)
$$

where we have renormalized the bath and interaction Hamiltonian as $\mathcal{H}'_{NV} = \alpha^2 \mathcal{H}_{NV}$ and $V' = \sum_j 2K'_j S^z I_j^z$ with $K'_j = \alpha K_j$. The parameter α is the inverse of the coupling strength; in the singular coupling limit we eventually take $\alpha \rightarrow 0$. Equation [\(S 9\)](#page-19-0) highlights the hierarchy of energy scales of our model (S_6) .

We start by considering the Nakajima-Zwanzig equation [\[66,](#page-39-14) [68\]](#page-39-15)

$$
\frac{d}{dt}\mathcal{P}\tilde{\rho}(t) = \alpha^{-1}\mathcal{P}\mathcal{V}(t)\mathcal{P}\tilde{\rho}(t) + \alpha^{-1}\mathcal{P}\mathcal{V}(t)\mathcal{G}(t,0)\mathcal{Q}\tilde{\rho}(0)
$$

$$
+\alpha^{-2}\int_0^t du\mathcal{P}\mathcal{V}(t)\mathcal{G}(t,u)\mathcal{Q}\mathcal{V}(u)\mathcal{P}\tilde{\rho}(u)(S\,10)
$$

where $\tilde{\cdot}$ denotes the time-evolved operator in the interaction picture; P and Q are two orthogonal projector operators (i.e., $\hat{\mathcal{P}}^2 = \mathcal{P}, \ \mathcal{Q}^2 = \mathcal{Q}, \ \text{and} \ \mathcal{P}\mathcal{Q} = \mathcal{Q}\mathcal{P} = 0$ given by $\mathcal{P}\rho =$ Tr_{NV}(ρ)⊗ ρ_{NV} and $Q\rho = (1-\mathcal{P})\rho$; $\mathcal{V}(t)(\cdot) = -i[\tilde{V}'(t), \cdot]$; $G(t, u) = \mathcal{T} e^{\int_u^t dt' \mathcal{Q} \mathcal{V}(t')}$ is the propagator with \mathcal{T} the timeordering operator.

The integro-differential equation $(S 10)$ is exact and describes the equation of motion of the relevant subspace $\mathcal{P}\tilde{\rho}(t)$ in the interaction picture. Unfortunately, it is usually as difficult to solve as the von Neumann equation describing the dynamics of the total system. Hence, we need to make a few more assumptions to proceed further: First, we assume that

$$
\mathcal{PV}(t)\mathcal{P} = 0, \tag{S.11}
$$

which corresponds to $Tr_{NV}(\tilde{V}'(t)\rho_{NV}) = 0$. The Hamiltonian (S₆) fulfils this condition since $Tr_{NV}(S^z \rho_{NV})$ = $Tr_{\text{NV}}(S^z/2) = 0$. Nonetheless, if the condition is not fulfilled one can shift the system Hamiltonian \mathcal{H}_{13} such that it is satisfied [\[68\]](#page-39-15). Second, we assume that

$$
\rho(0) = \rho_{^{13}\text{C}}(0) \otimes \rho_{\text{NV}}(0),\tag{S.12}
$$

which implies that we have control over the system of the 13 C spins (for example, we can prepare them in a pure state at $t = 0$). This assumption is known as the Born approximation and it is necessary to obtain a universal dynamical map [\[68\]](#page-39-15).

Assumptions $(S 11)$ and $(S 12)$ make the first and second term on the right-hand side of Eq. $(S10)$ vanish; the latter now becomes

$$
\frac{d}{dt}\mathcal{P}\tilde{\rho}(t) = \alpha^{-2} \int_0^t du \mathcal{K}(t, u)\mathcal{P}\tilde{\rho}(u), \qquad (S\,13)
$$

where $\mathcal{K}(t, u) = \mathcal{PV}(t)\mathcal{G}(t, u)\mathcal{QV}(u)$ is the memory kernel. Since the NV is always in thermal equilibrium, the memory kernel becomes homogeneous: $\mathcal{K}(t, u) = \mathcal{K}(t-u)$.

Equation $(S 13)$ is in general non-Markovian as the state of the system at time t depends on all the states at former times from 0 to t . By definition, a Markovian master equation for the system is obtained if the kernel $\mathcal{K}(t-u)$ behaves as a delta function with respect to $\tilde{\rho}(u)$. This is verified in the singular coupling limit, where the hierarchy of energy scales $(S 8)$ implies that the typical timescale at which the kernel vanish, τ_{NV} , is much smaller than the typical variation timescale of the system, $\tau_{^{13}C}$; thus, $\tau_{NV}/\tau_{^{13}C}$ → 0 and $\mathcal{K}(t-u)$ ∝ $\delta(t-u)$. This can be seen by integrating Eq. $(S 13)$ and taking the zeroth-order expansion in $1/\alpha$ of $\mathcal{K}(t-u)$ [\[70\]](#page-39-17); we obtain

$$
\mathcal{P}\tilde{\rho}(t) = \mathcal{P}\tilde{\rho}(0)
$$
\n
$$
+ \alpha^{-2} \int_0^t ds \int_0^s du \mathcal{P}\mathcal{V}(s)\mathcal{V}(u)\mathcal{P}\tilde{\rho}(u) + O(\alpha^{-3}),
$$
\n(S 14)

which is equivalent to

$$
\tilde{\rho}_{^{13}\text{C}}(t) = \tilde{\rho}_{^{13}\text{C}}(0)
$$
\n
$$
+ \alpha^{-2} \sum_{nm} \int_0^t ds \int_0^s du \frac{4K_n' K_m'}{r_n^3 r_m^3} \Biggl(C_{ij} (s - u) \Bigl[\tilde{I}_j^z(u) \tilde{\rho}_{^{13}\text{C}}(u), \tilde{I}_i^z(s) \Bigr]
$$
\n
$$
+ C_{nm}^* (s - u) \Bigl[\tilde{I}_n^z(s), \tilde{\rho}_{^{13}\text{C}}(u) \tilde{I}_m^z(u) \Bigr] \Bigr] + O(\alpha^{-3}), \quad (S 15)
$$

where the correlation functions are defined as

$$
C_{nm}(s-u) = \text{Tr}(\tilde{S}^z(s-u)S^z \rho_{\text{NV}}). \tag{S.16}
$$

By Fourier-decomposing the NV operator $\tilde{S}^{z}(s-u)$ and taking into account the factor α^{-2} in the free NV evolution, we get

$$
C_{nm}(s-u) = \int_{-a}^{a} d\omega \, e^{-\frac{i\omega(s-u)}{a^2}} \text{Tr}\big(S^z(\omega)S^z \rho_{\text{NV}}\big), \qquad (S\,17)
$$

where the integration limits a denotes the spectral support. We see that, when $\alpha \rightarrow 0$, the integral in Eq. [\(S 17\)](#page-19-5) tends to a delta function: $C_{nm}(s-u) \propto \delta(s-u)$. Thus, by making the change of variable $w = \alpha^{-2}u$, and taking the limit $\alpha \to 0$, Eq. [\(S 15\)](#page-19-6) becomes a Markovian master equation for the 13 C-spins; in the Schrödinger picture, it reads

$$
\frac{d}{dt}\rho_{^{13}\text{C}}(t) = -i\left[\mathcal{H}_{^{13}\text{C}} + \mathcal{H}_{\text{LS}}, \rho_{^{13}\text{C}}(t)\right] \n+ \sum_{nm} \frac{4K'_n K'_m}{r_n^3 r_m^3} \gamma_{nm} \left(I_m^z \rho_{^{13}\text{C}}(t) I_n^z - \frac{1}{2} \{I_n^z I_m^z, \rho_{^{13}\text{C}}(t)\}\right), \quad (S\ 18)
$$

where the Lamb shift Hamiltonian is

$$
\mathcal{H}_{LS} = \sum_{nm} L_{nm} I_n^z I_m^z. \tag{S.19}
$$

Here γ_{nm} and L_{nm} represents the Hermitian and anti-Hermitian components of the integral over time of the bath correlation functions [\(S 17\)](#page-19-5):

$$
\int_0^\infty ds \, C_{nm}(s) = \frac{\gamma_{nm}}{2} + i L_{nm} \tag{S.20}
$$

Hence, by inserting Eq. [\(S 17\)](#page-19-5), we have $\gamma_{nm} \propto 1$ and $L_{nm} = 0$. By absorbing constants of order unity into $K_i'K_j'$, we arrive at the final expression for the 13 C master equation:

$$
\frac{d}{dt}\rho_{^{13}\text{C}}(t) = -i\left[\mathcal{H}_{^{13}\text{C}}, \rho_{^{13}\text{C}}(t)\right] \n+ \sum_{nm} \frac{K'_n K'_m}{r_n^3 r_m^3} \left(I_m^z \rho_{^{13}\text{C}}(t) I_n^z - \frac{1}{2} \{I_n^z I_m^z, \rho_{^{13}\text{C}}(t)\}\right).
$$
\n(S21)

A few comments are in order. The hierarchy of energy scales (S_8) and, thus, the validity of the singular coupling limit approximation for this model greatly simplify the derivation of the Lindblad master equation. In particular, the Lindbladian term on the second line of Eq. $(S 21)$ is determined only by the bath Hamiltonian H_{NV} and the interaction Hamiltonian $\alpha V'$ of Eq. (S9), while it is completely agnostic of the system Hamiltonian \mathcal{H}_{13} . This is particularly useful if the system can be governed by different unitary dynamics \mathcal{H}_{13} , e.g., in the prethermal regimes determined by different kick angles (see Secs. S₈B and S₈C). Moreover, we note that the jump operators in Eq. $(S21)$ act as dephasing operators if the spins are polarized in the **z**ˆ direction, while they generate both dephasing and dissipation for a system that is polarized in the **x**ˆ direction. This result is in agreement with the experimental observations. In particular, it is at the origin of the non-decaying behavior of the normalized signal S as a function of t_{wait} for $\tau_0 = 0$ observed in Fig. [3E](#page-3-1) of the main text. Indeed, when τ_0 =0 the whole system is positively polarized along the \hat{z} axis. Therefore, during t_{wait} no diffusion nor dissipation affect the system, giving a uniform behavior for any t_{wait} . Finally, we note that the strength of the dissipative terms $K'_n K'_m / (r_n^3 r_m^3)$ decays faster with the distance from the NV center with respect to the dipole interaction. This allows us to consider the simplified dissipative one-dimensional toy model studied in Sec. [S8.](#page-25-0)

S7. EFFECTIVE HAMILTONIAN ANALYSIS

Since the NV system experiences fast dynamics compared to the 13 C-spins we neglect the NV-spin degree of freedom and replace it by its mean value. Hence, we replace the operator S^z in Eq. [\(S 5\)](#page-18-3) by its thermal expectation value $P = P(T)$, which depends on the temperature T , thus, leading to an effective onsite potential $\eta_i = 2K_i P$ for the ¹³C nuclear spins. Thereby, we also neglect the effect of dissipation.

The kick sequence (see main text Fig. [1B](#page-1-0)) at stroboscopic times $n\tau \approx n(t_{\text{acq}}+t_{\text{p}}), n \in \mathbb{N}$, can then be written as

with

$$
U = e^{-i\mathcal{H}t_{\text{acq}}}e^{-i\mathcal{H}_{\text{SL}}t_{\text{p}}},\qquad (S\,22)
$$

$$
\mathcal{H} = \mathcal{H}_{dd} + \mathcal{H}_{pot},
$$

\n
$$
\mathcal{H}_{SL} = \mathcal{H}_x + \mathcal{H}_{pot},
$$

\n
$$
\mathcal{H}_{pot} = \sum_{i} \eta_j I_j^z.
$$
\n(S 23)

Fig. S10. **Effective Hamiltonian Summary.** (A) Energy scale $E_{\text{NV}}(r)$ of magnetic field induced by the NV spin as a function of the distance from the NV, different colors correspond to different polarization of the NV spin $P = 0-1$. Gray regime corresponds to the experimentally inaccessible frozen core. (B) Spin locking at $\theta \ast \pi$: Effective Hamiltonian at small tilt of the components of the conserved axis \tilde{I} , Eq. [\(S 39\)](#page-22-1), for spin locking at $\theta \neq \pi$ as a function of distance from NV. (C) spin locking at $\theta \approx \pi$: (i) Effective on-site potential $\phi_{\text{eff}}(r)$, Eq. [\(S 29\)](#page-22-2), as a function of the distance r from NV and pulse width t_p , with (ii) Angle and radial distribution of effective on-site potential $\phi(r, \vartheta)$ for $t_p = 49.5 \,\mu s$. Zero crossing radius r_c is given by $r_c(\theta) \approx 3.4 \text{ nm} \times \sqrt[3]{|3 \cos(\theta)^2 - 1|}$. *Summary.*– In the case of the spin locking sequence at $\theta \neq \pi$, the spatially inhomogenous on-site potential induced by the NV spin only leads to a tilt in the spin locking axis but no qualitative change in the physics compared to the case of absent on-site potential. However, for spin locking at $\theta \approx \pi$ the strong NV-induced on-site potential also leads to spatially inhomogenous on-site potential in the effective Hamiltonian with a possible sign change in space. *Parameters.–* We choose Rabi frequency $\Omega = 10$ kHz, interpulse time $t_{\text{acq}} = 40 \,\mu s$ and for (B), (C) NV electron polarization $P = 0.1$.

In Eq. [\(S 22\)](#page-20-2) we additionally neglect the dipole-dipole coupling H_{dd} during the kicks, since its magnitude is much smaller compared to \mathcal{H}_x , i.e., $||\mathcal{H}_{dd}|| \ll ||\mathcal{H}_x||$. However, we consider the effective on-site potential during the kicks, since it can be of comparable strength at short distances from the NV, see also Fig. [S10](#page-20-3) (A) for a schematic of the on-site potential and other energy scales. Spins within a radius of ≤ 1.7 nm, indicated as a shaded area in Fig. $S10(A)$ $S10(A)$, are far detuned such that they are not contributing to the bulk dynamics and also cannot be measured by NMR experiments.

The kicked evolution in Eq. $(S 22)$ corresponds to a periodic (Floquet) evolution with period τ . Therefore, we can exploit Floquet's theorem, which states that stroboscopic dynamics $(t =$ $n\tau$, $n \in \mathbb{N}$) are described by an effective Hamiltonian

$$
U(n\tau) = U(\tau)^n = U_F^n \tag{S 24}
$$

with

$$
U_F = e^{-i\mathcal{H}t_{\text{acq}}}e^{-i\mathcal{H}_{\text{SL}}t_{\text{p}}} \equiv e^{-i\mathcal{H}_F\tau}.
$$
 (S 25)

Although the exact effective Hamiltonian H_F is, in general, a highly non-local object, analytical progress can be made by considering a high-frequency (small τ) expansion [\[71\]](#page-39-18) up to some order $O(\tau^n)$,

$$
\mathcal{H}_F = \sum_{n=0}^{\infty} \tau^n \mathcal{H}_F^{[n]} = \mathcal{H}_F^{(n)} + O(\tau^{n+1}), \quad (S\,26)
$$

valid up to some finite number of drive cycles. For sufficiently small period τ we expect that this Hamiltonian is a good description of the prethermal plateau [\[7,](#page-38-4)[8](#page-38-5)[,24](#page-38-21)[–26](#page-38-22)[,34,](#page-38-27)[71,](#page-39-18)[72\]](#page-39-19) observed in the experiment. Any deviations from the effective Hamiltonian are expected to result in Floquet heating to a featureless infinite temperature state at long times [\[40,](#page-38-34)[73\]](#page-39-20).

Before proceeding further, we outline the rest of this section and summarize the main results. We start with a description in Sec. [S7 A](#page-21-1) of the numerical algorithm used to support the analytical findings obtained in the rest of this section. Then, in Sec. S7B we will derive the effective Hamiltonian $\mathcal{H}_F^{(0)}$ to lowest order in the driving period τ . The derived effective Hamiltonians serve as the starting point of all other types of numerical and theoretical analysis.

Using a toggling frame expansion, we derive two effective Hamiltonians capturing the Floquet evolution at stroboscopic times for the two regimes of a kick-angle $\theta \neq \pi$ and near $\theta \approx \pi$ in the presence of the hyperfine splitting field η_i . In agreement with earlier findings [\[74,](#page-39-21)[75\]](#page-39-22), for $\theta \neq \pi$ we find that the effective Hamiltonian conserves the $\hat{\mathbf{x}}$ -polarization, while the hyperfine splitting η_i only leads to a quantitative change in axis $\hat{\mathbf{x}} \to \hat{\mathbf{x}}$. In the case, $\theta \approx \pi$, this conservation law is broken and the hyperfine splitting induces an effective spatially inhomogenous potential dominating the relaxation dynamics of the polarization.

In Sec. [S7 C](#page-23-1) we analyze the long-time dynamics generated by the derived effective Hamiltonians. We show that, for finite systems, the long-time expectation values are well described by ETH-like arguments. In particular, we find that, in the $\theta = \pi$ case, the local polarization follows the local on-site potential induced by the electron which can lead to a sign-inversion of the local polarization and hence – also of the integrated polarization. We close this section by introducing simplified toy-model effective Hamiltonians; they capture the main physics but, due to their reduced complexity, make the qualitative analysis easier to understand.

A. Exact diagonalization simulation

Throughout this section, we support our findings by numerically exact full Floquet simulations. However, these simulations are limited to small system sizes of $L=16$ spins. As we anticipate to find that the distance from the NV plays a crucial role, we will consider in the following a one-dimensional geometry to maximize the radial extension. Concretely, in this section we consider spins, labeled by $j = 1, \ldots, L$, to have positions on a one-dimensional chain described by $x_j = x_0 + a j + \delta x_j$, with lattice spacing $a = 1$, offset distance $x_0 = 5$, some independent identically distributed random displacements δx_i , drawn from a normal distribution $N(\mu=0, \sigma=0.01)$ with zero mean and standard deviation $\sigma = 0.01 a$. However, if not explicitly stated otherwise, we will consider the full Floquet evolution described by Eq. $(S 23)$, i.e. the spins interact via long-range interactions which decay as $1/r^3$ in the spin-spin distance r. In addition we choose $\Omega/J = 10$, $\delta \omega / J = 0$, $J t_{\text{acq}} = 0.1$ and t_{p} is chosen such that $\Omega t_p = \theta$ reproduces the desired angle θ , where *J* is the median coupling described below.

Fig. S11. **Spin Locking** $\theta \neq \pi$. Conservation of new spin direction (a) and the effective Hamiltonian H_{eff} [\(S 38\)](#page-22-3) (b) with respect to time evolved state $\tilde{I} = \langle \tilde{I} \rangle$ [\(S 39\)](#page-22-1) for different periods (colorbar). (c) Site resolved polarizations $\mathcal{I}_n = \langle \mathcal{I}_n \rangle$ for smallest period $J\tau = 10^{-3}$ at late times; circles correspond to simulation results and lines are the results from ETH arguments, Eq. [\(S 43\)](#page-24-1). Details of simulation are described in Sec. [S7 A.](#page-21-1) *Summary.–* The Floquet dynamics for intermediate times are well described by the effective Hamiltonian Eq. [\(S 38\)](#page-22-3) and the late time expectation value is in agreement with the ETH analysis, Eq. [\(S 45\)](#page-24-2). Deviations from the effective Hamiltonian description are parametrically suppressed in the driving period.

The median coupling J serves as an experimentally observable measure for the energy scale of the system, determined as the inverse $1/e$ decay time of a $\hat{\mathbf{x}}$ -polarized initial state in the absence of spin locking. Therefore, we can match numerics qualitatively with experimental results by re-expressing our quantities with this time scale.

B. Derivation of Floquet Hamiltonians

A common technique to derive the lowest-order Floquet Hamiltonian is the so-called *Floquet Magnus expansion* [\[76\]](#page-39-23) which here is equivalent to using the Baker-Campbell-Hausdorff (BCH) formula [\[77\]](#page-39-24):

$$
\exp(A)\exp(B) = \exp(A+B) + O(||A|| \cdot ||B||), \quad (S\,27)
$$

which is a good approximation if $||A||, ||B|| \ll 1$. However, with $||\mathcal{H}_{SL}t_p|| > 1$, as $\Omega t_p > 1$, this assumption is not met; moreover all powers $\mathcal{H}_{\text{SL}}^n$, $n = 0, 1, \ldots$, of $\mathcal{H}_{\text{SL}}^n$ are of similar magnitudes $||\mathcal{H}_{SL}||^n \approx ||\mathcal{H}_{SL}||^1$. Therefore, we cannot directly apply the BCH Formula [\(S 27\)](#page-21-2) but would formally need to resum an infinite number of contributions stemming from the kicks. To this end, we will perform a so-called toggling frame transformation.

Notice also that, in the vicinity of the NV centre, the magnetic on-site potential contribution from the NV is strong compared to the dipole-dipole couplings between the nuclear spins. Since these terms commute, $[\mathcal{H}_{dd}, \mathcal{H}_{pot}] = 0$, we can separate them into two exponentials $e^{-iHt} = e^{-i\mathcal{H}_{\text{dot}}t}e^{-i\mathcal{H}_{\text{pot}}t}$; hence, we can combine all strong contributions into a single one-particle unitary

where we defined $\mathcal{H}_{\text{SP}} t_{\text{acq}} = \sum_j \theta_j \hat{\mathbf{n}}_j \cdot \mathbf{I}_j$ with

$$
\theta_j = 2 \arccos \left[\cos(\alpha_j/2) \cos(\eta_j t_{\text{acq}}/2) - \frac{\eta_j t_p}{\alpha_j} \sin(\alpha_j/2) \sin(\eta_j t_{\text{acq}}/2) \right],
$$
 (S.29)

and $\alpha_j = t_p \sqrt{\Omega^2 + \eta_j^2}$. The components of the normalized direction vector $\hat{\mathbf{n}}_j = n_j^x \hat{\mathbf{x}} + n_j^y$ y_j^y \hat{y} + n_j^z \hat{z} are given by

$$
n_j^x = \frac{\Omega t_p}{\alpha_j} \frac{\sin(\alpha_j/2)\cos(\eta_j t/2)}{\sin(\theta_j/2)},
$$

\n
$$
n_j^y = \frac{-\Omega t_p}{\alpha_j} \frac{\sin(\alpha_j/2)\sin(\eta_j t/2)}{\sin(\theta_j/2)},
$$

\n
$$
n_j^z = \frac{\eta_j t_p}{\alpha_j} \frac{\sin(\alpha_j/2)\cos(\eta_j t/2)}{\sin(\theta_j/2)} + \frac{\cos(\alpha_j/2)\sin(\eta_j t/2)}{\sin(\theta_j/2)}.
$$

\n(S 30)

1. Spin locking for state engineering ($\theta \neq \pi$)

We can account for the strong kicks by transforming to the toggling frame considering the unitary evolution over N cycles

$$
U^{N} = \prod_{\ell=1}^{N} e^{-it_{\text{acq}} \mathcal{H}_{\text{dd}}} U_{\text{SP}}
$$

= $U_{\text{SP}}^{N} \prod_{\ell=1}^{N} U_{\text{SP}}^{-\ell} e^{-it_{\text{acq}} \mathcal{H}_{\text{dd}}} U_{\text{SP}}^{\ell}$ (S 31)
= $U_{\text{SP}}^{N} \prod_{\ell=1}^{N} e^{-it_{\text{acq}} \mathcal{H}_{\text{dd},\ell}}$,

where in the second line we introduced N identities $U_{SP}^{-k}U_{SP}^{k}$ =1 and in the last line we defined the rotated Hamiltonians $\tilde{H}_{dd,\ell} = U_{\rm SP}^{-\ell} \mathcal{H}_{dd} U_{\rm SP}^{\ell}$.

Notice that $\|\tilde{H}_{dd,\ell}\| = ||\mathcal{H}_{dd}||$ since they are related by a unitary transformation. Therefore, all contributions in the final expression in Eq. $(S31)$ are small, so we can apply the BCH formula $(S 27)$ to obtain

$$
\mathcal{H}_{\text{eff}}^{\theta \neq \pi} = \sum_{j=1}^{L} \frac{(\theta_j N) \text{mod} (2\pi)}{N} \hat{\mathbf{n}}_j \mathbf{I}_j + \mathcal{H}_{F, \text{dd}}^{(0)},
$$
(S 32)

where $\mathcal{H}_{F,\text{dd}}^{(0)} = \sum_{\ell=1}^{N} \tilde{\mathcal{H}}_{\text{dd},\ell}$. In the following, we will evaluate the second term in Eq. [\(S 32\)](#page-22-5) explicitly in the limit of a large number of cycles $N \rightarrow \infty$. To this end, let us first write the dipole-dipole term as

$$
\mathcal{H}_{dd} = \sum_{k < l} b_{kl} \mathbf{I}_k^T \mathbf{D} \mathbf{I}_k \tag{S.33}
$$

where T denotes transpose, and we introduced the diagonal matrix $D = (-\hat{x}\hat{x}^T + \hat{y}\hat{y}^T + 2\hat{z}\hat{z}^T)$. Then, the action of U_{SP} amounts to the matrix-vector product:

$$
U_{\rm SP}^{-\ell} \mathbf{I}_j U_{\rm SP}^{\ell} = \mathbf{r}(\ell \theta_j, \hat{\mathbf{n}}_j) \mathbf{I}_j , \qquad (S \, 34)
$$

with the 3×3 rotation matrix $\mathbf{r}(\theta, \hat{\mathbf{n}})$ rotating about the axis $\hat{\mathbf{n}}$ by the angle θ . Hence, we have $\sum_{\ell=1}^{N} \tilde{H}_{dd,\ell} = \sum_{k < l} b_{kl} I_k M_{kl} I_l$, with the matrix $M_{kl} = N^{-1} \sum_{\ell=1}^{N} \mathbf{r}^T (\ell \theta_k, \hat{\mathbf{n}}_k) \mathbf{D} \mathbf{r}(\ell \theta_l, \hat{\mathbf{n}}_l).$

In order to evaluate M_{kl} , we make use of the Rodrigues representation of rotation matrices:

$$
\mathbf{r}(\theta, \hat{\mathbf{n}}) = \hat{\mathbf{n}} \hat{\mathbf{n}}^T + \cos(\theta) (1 - \hat{\mathbf{n}} \hat{\mathbf{n}}^T) + \sin(\theta) \epsilon(\hat{\mathbf{n}}),
$$
 (S 35)

where $\epsilon_{ij}(\hat{\mathbf{n}}) = \sum_{k} \epsilon_{ikj} \hat{\mathbf{n}}_{k}$ and ϵ_{ijk} is the fully antisymmetric Levi-Civita symbol. Thus, M_{kl} reads as

$$
M_{kl} = \frac{1}{N} \sum_{\ell=1}^{N} \Biggl(\left[\hat{\mathbf{n}}_{k} \hat{\mathbf{n}}_{k}^{T} + \cos(\ell \theta_{k}) (1 - \hat{\mathbf{n}}_{k} \hat{\mathbf{n}}_{k}^{T}) + \sin(\ell \theta_{k}) \epsilon(\hat{\mathbf{n}}_{k}) \right] - D \left[\hat{\mathbf{n}}_{l} \hat{\mathbf{n}}_{l}^{T} + \cos(\ell \theta_{l}) (1 - \hat{\mathbf{n}}_{k} \hat{\mathbf{n}}_{l}^{T}) + \sin(\ell \theta_{l}) \epsilon(\hat{\mathbf{n}}_{l}) \right] \Biggr).
$$
\n(S 36)

The sums of the sin and cos contributions in M_{kl} can be evaluated as

$$
\mathcal{G}_{s}(N,\theta) = \sum_{j=1}^{N} \sin(j\theta) = \frac{\sin(N\theta/2)}{N\sin(\theta/2)} \sin((N-1)\theta/2),
$$

$$
\mathcal{G}_{c}(N,\theta) = \sum_{j=1}^{N} \sin(j\theta) = \frac{\sin(N\theta/2)}{N\sin(\theta/2)} \cos((N-1)\theta/2).
$$
(S 37)

Using the relation $\lim_{N\to\infty} G_{s,c}(N,\theta) = 0$ for $\theta \neq 2\pi k$, $k \in \mathbb{N}$, all contributions appearing in Eq. [\(S 36\)](#page-22-6) which are not proportional to unity, $cos(\theta_i) cos(\theta_k)$, or $sin(\theta_i) sin(\theta_k)$ vanish in the large N limit.

In summary, in the large N limit, we find the following expression for the leading-order Floquet Hamiltonian:

$$
\mathcal{H}_{\text{eff}}^{\theta \neq \pi} = \sum_{k} \frac{(\theta_k N) \text{mod} (2\pi)}{N} \hat{\mathbf{n}}_k \cdot \mathbf{I}_k + \sum_{k < l} b_{kl} \mathbf{I}_k \mathbf{M}_{kl}^{(0)} \mathbf{I}_l \,,
$$
\n(S.38)

with

$$
M_{kl}^{(0)} = \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T D \hat{\mathbf{n}}_l \hat{\mathbf{n}}_l^T + \mathcal{G}_c(\Delta_{kl}\theta) (1 - \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T) D (1 - \hat{\mathbf{n}}_l \hat{\mathbf{n}}_l^T) + \mathcal{G}_c(\Delta_{kl}\theta) \epsilon (\hat{\mathbf{n}}_k)^T D \epsilon (\hat{\mathbf{n}}_l).
$$

Notice that Eq. $(S 38)$ is invariant under the basis transformation $U(\theta) = \exp(-i\theta \sum_k \hat{\mathbf{n}}_k I_k)$ for any θ . This can be immediately checked by applying the transformation rules

$$
\left(1 - \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T\right) \boldsymbol{I}_k \stackrel{U(\theta)}{\longrightarrow} \cos(\theta) \left(1 - \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T\right) \boldsymbol{I}_k + \sin(\theta) \epsilon(\hat{\mathbf{n}}_k) \boldsymbol{I}_k ,
$$

$$
\epsilon(\hat{\mathbf{n}}_k) \boldsymbol{I}_k \stackrel{U(\theta)}{\longrightarrow} -\sin(\theta) \left(1 - \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T\right) \boldsymbol{I}_k + \cos(\theta) \epsilon(\hat{\mathbf{n}}_k) \boldsymbol{I}_k ,
$$

$$
\hat{\mathbf{n}}_k^T \boldsymbol{I}_k \stackrel{U(\theta)}{\longrightarrow} \hat{\mathbf{n}}_k^T \boldsymbol{I}_k ,
$$

to Eq. [\(S 38\)](#page-22-3), leading to $\mathcal{H}_F^{(0)}$ $\stackrel{U(\theta)}{\longrightarrow} H_F^{(0)}$. Therefore, the total rotated polarization

$$
\widetilde{I} = \sum_{k} \hat{\mathbf{n}}_{k} \cdot \mathbf{I}_{k},
$$
 (S 39)

is a quasi-conserved quantity, i.e. $[\tilde{I}, \mathcal{H}_{\text{eff}}^{\theta \neq \pi}] = 0$.

In the absence of the local on-site potential from the NV $(\eta_i=0)$, which enters the expression for $\hat{\mathbf{n}}_k$, the conserved quantity simplifies to the total $\hat{\mathbf{x}}$ -polarization, $\overline{I} = I_{x}$. This is consistent with previous expressions [\[74,](#page-39-21)[75\]](#page-39-22) where the spatially-dependent on-site potential of the NV was neglected. By contrast, in the

Fig. S12. **Spin Locking at** $\theta \approx \pi$ – (a) (i) Exact Floquet evolution for $L =$ 16 spins $\hat{\mathbf{x}}$ -polarization $\langle \sigma_n^x \rangle$ (*t*) of each spin, indexed by *n*, as a function of time. (ii) Same as (i) but for effective Hamiltonian [\(S 41\)](#page-23-2). (b) Total **x**ˆpolarization $I_x = \sum_{n=1}^{N} \langle \sigma_n^x \rangle$ as a function of time for Floquet (blue) and effective Hamiltonian (orange) evolution. (c) Spatially resolved late time expectation value of the \hat{x} -polarization for Floquet (blue crosses) and effective Hamiltonian (orange pluses) evolution compared to the ETH thermal expectation values (black circles) with finite inverse temperature $\beta \approx -0.45$ J. Error bars correspond to standard deviation around mean value over the last 1000 cycles. *Summary*– The Floquet evolution is well described by the effective Hamiltonian approach for all considered times. Moreover, pre-thermalization follows the predictions from ETH arguments for the effective Hamiltonian as discussed around Eq. [\(S 50\)](#page-24-3). *Parameters–See Sec.* [S7 A](#page-21-1) and $Jt_p \approx 0.341$ is chosen such that the crossing appears at the $n = 7$ spin.

presence of the NV-induced on-site potential $(\eta_i \neq 0)$, the conserved quantity is locally tilted away from the **x**ˆ-axis close to the NV, see Fig. $S10(b)$ $S10(b)$ and Fig. $S11(c)$ $S11(c)$.

In Fig. $S11(a,b)$ $S11(a,b)$ we compare the dynamics generated by the lowest order Floquet Hamiltonian $\mathcal{H}_F^{(0)}$ derived above, against the exact kicked quantum simulation performed for $L=16$ spin; in particular, we measure the conservation of the effective axis and the effective Hamiltonian. We find that both quantities are conserved up to errors which parametrically scale down in t_{aco} , as expected from the regime of validity of the lowest order approximation.

In summary, the presence of the NV-induced on-site potential η_i only leads to minor quantitative corrections to the spin-locking sequence far away from $\theta = \pi$. In the next section, we show that this is not true for spin locking in the vicinity of $\theta = \pi$, where the situation is much more intriguing.

2. Spin locking for Hamiltonian engineering ($\theta \approx \pi$)

The analysis performed in Sec. [S7 B 1](#page-22-0) breaks down as the spatially-dependent kick-angle θ_i , see Eq. [\(S 29\)](#page-22-2), approaches π , as we can no longer assume $\lim_{N\to\infty} G_{s,c}(N,\theta)=0$. In this section, we will analyze this case in detail.

Let us first focus on the fine-tuned case $\theta = \pi$. Notice that, for $\theta = \pi$ the kick unitary squares to the identity, $U_{\text{kick}}^2 = 1$. Therefore, the toggling frame unitary from Eq. $(S31)$,

$$
U^N = U_{\rm SP}^N \prod_{n=1}^N U_{\rm SP}^{-n} e^{-i \mathcal{H}_{\rm dd} t_{\rm acq}} U_{\rm SP}^n\,,
$$

reduces to

$$
U^N = \prod_{n=1}^{N/2} e^{-i\mathcal{H}t_{\text{acq}}} U_{\text{SP}}^\dagger e^{-i\mathcal{H}_{\text{dd}}t_{\text{acq}}} U_{\text{SP}}.
$$

Thus, at exactly $\theta = \pi$ the lowest order Floquet Hamiltonian is simply given by

$$
\bar{H} \equiv \frac{1}{2} \Big(\mathcal{H}_{dd} + U_{SP}^{\dagger} \mathcal{H}_{dd} U_{SP} \Big). \tag{S.40}
$$

If $\theta \approx \pi$ but not exactly π , we may split the unitary $U_{\text{SP}} = \exp(-i\delta\theta \hat{\mathbf{n}} \cdot \mathbf{I}) \exp(-i\pi \hat{\mathbf{n}} \cdot \mathbf{I})$ into a $\theta = \pi$ and a $\delta\theta = (\theta - \pi)$ contribution. Notice that the $\delta\theta$ -contribution is small by assumption. Hence, to lowest order $O(\delta\theta, J\tau)$ we may include this contribution into the dipole-dipole Hamiltonian $\exp(-i\mathcal{H}_{dd}t_{acq}) \rightarrow \exp(-i[\mathcal{H}_{dd}t_{acq} + \delta\theta \hat{\mathbf{n}} \cdot \mathbf{I}]) + O(\delta\theta, J\tau)$. Thus, the lowest-order toggling frame expansion reads as

$$
\mathcal{H}_{\text{eff}}^{\theta \approx \pi} = \bar{H} + \sum_{k=1}^{L} \phi_{\text{eff},k} \cdot \bm{I}_k , \qquad (S.41)
$$

where $\phi_{\text{eff},k} = \delta \theta_k \hat{\mathbf{n}}_k / \tau$.

Let us emphasize that around $\theta = \pi$ the effective Hamiltonian does not conserve the (tilted) total net polarization $\sum_{k=1}^{L} \phi_{\text{eff},k} \cdot I_k$. This is in stark contrast to the results for spin locking far away from $\theta = \pi$, see discussion after Eq. [\(S 39\)](#page-22-1).

In Fig. [S12](#page-23-3) we compare the exact Floquet Evolution at $\theta \approx \pi$ with the effective Hamiltonian evolution $(S 41)$ for a system of $L=16$ spins. The effective Hamiltonian dynamics capture the exact Floquet evolution for all observed times. At even longer times we expect Floquet heating to become dominant, leading to a heat death of the Floquet system; notice that this does not happen in the dynamics generated by the effective Hamiltonian shown in Fig S₁₂.

C. Analysis based on the Eigenstate Thermalization Hypothesis

Any generic many-body system is expected to thermalize according to the eigenstate-thermalization hypothesis [\[1,](#page-38-0)[3,](#page-38-1)[22\]](#page-38-19) (ETH). As a periodically driven system does not conserve energy it is expected to thermalize to a featureless, infinite temperature state \propto 1 for long times [\[78](#page-39-25)[–80\]](#page-39-26). However, heating is suppressed at high driving frequency, leading to a separation of time scales in the high-frequency regime and to the build-up of a so-called prethermal plateau [\[40,](#page-38-34) [73\]](#page-39-20): the system first (pre-)thermalizes with respect to the low order effective Hamiltonian, before eventually fully thermalizing at long times towards the infinite temperature state.

In this section, we analyze the prethermal plateau characterized by the effective Hamiltonians derived in Sec. [S7 B.](#page-21-0) ETH suggests that if a system evolves under some generic unitary evolution $U(t)$, and this unitary preserves some local operators ${O_i}^{no}$ $_{j=1}^{n_O}$, then the system is expected to thermalize to a state which is locally equivalent to

$$
\rho(\lambda_1, \ldots, \lambda_{n_O}) = e^{\sum_{j=1}^{n_O} \lambda_j O_j} / Z, \qquad (S 42)
$$

where $Z = \text{Tr}(e^{\sum_{j=1}^{n} \lambda_j O_j})$. The parameters $\lambda_1, \ldots, \lambda_{n_Q}$ are Lagrange multipliers fixed by the initial conditions using the self-consistency relation

$$
\left\langle O_j \right\rangle_{\psi_0} \stackrel{!}{=} \text{Tr}(\rho(\lambda_1, \ldots, \lambda_{n_O}) O_j),
$$

where $|\psi_0\rangle$ is the initial state.

Thermalization at $\theta \neq \pi$. – In the regime $\theta \neq \pi$, both the effective Hamiltonian $\mathcal{H}_F^{(0)}$ and the rotated polarization \widetilde{I}_x are (prethermally, i.e., quasi-) conserved quantities, as $\left[\tilde{I}_x, \mathcal{H}_F^{(0)}\right] = 0$ (see discussion around Eq. [\(S 39\)](#page-22-1)). Therefore, using Eq. [\(S 42\)](#page-23-4) expectation values of local observables in the (pre-)thermal plateau are obtained from

$$
\rho_{\theta \neq \pi}(\beta, \mu) = e^{-\beta \mathcal{H}_{F, \text{dd}}^{(0)} + \mu \widetilde{I}_x} / Z, \qquad (S 43)
$$

where we collected all contributions $\alpha \widetilde{I}_x$ and with $Z = Tr(e^{-\beta \mathcal{H}_{F,\text{dd}}^{(0)} + \mu \tilde{I}_x})$. The parameters β and μ are fixed by the energy and polarization of the initial state $|\psi_0\rangle$:

$$
\left\langle \mathcal{H}_F^{(0)} \right\rangle_{\psi_0} = \text{Tr} \left\{ \mathcal{H}_F^{(0)} \rho_{\theta \neq \pi} \right\}
$$
\n
$$
\left\langle \widetilde{I}_x \right\rangle_{\psi_0} = \text{Tr} \left\{ \widetilde{I}_x \rho_{\theta \neq \pi} \right\}. \tag{S 44}
$$

In particular, the local polarizations $\langle \sigma_n^{\alpha} \rangle$, $n = 1, \dots L$ and $\alpha = x, y, z$, at long times are expected to be described by the thermal expectation value

$$
I_n^{\alpha} = \langle I_n^{\alpha} \rangle = \text{Tr}\big(I_n^{\alpha} \rho_{\theta \neq \pi}(\beta, \mu)\big)
$$

\n
$$
\approx \text{Tr}\Big(I_n^{\alpha} e^{\mu \widetilde{I}_x}/Z\Big)
$$

\n
$$
= \hat{\mathbf{n}}_n^{\alpha} \tanh(\mu/2), \qquad (S 45)
$$

where we used in the second line, that β is expected to be small, β \ll 1. Further we exploit the tracelessness of all non-trivial pauli strings

$$
\operatorname{Tr}(\sigma^{\mu} \otimes \sigma^{\nu} \otimes \dots \sigma^{\rho}) \neq 0 \Longleftrightarrow \sigma^{\mu} = \sigma^{\nu} = \dots = \sigma^{\rho} = 1. \tag{S 46}
$$

Therefore, the spins also locally align with the rotated axis $\hat{\mathbf{n}}_n$, i.e.

$$
\frac{T_n}{\|T_n\|} = \hat{\mathbf{n}}_n. \tag{S.47}
$$

In Fig. $S11(c)$ $S11(c)$ we compare the numerically exact, Floquet dynamics at long times against the results expected from the ETH analysis (Eq. $(S 47)$). We find excellent agreement between the numerical Floquet evolution results and the analytical predictions in Eq. [\(S 47\)](#page-24-4).

Thermalization around $\theta = \pi$. – In the regime $\theta \approx \pi$ only the Hamiltonian $\mathcal{H}_{\text{eff}}^{\theta \approx \pi}$ is conserved in the prethermal plateau. Thus, the (pre-)thermal steady state for a finite system at long times is expected to be locally equivalent to the thermal density matrix

$$
\rho_{\pi}(\beta) = e^{-\beta \mathcal{H}_{\text{eff}}^{\theta \approx \pi}} / Z, \qquad (S 48)
$$

where $Z = \text{Tr}(e^{-\beta \mathcal{H}_{\text{eff}}^{\theta \approx \pi}})$. The inverse temperature β is determined due to (prethermal) energy conservation by the energy expectation in the initial state $|\psi_0\rangle$:

$$
\langle \psi_0 | \mathcal{H}_{\text{eff}}^{\theta \approx \pi} | \psi_0 \rangle \stackrel{!}{=} \text{Tr} \Big(\mathcal{H}_{\text{eff}}^{\theta \approx \pi} \rho_{\pi}(\beta) \Big). \tag{S.49}
$$

Notice that this so-called temperature is an intrinsic property of the evolution and the initial state, and is not related to the actual temperature the experiment is operated at.

Using a high-temperature, $\beta \left\| \mathcal{H}_{\text{eff}}^{\theta \approx \pi} \right\| \ll 1$, expansion of the density matrix $\rho_{\pi} \approx (1 - \beta \mathcal{H}_{\text{eff}}^{\theta \approx \pi})/Z$, where now $Z = \text{Tr}(1) =$ 2^L , in Eq. (S48) we can compute the local polarization

$$
I_n^{\alpha} = \text{Tr}(\rho_{\pi} I_n^{\alpha})
$$

\n
$$
\approx -\beta \text{Tr} \left(\mathcal{H}_{\text{eff}}^{\theta \approx \pi} I_n^{\alpha} \right) / Z
$$

\n
$$
= -\beta \phi_{\text{eff},n}^{\alpha} / 2
$$

\n
$$
\propto \phi_{\text{eff},n}^{\alpha},
$$
 (S 50)

where we used in the last equality the definition of $\mathcal{H}_{\text{eff}}^{\theta \approx \pi}$, Eq. $(S 41)$, and tracelessness of all non-trivial pauli-strings, Eq. [\(S 46\)](#page-24-6). In addition, the inverse temperature can be obtained similarly from Eq. $(S 49)$

$$
\beta = -\frac{\langle \psi_0 | \mathcal{H}_{\text{eff}}^{\theta \approx \pi} | \psi_0 \rangle}{\text{Tr} \left(\mathcal{H}_{\text{eff}}^{\theta \approx \pi} \mathcal{H}_{\text{eff}}^{\theta \approx \pi} \right) / Z} \,. \tag{S 51}
$$

In Fig. [S12\(](#page-23-3)c) we compare the exact long time steady states for numerically exact Floquet and Hamiltonian evolution with the thermal expectation value Eq. $(S 50)$. We find excellent agreement between all three methods. In particular, let us emphasize that due to $\phi_{\text{eff},n}^{\alpha} \propto \delta \theta_n = \theta_n - \pi$ the effective magnetic on-site potential acting on the spins experiences a sign change around $\theta_n = \pi$ as a function of the distance from the NV. Therefore, since $\langle I_n^{\alpha} \rangle \propto \phi_{\text{eff},n}^{\alpha}$, see Eq. [\(S 50\)](#page-24-3), the final polarization profile is inhomogenous in space and can have positive and negative distribution although the initial state is fully positively polarized. This is a key result of this work as it allows for engineering desired non-homogeneous states via Hamiltonian-engineering. We will

D. Estimating the crossing radius r_c

In the previous section we have shown that combining Floquet engineering with ETH-like arguments leads to a (pre-)thermal steady states which has a spatially inhomogenous polarization profile with positive and negative contributions. In particular the polarization profile follows the effective on-site potential $I_n^{\alpha} \propto \phi_{\text{eff},n}^{\alpha}$, which in turn is determined by the microscopic on-site potential B_n induced by the NV electron and the kick angle θ via Eq. [\(S 29\)](#page-22-2). Therefore, by tuning the kick-angle θ close to $\theta = \pi$ we can engineer states with robust domain-wall like spatial polarization profiles. The boundary of the domain wall is given by the crossing radius r_c which defines the distance from the NV at which the spatial profile has zero polarization

$$
\phi(r = r_{\rm c}) \equiv 0. \tag{S 52}
$$

It is directly obtained from setting $||\phi_{\text{eff}}(r)|| = 0$, i.e. $\delta \vartheta(r)$ r_c) = 0. Using Eq. [\(S 29\)](#page-22-2) we find the implicit equation for the crossing radius

$$
\tan\left(\frac{t_{\rm p}\sqrt{\Omega^2+\eta(r)^2}}{2}\right)\tan\left(\frac{\eta(r)t_{\rm acq}}{2}\right)=\frac{\sqrt{\Omega^2+\eta(r)^2}}{\eta(r)}\,. \tag{S.53}
$$

Fig. S13. **Estimation of Crossing Radius:** Estimated crossing radii r_c as functions of the kick angle θ for experimental data in Fig. [4,](#page-4-0) obtained as described in Sec. [S7 D.](#page-24-0) *Inset:* Estimated number of spins within crossing radius for given kick angle θ . *Summary*. – We can use the kick angle θ to tune the microscopic structure of the polarization profile.

Note that in 3D the on-site potential $\eta = \eta(r, \vartheta)$ has a radial and angular dependence. However, if the detuning δ vanishes, which we generally assume to be the case, the angular dependence for the crossing radius simply reduces to a multiplicative factor $r_c(\theta) = r_{c,0} \times \sqrt[3]{|3 \cos^2(\theta) - 1|}$, where $r_c(\theta)$ is determined from setting $\sqrt[3]{|3\cos^2(\vartheta)-1|} = 1$.

Using the parameters in the experiment, Fig. [4,](#page-4-0) i.e. the Rabi frequency $\Omega \approx 50$ kHz and $t_{\text{acq}} \approx 51 \,\mu s$ we can estimate the crossing radius for the different pulse widths t_p , i.e. different kick angles $\theta = \Omega t_{\rm p}$, which lead to a spin-polarization inversion. The results are shown in Fig. [S13.](#page-25-2) There we also estimated the average number of spins $N_{r \le r_c}$ which are within the crossing radius, using a ¹³C-spin density of $\approx 1/nm^3$. For example using $\theta = 94 \pi$ we find a crossing radius of $r_c(\theta) \approx 2.8 \times \sqrt[3]{|3 \cos^2(\theta) - 1|}$ encompassing on average around \approx 150 spins. Let us emphasize, that the results above are not limited to finite size systems and are also expected to hold in the thermodynamic limit.

E. Simplifications

In this section we repeatedly found that the non-equilibrium dynamics for intermediate times are well-captured by effective Hamiltonians, in particular Eqs. $(S 38)$ and $(S 41)$, derived using a high-frequency expansion. Therefore, in the following, we consider only time-evolution generated by these time-independent effective Hamiltonians. The corresponding results are expected to describe the intermediate time dynamics well but ignore any Floquet heating effects. However, Floquet heating will only lead to an onset of slow homogeneous decay of all local observables at times beyond the prethermal plateau.

Moreover, in the following, we will consider simplified versions of the effective Hamiltonians derived above. While the details of Eqs. $(S 38)$ and $(S 41)$ are needed to derive quantitative results, like the crossing radius, Eq. $(S 52)$, their key qualitative properties can be described by simplified models. In particular, the key property of Eq. $(S38)$ is the conservation of a (tilted) global polarization, see discussion around Eq. [\(S 39\)](#page-22-1). However, the tilt leads to only minor quantitative changes in the exact dynamics so we can neglect the tilt for a qualitative understanding of the dynamics. Analogously, the main properties of Eq. [\(S 41\)](#page-23-2) consist in the absence of a conserved polarization axis and in the presence of a spatially inhomogeneous on-site potential which can take positive and negative values and is not conserved by the Hamiltonian.

Therefore, in what follows, we will study the simplified effective Hamiltonians

$$
\mathcal{H}_{\text{eff}}^{\theta \neq \pi} \approx \sum_{j < k} J_{jk} \left(\frac{3}{2} \left[I_j^z I_k^z + I_j^y I_k^y \right] - \mathbf{I}_j \cdot \mathbf{I}_k \right), \tag{S 54}
$$

for the regime far away from $\theta \approx \pi$, and

$$
\mathcal{H}_{\text{eff}}^{\theta \approx \pi} \approx \sum_{j < k} J_{jk} \left(3I_j^z I_k^z - \mathbf{I}_j \cdot \mathbf{I}_k \right) + \sum \phi_k I_k^x \tag{S 55}
$$

for $\theta \approx \pi$, where we also dropped the eff subscript on the onsite potential and removed all terms not poiting along the \hat{x} direction. Moreover, in the following we will not use the exact expression for ϕ_k given below Eq. [\(S 41\)](#page-23-2), but rather use different approximations including the various properties of ϕ_k without using the complicated exact expression.

S8. ONE-DIMENSIONAL APPROXIMATE QUANTUM DYNAMICS

While the ETH analysis outlined in Sec. $S7C$ is able to explain some aspects of the experimentally observed signatures, it fails, for instance, to explain the slow transient dynamics.

To fully understand the qualitative physics behind the experimentally observed signatures, we need a more comprehensive theory that takes into account the effects of both diffusion and dissipation. The description of diffusive effects requires large systems which typically exceed those accessible in an exact diagonalization (ED) approach by at least one order of magnitude. To circumvent the system size constraint imposed by ED, several algorithms were introduced in the context of approximate quantum simulations and dynamics [\[44](#page-38-38)[,81](#page-39-27)[–87\]](#page-39-28).

In this work, we employ a new algorithm – the localinformation time-evolution (LITE) algorithm – that was recently developed by some of the authors to deal with the outof-equilibrium transport of one-dimensional systems [\[44,](#page-38-38) [45\]](#page-38-39). The crucial difference with respect to other algorithms is that LITE preserves all local constants of motion with a support below a specified truncation scale. In the following, we apply LITE to perform a series of numerical simulations using a one-dimensional short-range toy model akin to the true longrange three-dimensional experimental Hamiltonians of the different regimes (i.e., the different effective Hamiltonians found in Sec. [S7\)](#page-20-0).

In Subsec [S8 A](#page-26-0) we give a brief introduction to the LITE algorithm. We then study the two approaches of Hamiltonian Engineering and State Engineering in great detail in Subsecs. [S8 B](#page-27-1) and [S8 C,](#page-32-0) respectively. We close this section by a short comparison between the two cases, Subsec [S8 D,](#page-33-4) and a brief summary, Subsec [S8 E.](#page-34-0)

A. Introduction to the LITE algorithm

Let us briefly outline the basic concepts behind the LITE algorithm. For a detailed introduction to the topic we refer the reader to Refs. [\[44,](#page-38-38)[45\]](#page-38-39). Our goal is to solve the von Neumann equation

$$
\partial_t \rho = -i[\mathcal{H}, \rho], \qquad (S.56)
$$

for the density matrix ρ under the generic local Hamiltonian . The algorithm uses a decomposition of the full system into smaller subsystems. Each subsystem can be characterised by two indices, ℓ and n . The integer number ℓ denotes the scale or range of the subsystem, i.e., one plus the number of neighboring sites within the subsystem under consideration. The integer or half-integer number n defines the center of the subsystem. For example, the subsystem C_n^{ℓ} is defined by the $\ell+1$ spins centered around the physical lattice site n . By virtue of partial trace operations, one can write the von Neumann equation for the subsystem C_n^{ℓ} as

$$
\partial_t \rho_n^{\ell} = -i \left[H_n^{\ell}, \rho_n^{\ell} \right]
$$
 (S 57)
- $i \text{Tr}_L \left(\left[\mathcal{H}_{n-1/2}^{\ell+1} - \mathcal{H}_n^{\ell}, \rho_{n-1/2}^{\ell+1} \right] \right)$
- $i \text{Tr}_R \left(\left[\mathcal{H}_{n+1/2}^{\ell+1} - \mathcal{H}_n^{\ell}, \rho_{n+1/2}^{\ell+1} \right] \right).$

Here, ρ_n^{ℓ} (\mathcal{H}_n^{ℓ}) denotes the subsystem density matrix (subsystem Hamiltonian) associated with C_h^{ℓ} . Note that Tr_L and Tr_R denote partial trace operations over the leftmost (L) and the rightmost (R) spin, respectively. In Eq. [\(S 57\)](#page-26-1) we have assumed a nearest neighbor Hamiltonian. To solve Eq. [\(S 57\)](#page-26-1), we require knowledge of the density matrices of the subsystems C_n^{ℓ} , $C_{n+1/2}^{\ell+1}$, and $C_{n-1/2}^{\ell+1}$. Thus, Eq. [\(S 57\)](#page-26-1) is not closed, and to solve the equations of motion for the subsystem C_n^{ℓ} we need to solve them for higher level subsystems as well. Therefore, the problem is as complex as the one in Eq. $(S 56)$.

The LITE algorithm solves Eq. $(S 57)$ at a subsystem scale ℓ^* smaller than the original system size. This is done in a twostep approach: First, if quantum entanglement is only present at small scales $\langle \ell^* \rangle$, thanks to Petz recovery maps [\[88\]](#page-39-29), we can exactly recover the density matrices at scales $\geq \ell^*$ from the density matrices at scale ℓ^* and numerically solve Eq. [\(S 57\)](#page-26-1) for a small time increment δt . Over time, entanglement spreads and quantum mutual information builds up on increasing scales. Thus, to continue the time-evolution using the above recipe, the scale ℓ^* , which is the length at which we solve the equations of the kind of $(S 57)$, has to be increased accordingly.

The important second step of the algorithm is activated when ℓ^* has reached a maximum length scale ℓ_{max} (which is the largest value we are able to handle efficiently, given a fixed amount of computation power and time) and a finite portion q_{max} of the total information has accumulated at $\ell_{\rm max}$. Then, the algorithm removes mutual information at a truncation length $\ell_{\min} < \ell_{\max}$ so that time evolution can be continued without further increasing ℓ^* , and the entanglement blockade can be (approximately) bridged. Importantly, this removal of quantum information has to be done so that the density matrices in the smaller subsystem, as well as the information currents, remain unaffected. In contrast to many other established algorithms (such as those based on the time-dependent variational principle [\[81–](#page-39-27)[84\]](#page-39-30) or time-evolving block decimation [\[89–](#page-39-31)[93\]](#page-39-32)), all steps involved in the present algorithm preserve all local constants of motion up to scale ℓ_{\min} . This makes LITE particularly well suited to investigate hydrodynamics effects. The truncation length ℓ_{\min} is the most important parameter of the algorithm, and should be chosen as large as possible (while keeping $\ell_{\min} < \ell_{\max}$); q_{\max} , instead, has to be empirically chosen. For the model investigated in the present study, we find $q_{\text{max}} \sim 1\%$ as the optimal value. For a detailed introduction to the algorithm, we refer the reader to Ref. [\[44](#page-38-38)[,45\]](#page-38-39).

The LITE algorithm can be straightforwardly generalized to open quantum systems described by the Lindblad master equation,

$$
\partial_t \rho = -i[\mathcal{H}, \rho] + \sum_j \gamma_j \left(L_j \rho L_j^{\dagger} - \frac{1}{2} \{ L_j^{\dagger} L_j, \rho \} \right), \quad (S 58)
$$

where L_j (L_j^{\dagger}) denote Lindblad jump operators describing the system-environment interaction, and γ_i are the respective coupling constants. Assuming on-site jump operators, the corresponding subsystem equation reads as

$$
\partial_t \rho_n^{\ell} = -i \Big[H_n^{\ell}, \rho_n^{\ell} \Big] + \sum_{j \in C_n^{\ell}} \gamma_j \Big(L_j \rho_n^{\ell} L_j^{\dagger} - \{ L_j^{\dagger} L_j, \rho_n^{\ell} \} \Big) \n- i \text{Tr}_L \Big(\Big[\mathcal{H}_{n-1/2}^{\ell+1} - \mathcal{H}_n^{\ell}, \rho_{n-1/2}^{\ell+1} \Big] \Big) \n- i \text{Tr}_R \Big(\Big[\mathcal{H}_{n+1/2}^{\ell+1} - \mathcal{H}_n^{\ell}, \rho_{n+1/2}^{\ell+1} \Big] \Big).
$$
\n(S 59)

The LITE algorithm removes information that is exclusively found at scales $> \ell_{\text{min}}$, while keeping all (sub-)subsystem density matrices on smaller scales and corresponding information currents fixed. Thus, at the time of the (first) removal, the state of the system on scales $\langle \ell_{\rm min} \rangle$ coincides with the exact state of the system. However, removing information changes the information flow or, in other words, the time dependence of the information currents that flow between different scales. As the information flow might be accelerated or slowed down, this changes the microscopic dynamics at later times. The parameter that controls how much this distorted distribution of information affects expectation values of local observables is ℓ_{\min} . In the limit $\ell_{\min} \to \infty$, the algorithm becomes exact. Therefore, the corresponding scaling in ℓ_{\min} allows to extract asymptotic values of local observables. At (intermediate) times $t \sim \ell_{\text{min}}/v_{LR}$ (with the Lieb-Robinson speed v_{LR} [\[94\]](#page-39-33)), the distortion of the information distribution is expected to be the largest and so are the deviations from the exact dynamics.

At late times, the state of the system on small scales can be well approximated by a local Gibbs state. This is the case also for an infinite system, where the corresponding thermalization time diverges, so a true steady state cannot be reached: The ongoing thermalization process translates into information currents flowing from small to large scales and applying the local Gibbs approximation [\[44\]](#page-38-38) for different snapshots in time yields different results. In this regime, a removal of information at scales larger than those present in the Hamiltonian has only minor effects on the dynamics. When the system is finite and equilibrium is reached, no information currents flow between small and large scales and the local Gibbs approximation becomes exact. At this stage also the LITE algorithm becomes exact even at finite ℓ_{\min} (up to errors imprinted into the dynamics at earlier times).

B. Energy diffusion around $\theta \approx \pi$: Hamiltonian engineering

The three-dimensional long-range Hamiltonian of Eq. [\(S 55\)](#page-25-3) is not suitable to be analyzed with the LITE algorithm since correlations are expected to appear on all length scales at very short times, and there are no Lieb-Robinson bounds restricting the spread of information and entanglement in the system. Furthermore, the three-dimensional nature of the experimental (effective) Hamiltonian poses a challenge. However, on a qualitative level, the relevant physical processes are not exclusively related to three-dimensional long-range systems but can also be observed in much simpler models. To obtain a qualitative picture within the constrains of the LITE algorithm, we condense the problem into an effective numerically tractable one-dimensional short-range Hamiltonian that we subsequently use as a toy model.

1. Toy model Hamiltonian

Let us assume a very sparse density of 13 C spins so that for any 13^C spin there is exactly one other spin with a dominant mutual coupling. In that case, we can reduce the three-dimensional long-range model to an effective one-dimensional short-range nearest-neighbour model keeping only the dominant couplings

$$
\mathcal{H}_{\pi} = \sum_{k} J_k \left(3I_k^z I_{k+1}^z - \mathbf{I}_k \cdot \mathbf{I}_{k+1} \right) + \phi_k I_k^x. \tag{S 60}
$$

While this might appear as a very crude approximation at first sight, it is indeed a valid approximation in related systems (see for example Ref. [\[26\]](#page-38-22)). To mimic the random spin position of ¹³C atoms in the original model, we use $J_k = J_0 + W_k$ where $W_k \in [-W, W]$ is a uniformly distributed random number.

We emphasize that the goal of this section is not to find a comprehensive quantitative agreement with the experimental results; rather, we aim to understand the fundamental physical processes that can potentially have a qualitative influence on the experiment: While quantitative details of the many-body dynamics might differ drastically between long and short-range systems in low and high dimensions, the qualitative behavior we discuss below applies in all cases provided basic principles, such as ergodicity, hold.

For the short-range nearest-neighbor model of Eq. $(S 60)$ we now approximately solve the von Neumann equation using the LITE algorithm introduced in Refs. [\[44,](#page-38-38)[45\]](#page-38-39).

2. Initial states

By virtue of hyperpolarization, the experimentally prepared initial state resembles a mixed product state with a finite polarization of 13 C nuclei in the proximity of a NV center (see Fig. [S14\)](#page-27-5). The absence of long-range correlations in combination with their asymptotic nature make such states well-suited as initial states in the LITE algorithm. In analogy to the experiment we thus choose an initial state of the form

$$
\rho_{\text{init}} = \frac{\mathbb{1}_2}{2} \otimes \frac{\mathbb{1}_2}{2} \otimes \cdots \otimes \frac{\mathbb{1}_2}{2} \otimes \rho_{\text{p}} \otimes \frac{\mathbb{1}_2}{2} \otimes \cdots \otimes \frac{\mathbb{1}_2}{2} \otimes \frac{\mathbb{1}_2}{2}, \quad (S \ 61)
$$

Fig. S14. **System** – Schematic of the region of polarization in the experimental (three-dimensional) system and the theoretical (onedimensional) model: the green ball indicates the NV center and the blue region is polarized after hyperpolarization. The orange dots depict ¹³Cnuclear spins. In the theoretical model with $n_{\rm NV}$ we denote the center of the polarized region of the initial state. The NV-center is not explicitly part of the model but its action on the 13 C spins is modeled by on-site potentials and dissipation.

where

$$
\rho_{\rm p} = \bigotimes_{\substack{j \in \{\text{region} \}\\ \text{of polarization}\}} \frac{1}{2} \Big(\mathbb{1}_2 + p \sigma_j^x \Big) \tag{S 62}
$$

describes the initially polarized subsystem with a **x**ˆ- polarization p for each spin in the region of polarization. $\mathbb{1}_2$ is an identity matrix of dimension 2. In the experiment, hyperpolarization induces polarization of nuclear 13 C spins in the vicinity of NVcenters while spins far away from NV-centers can be assumed to be in an infinite-temperature mixed state. The initial state in Eq. (S_61) is thus similar to the initial state of the experiment: here the (imaginary) NV-center is located at the center of the polarized region defined by ρ_p (Eq. [\(S 62\)](#page-27-7), see also Fig. [S14\)](#page-27-5).

Note that infinite-temperature density matrices $(\propto 1)$ are invariant under time evolution with any Hamiltonian. Thus, on short timescales all the dynamics generated from time evolving the state of Eq. $(S 61)$ is expected to happen close to the region defined by ρ_p ; subsystems far away from ρ_p remain in an infinitetemperature (time-invariant) state. Thus, initial states of the form of Eq. $(S61)$ in principle allow us to investigate an (effectively) infinitely extended system. In this case, the (effective) system size is adaptive and updated during time evolution (using the routines in LITE), capturing only those parts which are sufficiently different from the time-invariant infinite-temperature state.

3. Energy diffusion

Assuming no dissipative processes and disregarding the slow heating due to the Floquet drive (which is a good approximation within the prethermal plateau, see Sec. [S7\)](#page-20-0), the total energy of the (closed) quantum system described by Eq. $(S 60)$ is (quasi-) conserved, and the system undergoes equilibration. Evidently, an initial state of the form of Eq. $(S61)$ possesses a spatially dependent distribution of energy density: if the total energy of ρ_{init} is non-zero with respect to H (which is the case when ϕ_k is non-zero in the region of polarization), then the energy density is initially localized in the region of polarization.

To define a local energy, let us rewrite the Hamiltonian H_{π} as a sum of local terms

$$
\mathcal{H}_{\pi} = \sum_{k} h_{k+1/2} \equiv \sum_{n} h_{n}, \qquad (S\,63)
$$

where

$$
h_{k+1/2} = J_k \left(3I_k^z I_{k+1}^z - I_k \cdot I_{k+1} \right) + \frac{1}{2} \phi_k I_k^x + \frac{1}{2} \phi_{k+1} I_{k+1}^x (S \ 64)
$$

with k being a physical site index. The expectation value of $h_{k+1/2}$ can be interpreted as the energy located at the two sites k and $k+1$, i.e., the energy of the subsystem with center $n = k+1/2$. Thus, in the system under consideration [\(S 60\)](#page-27-4), $h_n \equiv \mathcal{H}_n^1$.

Equation $(S 63)$ allows us to define the variance of the energy distribution as

$$
\sigma_E^2 = \sum_n (n - \overline{n})^2 \frac{\langle h_n \rangle}{\langle H \rangle},\tag{S 65}
$$

where $\bar{n} = \sum_{n} n \langle h_n \rangle / \langle H \rangle$ can be seen as the spatial expectation value of energy. σ_E^2 tracks the spread of the local energy distribution and, thus, contains essential information about ongoing equilibration processes. For example, in diffusive systems, the diffusion equation predicts a linear growth of σ_E^2 with time, $\sigma_E^2 \propto t$ (or correspondingly for the standard deviation $\sigma_E \propto \sqrt{t}$). By contrast, in ballistic systems, σ_E^2 is expected to grow as $\sigma_E^2 \sim t^2$. Thus, σ_E^2 might be used to distinguish distinct energy transport regimes in the out-of-equilibrium dynamics of many-body systems [\[44](#page-38-38)[,87\]](#page-39-28).

4. Constant on-site potential

In Fig. [S15](#page-28-0) we show the time evolution of the total (or net) $\hat{\mathbf{x}}$ -polarization $I_x = \sum_k I_k^x$ as well as the corresponding value of σ_E^2 for the weakly-disordered Hamiltonian of Eq. [\(S 60\)](#page-27-4) with constant on-site potential $\phi_k = \phi \neq 0$. The initial state is of the form of Eq. $(S 61)$. The polarized region at $t = 0$ extends over $N_p = 11$ spins with a polarization $p = 0.6$ per spin. We keep the disorder in J_k small to avoid many-body localization effects [\[95\]](#page-39-34), which reflects the regime of the experiment. There are two notable points in Fig. [S15:](#page-28-0) (i) apart from deviations at intermediate times $J\tau \sim 1-10$ the truncation length-scale ℓ_{\min} has little effect on the late time dynamics of short-range observables. In this regime, the total **x**ˆ-polarization essentially takes a steady value. (ii) The energy, on the other hand, continues to spread at a rate $\sigma_E^2 \propto t$, as expected for a diffusive system. The observed scaling also indicates that many-body localization effects are not present in the current parameter regime (related models indeed develop many-body localization in the strongly disordered regime [\[95](#page-39-34)[,96\]](#page-39-35)). Note that whether the energy spread happens ballistically, superdiffusively, or diffusively is not of significant importance for our main result. The primary observation is that the energy density spreads in the system in the first place; the particular scaling at which this happens might influence the corresponding timescales, though. However, particularly in light of the enormous differences to the actual experimental model,

Fig. S15. **Diffusive energy spread** – Approximate time-evolution of ρ_{init} under H_{π} where the region of polarization initially extends over $N_p = 11$ neighbouring spins with $p = 0.6$. (a) Time-evolution curve of the total $\hat{\mathbf{x}}$ -polarization $\overline{I_x} = \sum_k \sigma_k^x$ for different truncation lengthscales ℓ_{min} . The dashed-dotted line corresponds to the expected steady value at vanishing disorder (i.e., $J_n = J_0$, see Eq. [\(S 71\)](#page-29-1)). (b) Time-evolution of σ_E^2 . The dashed-dotted line is a fit to the curve with truncation value $\ell_{\text{min}} = 5$. The system size is effectively infinite (i.e. adaptively increased according to the spread of energy throughout the evolution). Further parameters are $J_0 = -0.025$, $W = 0.3J_0$ and $\phi_k = 0.05\pi$; $\ell_{\text{max}} = \ell_{\text{min}} + 2$ and $q_{\text{max}} = 0.01$. The characteristic single particle energy is $J = 4J_0 = -0.1$. *Summary.*– Time evolution with respect to \mathcal{H}_{π} does not conserve $\hat{\mathbf{x}}$ -polarization but is characterized by energy diffusion.

we do not expect to quantitatively capture the values measured in the experiment.

Yet, we can get an idea of the relevant physical mechanisms. In that respect, analyzing the late-time state ($Jt > 10$ in Fig. [S15\)](#page-28-0) is very instructive: The initial state in Eq. $(S61)$ has a finite \hat{x} polarization and a finite energy E – since ϕ is non-zero in the region of initial polarization. At late times, the variance of the energy distribution grows as $\sim \sqrt{t}$ (see Fig. [S15\)](#page-28-0) as expected for diffusive processes. We can thus expect the energy distribution to resemble a Gaussian in this regime:

$$
\text{Tr}[h_n \rho(t)] \approx \text{Tr}[\mathcal{H}_\pi \rho_{\text{init}}] p_E(n, t), \quad (S\,66)
$$

where

$$
p_E(n, t) = \frac{1}{\sigma_E(t)\sqrt{2\pi}} \exp\left(-\frac{(n - n_{\rm NV})^2}{2\sigma_E^2(t)}\right).
$$
 (S 67)

We explicitly added the time dependence in $\rho(t)$ and $\sigma_E(t)$ to emphasize that the system is *not* in a steady state. In particular, this implies that there is some non-zero information (and information currents) on all lengthscales.

Nevertheless, on small scales (compared to the scales present in \mathcal{H}_{π}) we can approximate the state $\rho(t)$ as a ℓ -local Gibbs state

$$
\rho_n^{\ell}(t) = \text{Tr}_{\overline{C_n^{\ell}}}[\rho(t)] \approx \frac{1}{Z_n^{\ell}} \exp\left(-\beta_n(t)\mathcal{H}_n^{\ell}\right) \quad (S 68)
$$

$$
= \frac{\mathbb{1}_{\mathcal{D}_n^{\ell}}}{\mathcal{D}_n^{\ell}} - \frac{\beta_n(t)\mathcal{H}_n^{\ell}}{\mathcal{D}_n^{\ell}} + O(\beta_n^2),
$$

with the subsystem partition function $Z_n^{\ell} = \text{Tr}(\exp(-\beta_n(t) \mathcal{H}_n^{\ell}))$; $\rho_n^{\ell}(t)$ is the density matrix at time t in the subsystem C_n^{ℓ} , defined

by $\ell+1$ spins centered around *n*. Likewise, \mathcal{H}_n^{ℓ} is the subsystem Hamiltonian (of the full Hamiltonian \mathcal{H}_{π}) associated with subsystem C_n^{ℓ} . Tr $\overline{C_n^{\ell}}$ is a partial trace over the complementary subsystem $\overline{C_n^{\ell}}$. $\mathcal{D}_n^{\ell} = 2^{\ell+1}$ is the dimension of the subsystem C_n^{ℓ} .

In the second line of Eq. (S68), we assumed $\beta_n(t) \ll 1$ (and $Z_n^{\ell} \approx \mathcal{D}_n^{\ell}$). Using Eq. (S68) in Eq. (S66), we obtain an expression for the local inverse temperature [\[97\]](#page-39-36)

$$
\beta_n(t) \approx \frac{-4}{\frac{3}{2}J_n^2 + \frac{1}{2}(\phi_n^2 + \phi_{n+1}^2)} \text{Tr}[\mathcal{H}_\pi \rho_{\text{init}}] \ p_E(n, t). \tag{S 69}
$$

Equation $(S 68)$ produces the (almost) exact expectation values for local observables on scales less than, or at most equal to, those present in the Hamiltonian itself. However, the subsystem density matrix $\rho_n^{\ell}(t)$ from Eq. [\(S 68\)](#page-28-3) does not reproduce the same dynamics observed at time t : if we stop the dynamics at time t , replace the actual state of the system by the snapshot approximation of Eq. $(S 68)$ at time t, and restart the evolution with the exchanged state, then the subsequent dynamics differs from the one created by the actual state [\[25](#page-38-45)[,72\]](#page-39-19). The differences arise as the local Gibbs state of Eq. $(S 68)$ is a maximum-entropy state with just enough information to reproduce the correct expectation values of local constants of the motion and information decays rapidly on larger scales. In the actual time-evolved state at time t this is not the case (i.e., the state is not a maximumentropy state at time t). Consequently, the local Gibbs state is incapable of capturing correct expectation values on scales larger than those present in the Hamiltonian.

Note that this analysis is subtly different from the ETH discussion employed in Sec. [S7 C,](#page-23-1) which is based on equilibrium arguments. In contrast, here the system is inherently in a nonsteady state as energy continues to diffuse. Nonetheless, expectation values of local observables can yield steady values, as we now show. Applying the local Gibbs approximation, the total **x**ˆ-polarization is given by

$$
I_x(t) = \text{Tr}\left[\left(\sum_n I_n^x\right)\rho(t)\right] \approx \sum_n -\beta_n(t) \frac{\text{Tr}\left[I_n^x \mathcal{H}_n^{\ell}\right]}{\mathcal{D}_n^{\ell}} \quad (S \text{ 70})
$$

$$
= \text{Tr}\left[\mathcal{H}_\pi \rho_{\text{init}}\right] \sum_n \frac{\phi_n}{\frac{3}{2} J_n^2 + \frac{1}{2} (\phi_n^2 + \phi_{n+1}^2)} p_E(n, t).
$$

For vanishing disorder $J_n \to J_0$ and a constant on-site potential $\phi_n \rightarrow \phi$, I_x becomes steady:

$$
I_x = \frac{\phi}{\frac{3}{2}J_0^2 + \phi^2} \left(N_p p \phi - \frac{J}{2} p^2 (N_p - 1) \right)
$$
 (S 71)

where we used $\text{Tr}[\mathcal{H}_{\pi}\rho_{\text{init}}] = (N_p p \phi - \frac{J}{2})$ $\frac{J}{2}p^2(N_p-1)/2$ with N_p the number of initially polarized spins. The steady value of I_x is indicated by the dashed-dotted line in Fig. [S15](#page-28-0) (a) for $J_n = J_0$. Note that the data shown in Fig. [S15](#page-28-0) are obtained using disordered J_n , whence the small deviations.

In the (three-dimensional, long-range) experimental system spin-spin interaction terms average to zero and yield no contribution to the initial state energy (see Sec. [S6 A\)](#page-17-4). In contrast, in our one-dimensional short-range toy model, we obtain contributions from the spin-spin interaction terms to the initial energy $\propto Jp^2$. Thus, in the following, we consider the limit $p \to 0$ and keep only terms up to linear order in p .

Fig. S16. **Schematic of** ϕ_n – The pure $1/((n-n_{\text{NV}}))^3$ dependence is shifted by $\delta\theta$ and truncated at $\phi_{\text{max}} - \delta\theta$ as $n \to n_{\text{NV}}$. The distances $n-n_{NV}$ are measured in units of a lattice constant a, which (unless stated explicitly different) is set to $1/\sqrt[3]{\pi}$.

5. Space-dependent on-site potential

To analyze a site-dependent on-site potential ϕ_n we can immediately adapt almost all of the above analysis. In fact, apart from the last step, the derivation of the previous section is completely general. As outlined in Sec. [S7,](#page-20-0) the remaining effective on-site potential is expected to approximately scale as

$$
\phi_n \propto \frac{1}{|n - n_{\rm NV}|^3} - \delta\theta,\tag{S 72}
$$

where n_{NV} is the location of the NV-center [\[98\]](#page-39-37). To avoid dealing with divergences, we truncate the potential at $\phi_{\text{max}}-\delta\theta$ as $n \rightarrow n_{\text{NV}}$ (see Fig. [S16\)](#page-29-2):

$$
J^{-1}\phi_n = \begin{cases} \frac{1}{|n - n_{\text{NV}}|^3} - \delta\theta, & \text{if } \frac{1}{|n - n_{\text{NV}}|^3} < J^{-1}\phi_{\text{max}}.\\ J^{-1}\phi_{\text{max}}, & \text{otherwise.} \end{cases} \tag{S.73}
$$

Plugging ϕ_n in Eq. [\(S 70\)](#page-29-3) and assuming $\sigma_E = \sqrt{Dt}$, we obtain the absolute value of the total net polarization over time in the presence of an on-site potential of the form in Eq. $(S 73)$. Fig-ure [S17](#page-30-1) displays the obtained time evolution curve for $D = 1$. $\delta\theta$ is chosen positive so that far away from $n_{\rm NV}$, we obtain $\lim_{|n-n_{\text{NV}}| \to \infty} \phi_n / J = -\delta \theta$. Initially, the energy density is localized in the regime where $\phi_n > 0$; hence, we find a positive total net polarization. As time progresses an increasing amount of energy diffuses into the regime where $\phi_n < 0$, leading to a decrease and, eventually, a sign inversion of the total net polarization. The timescale of the crossing depends sensitively on the initial state and the diffusion constant D . Notably, at late times when almost all energy is located in the region with $\phi_n < 0$, the total net polarization reaches a steady value given by

$$
\lim_{t \to \infty} I_x(t) = -\frac{J\delta\theta}{\frac{3}{2}J^2 + J^2\delta\theta^2} \text{Tr}[\mathcal{H}_\pi \rho_{\text{init}}].
$$
 (S74)

For large values of the offset $\delta\theta$, the late-time steady value scales as ~ $1/\delta\theta$.

Evidently, the steady value of the polarization is not only controlled by $\delta\theta$ but also by the total initial energy. Assuming a fixed initial polarization per spin p as well as a fixed region of polarization, and given Eq. $(S 73)$, the energy of the initial state

Fig. S17. **Analytic expectation value of the total net polarization** – The expectation value of the total net polarization (solid blue) is evaluated using Eq. $(S70)$ together with Eq. $(S73)$ and the (norm of the) asymptotic value (dashed-dotted black) using Eq. $(S74)$ with $Tr[\mathcal{H}\rho_{init}] = 1/2 N_p p \delta\theta$. We used $\delta\theta = 0.05\pi$ and $D = 1$; the parameters (N_p, p, J) are the same as in Fig. $S15$. *Summary.*– Using the local Gibbs approximation and the spatially inhomogenous potential gradient, we can analytically reproduce the (global) polarization inversion.

is given by

$$
\text{Tr}[\mathcal{H}_{\pi}\rho_{\text{init}}] = p \sum_{\substack{\text{region of} \\ \text{polarization}}} \left(\frac{1}{|n - n_{\text{NV}}|^3} - \delta\theta \right) + O(p^2)
$$

$$
= \frac{p}{2} (c - N_p \delta\theta) + O(p^2), \qquad (S.75)
$$

where $c = \sum_{\text{region of}} \frac{1}{|n - n_{\text{NV}}|^3}$ is a positive constant, and N_p polarization is the total number of spins in the region of polarization. The

late-time steady value thus has two zeros, cf. Eq. $(S 74)$: $\delta\theta = 0$ and $\delta\theta = c/N_p$. Clearly, the second zero depends strongly on the polarization in the initial state. The two zeros constrain the regime where we expect to find a diffusion-induced sign inversion (see Fig. [S18\)](#page-30-2). As N_p increases, the $\delta\theta$ window, where the sign inversion can be observed, shrinks.

In the experiment, N_p is related to the hyperpolarization time: longer hyperpolarization times imply that more ${}^{13}C$ spins further away from the NV-center are partially polarized.

6. Polarization gradients

A very interesting aspect emerging from the above analysis is that the local polarization of a given spin at position n (to leading order in ϕ_n) is given by

$$
I_n^x(t) = \frac{\phi_n}{\frac{3}{2}J_n^2 + \frac{1}{2}(\phi_n^2 + \phi_{n+1}^2)} \text{Tr}[\mathcal{H}_\pi \rho_{\text{init}}] p_E(n, t) \quad (S.76)
$$

In particular, in the limit of a small on-site potential ϕ_n we obtain a linear dependence

$$
I_n^x(t) = \frac{2\phi_n}{3J_n^2 + \left(a\frac{\partial\phi_n}{\partial n}\right)^2} p_E(n, t) \text{Tr}[\mathcal{H}_\pi \rho_{\text{init}}] + O(\phi_n^2), \text{ (S 77)}
$$

where we used $\phi_{n+1} = \phi_n + a \frac{\partial \phi_n}{\partial n} + O(a^2)$ with the lattice constant a . The local polarization at site n is expected to be proportional to the on-site potential ϕ_n . The latter is induced by the nearby presence of the NV center and is expected to vary on a length

Fig. S18. **Steady value of the total** \hat{x} **-polarization** – Analytic late time (steady) expectation value of the total **x**ˆ-polarization with different initial states characterised by different values of N_p . Further parameters are as in Fig. [S15.](#page-28-0) *Summary.–* Depending on the initial state, the sign inversion of the total **x**ˆ-polarization only occurs for a finite interval of $\delta\theta$ -values, see also Fig. [S24.](#page-32-1)

Fig. S19. **Spatially resolved** \hat{x} **-polarization** – Local polarization ac-cording to Eq. [\(S 77\)](#page-30-3) for ϕ_n given by Eq. [\(S 73\)](#page-29-4) with lattice constant $a = 0.2/\sqrt[3]{\pi}$. As initial energy we use $\text{Tr}[\mathcal{H}\rho_{\text{init}}] = 1$. We assume $p_E(n, t)$ to be Gaussian with $\sigma_E = \sqrt{Dt}$ and $\bar{D} = 1$, $\phi_{\text{max}} = \pi$ and $\delta\theta = 0.05\pi$. Further parameters are as in Fig. [S15.](#page-28-0) *Summary.*– With increasing time spins further away from the NV are getting more negatively polarized. However, the spatial zero crossing is fixed at $\phi_n = 0$ for all times.

scale of nanometers which in turn implies a polarization gradient imposed on a nanometer lengthscale.

In Fig. [S19](#page-30-4) we show the distribution of the polarization for three different snapshots in time. The zero-crossing points (in space) that separate the positively polarized from the negatively polarized regime are found from Eq. [\(S 73\)](#page-29-4) setting $\phi_n = 0$. Note that this crossing point is time-independent and only determined by the applied on-site potential. As time progresses, spins further away from n_{NV} develop negative polarization, while simultaneously spins close to $n_{\rm NV}$ lose polarization (recall that the total net polarization is not conserved; thus these processes can happen in unequal proportions). Depending on the energy of the initial state (and more precisely, on the sign of the effective temperature in the prethermal plateau), a total negative polarization can develop over time and serve as a non-fine-tuned indicator for the presence of a nanoscale polarization gradient.

7. Energy diffusion in inhomogeneous systems

Let us first assume a constant $\phi_n = \phi$. As discussed in Sec. [S8 B 4,](#page-28-1) in this case energy spreads diffusively in the system with a spatially uniform diffusion constant $D \neq 0$. In the limit $\phi \rightarrow \infty$ the Hamiltonian \mathcal{H}_{π} reduces to a single-particle problem with vanishing energy diffusion, $D \rightarrow 0$. For increasing values of ϕ , we thus expect a decrease of D.

Let us now introduce the spatial dependence of ϕ_n given in Eq. $(S 73)$. Far away from n_{NV} we expect to find a (spatially constant) diffusion constant D_{asympt} . Likewise, close to n_{NV} (assuming the cut-off depicted in Fig. [S16\)](#page-29-2) we have $D_{n_{\text{NV}}}$. Since the asymptotic value $\delta \theta \ll \phi_{n_{\rm NV}}/J$, we expect $D_{n_{\rm NV}} < D_{\text{asympt}}$. The necessary interpolation between these two values implies a spatially dependent diffusion constant. Such a diffusion problem can be recast in a Fokker-Planck equation, which has no flat steady-state solution as $D \to D(n)$.

Figure [S20](#page-31-2) shows the energy distribution as a function of time for three different truncation values of ϕ_{max} at fixed $\delta\theta$. For $\phi_{\text{max}}/|J_0| \gg 1$ (panel (a)), the distribution of energy is significantly distorted compared to the Gaussian distribution of Eq. $(S 67)$. In particular, the spread of energy slows down significantly with increasing time. When lowering ϕ_{max} , this effect is reduced and the spread of energy continues even at late times (panels (b) and (c)). Since our simulations can only reach finite times, we cannot rule out the possibility that the spread of energy slows down in (b) and (c) as well, and eventually comes to a halt with a space-dependent steady state. The slowing down observed in the closed one-dimensional short-range toy model resembles similar effects discussed in recent papers on Stark many-body localization [\[99](#page-39-38)[–101\]](#page-39-39). As shown in the next section, such effect is mitigated by virtue of dissipation.

Finally, let us notice that in the experimental three-dimensional long-range system, the (here) observed slowdown of diffusion is expected to be less pronounced as the relative importance of the pinning potential is drastically reduced. In that case, we expect that energy spreads diffusively and the late time steady value analysis of Sec. [S8 B 5](#page-29-0) remains valid.

8. Dissipation

In Section [S6 B,](#page-18-0) we discussed the impact of decoherence and dissipation on the 13 C spins, which are influenced by the phonon bath generated by the diamond lattice and mediated by the NV center. Under the singular coupling limit, we derived the explicit form of the Lindblad master equation, which exhibits two crucial characteristics for our subsequent analysis. First, the Lindblad jump operators induce both dephasing and dissipation on the ¹³C spins when they are polarized along the **x**ˆ axis. Second, the coupling strength of the Lindblad jump operators decays more rapidly with distance from the NV center $({\sim}1/r^6)$ compared to the dipole interaction $({\sim}1/r^3)$. These properties enable us to simplify the effect of dissipation in our one-dimensional toy model used for the numerical simulations. Specifically, we only apply local jump operators for $n = n_{\text{NV}}$, which represents the spin closest to the hypothetical NV center in our simulations. Moreover, in Eq. $(S 58)$ we employ the three jump operators

$$
L_{+} = \frac{1}{2} \left(\sigma_{n_{\rm NV}}^{x} + i \sigma_{n_{\rm NV}}^{y} \right), \ \ L_{-} = \frac{1}{2} \left(\sigma_{n_{\rm NV}}^{x} - i \sigma_{n_{\rm NV}}^{y} \right), \ \ L_{z} = \sigma_{n_{\rm NN}}^{z} (S \cdot 78)
$$

Fig. S20. **Time dependence of the energy distribution** – Normalized distribution of energy when evolving a state of the form of Eq. $(S 61)$ under the Hamiltonian of Eq. $(S 60)$ with the on-site potential schemati-cally shown in Fig. [S16,](#page-29-2) using $\delta\theta = 0.04\pi$ and three different truncation values (a) $\phi_{\text{max}} = 1.0\pi$, (b) $\phi_{\text{max}} = 0.5\pi$, and (c) $\phi_{\text{max}} = 0.25\pi$. The black dotted-dashed line corresponds to the Gaussian distribution of Eq. [\(S 67\)](#page-28-5) with $\sigma_E^2 = Dt$ where $D = 1.35$. All remaining parameters are the same as inf Fig. [S15.](#page-28-0) *Summary.–* A strong spatial dependence of the on-site potential ϕ_n leads to a significant slowing down of energy transport.

Fig. S21. **Time evolution of the total energy** – Total energy as a function of time for the closed and open quantum dynamics with on-site dissipation at $n = n_{\text{NV}}$ with coupling constants $\gamma_+ = \gamma_- = \gamma_z = |J_0|$. Further parameters are the same as in Fig. $S20(a)$ $S20(a)$, Fig. $S15$, respectively. *Summary.–* Coupling of the NV center to a phonon-bath acts as an energy sink on the spin system leading to energy leakage, in contrast to the energy-conserving close system dynamics.

where L_{+} and L_{-} generate dissipation, while L_{z} is responsible of dephasing. Note that in an open quantum system, energy is not a globally conserved quantity: the Lindblad jump operators in Eq. [\(S 78\)](#page-31-3) with coupling constants $\gamma_+ = \gamma_- = \gamma_z$, as implemented in the numerical simulations, act as an energy sink (see Fig. [S21\)](#page-31-4).

Fig. S22. **Time dependence of the energy distribution** – Same plots as Fig. [S20](#page-31-2) (a) with additional on-site dissipation at $n = n_{\rm NV}$ of coupling strength $\gamma_+ = \gamma_- = \gamma_z = |J_0|$. Further parameters are the same as in Fig. [S20](#page-31-2) (a), Fig. [S15,](#page-28-0) respectively. *Summary.–* In contrast to Fig. [S20](#page-31-2) including dissipation leads to a Gaussian profile of the energy distribution at late times regardless of the cutoff ϕ_{max} .

Solving the respective subsystem Lindblad equation $(S 58)$ with the jump operators of Eq. $(S 78)$ and the on-site potential sketched in Fig. [S16,](#page-29-2) yields the time-dependent energy distribution shown in Fig. [S22.](#page-32-2)

Apart from the local jump operators at $n = n_{\text{NV}}$, in Fig. [S20](#page-31-2) (a) and Fig. [S22](#page-32-2) we employ identical simulation parameters. Contrasting both figures, it is evident that dissipation changes the energy distribution, especially at late times: instead of having the bulk of the energy density accumulated around $n = n_{NV}$ as in Fig. $S20$ (a), the distribution in Fig. $S22$ resembles a Gaussian distribution with standard deviation $\sigma_E \sim \sqrt{Dt}$.

In Fig. [S23](#page-32-3) we show the time-evolution curves corresponding to Fig. [S20](#page-31-2) (a) and Fig. [S22:](#page-32-2) notice that, while there is no sign-inversion of the total net polarization in case of a closed quantum system (where the majority of energy density remains localized around $n = n_{\text{NV}}$, the open quantum system develops negative polarization whose value asymptotically approaches the expected late time steady-state (dashed black line in Fig. [S23\)](#page-32-3):

$$
I_x(Jt \gg 1) = -\frac{J\delta\theta}{\frac{3}{2}J^2 + J^2\delta\theta^2} \text{Tr}[\mathcal{H}_{\pi}\rho(t)].
$$
 (S79)

Equation $(S 79)$ corresponds to Eq. $(S 74)$ weighted with the fraction of energy left in the system at time t ; this is brought in by using the time-dependent density matrix $\rho(t)$. The latter is justified whenever the diffusion timescales are much faster than the dissipation timescales, so that at every fixed time t the system can still be approximated by a local Gibbs state.

With dissipation acting only at $n = n_{\text{NV}}$ we find a single sign inversion of the total **x**ˆ-polarization in a bounded region of $\delta\theta$ values, which indeed coincides with the analytical analysis carried out in Secs. [S8 B 3-](#page-27-0) [S8 B 5.](#page-29-0) Fig. [S24](#page-32-1) shows the corresponding results. Note that the shape of the sign-inversion arc can depend on the relative weight of the different parameters. However, for the applied potential (Eq. $(S 73)$), we expect the upper asymptotic value to approach $\delta\theta = 0$ for any set of parameters and different initial states. This offers an experimentally accessible way to calibrate the \hat{x} -kick angle at π (corresponding to $\delta\theta = 0$ in the toy model): an $\hat{\mathbf{x}}$ -kick angle of π is expected to be insensitive to changes of the initial state. This holds true even in the presence of dissipation (decaying with the distance from the NV center). In contrast, the lower asymptotic value (here around $-\delta\theta \approx -0.6$) depends strongly on the initial state (see

Fig. S23. **Time-evolution of the total net polarization** – Timeevolution of the total net polarization with (orange) and without (blue) on-site dissipation at $n = n_{\text{NV}}$. The black dashed line indicates the expected late time value in the presence of dissipation (at $n = n_{\rm NV}$ of coupling strength $\gamma_+ = \gamma_- = \gamma_z = |J_0|$. The inset shows a zoomin. Further parameters are as in Fig. [S20](#page-31-2) (a), Fig. [S15,](#page-28-0) respectively. *Summary.–* Additional dissipation can lead to sign inversion of the total **x**ˆ-polarization as positive polarization close to the NV is absorbed.

Fig. S24. **Time- and** $\delta\theta$ -dependence of the total net polarization – Time dependence of the total net polarization for different values of the asymptotic on-site potential $-\delta\theta$ for $\gamma_+ = \gamma_- = \gamma_z = |J_0|$, $\phi_{\text{max}} = 0.5\pi$ and the lattice constant is $a = 0.2/\sqrt[3]{\pi}$. Further parameters are as in Fig. [S15.](#page-28-0) *Summary.–* As indicated in Fig. [S18](#page-30-2) the sign inversion of the total $\hat{\mathbf{x}}$ -polarization only appears for a limited window of shifts $\delta\theta$, in agreement with the experimental results in Fig. [4.](#page-4-0)

also the discussion of Sec. [S8 B 5,](#page-29-0) in particular, Fig. [S18\)](#page-30-2) [\[102\]](#page-39-40)

C. Polarization diffusion around $(\theta \approx \pi/2)$: state engineering

In contrast to the \hat{x} -kick angle close to π where the only globally (quasi-)conserved quantity is energy, at kick angles around $\pi/2$ the corresponding effective Hamiltonian of Eq. [\(S 54\)](#page-25-4) additionally preserves the total **x**ˆ-polarization. This significantly changes the relevant physics since, in this case, besides energy, also the **x**ˆ-polarization (i.e., the spatially resolved **x**ˆ-polarization) diffuses in the system. Thus, a uniformly polarized initial state

Fig. S25. **Polarization profile** – polarization of individual spins of the initial state (blue) and the state at later snap-shots in time (see legend) for half of the investigated system evolved with LITE. The initial domain wall melts and diffuses through the system. We plot the polarization as a function of $n+1$ to be able to show all the (half-chain) distribution on a log-scale. The region of polarization includes a total of $N_p = 31$ spins where the $N_+ = 11$ spins closest to $n_{\rm NV}$ have $p_n = 0.6$, while the remaining $N = 20$ spins have $p_n = -0.2$. Further parameters are as in Fig. [S15.](#page-28-0) *Summary.–* In the case of conserved **x**ˆ-polarization an engineered inhomogenous spatial profile is flattened out over time with a time-dependent zero crossing.

cannot lead to a stable polarization gradient. Moreover, even for more complex initial states – where polarization gradients might be present – they cannot be detected by the experimentally available global measurements of the (quasi-)conserved energy and polarization. The only way to induce a sign inversion of the total net polarization is to break conservation of the total **x**ˆ-polarization by dissipation.

1. Toy model Hamiltonian

Along the lines of Sec. $S8B1$, we use a one-dimensional short-range toy model Hamiltonian akin to the effective Hamiltonian of Eq. $(S 54)$

$$
\mathcal{H}_{\pi/2} = \sum_{k} J_k \bigg(\frac{3}{2} \Big(I_k^z I_{k+1}^z + I_k^y I_{k+1}^y \Big) - I_k \cdot I_{k+1} \bigg). \tag{S 80}
$$

Once again, to mimic the random spin position of 13 C atoms in the original model, we use $J_k = J_0 + W_k$ where $W_k \in [-W, W]$ is a uniformly distributed random number.

2. Initial states

Similar to Sec. [S8 B 2,](#page-27-3) we work with asymptotically translationally invariant states akin to Eq. $(S 61)$; however, in the region of polarization, the local polarization now depends on the site index, i.e., $p \rightarrow p_n$. In practice, to mimic the experiment, we initialize a polarization profile that is positive close to n_{NV} and negative further away from n_{NV} . The profile is shown in Fig. [S25.](#page-33-0) We evolve this state with the Hamiltonian of Eq. [\(S 80\)](#page-33-5) and perform numerical simulations using the LITE algorithm. Over time, the initial domain wall melts and diffuses through the system (see Fig. [S25\)](#page-33-0).

Fig. S26. **Time-evolution of the total net polarization** – (a) Spatially resolved polarization of individual spins for two different snapshot times with (dashed-dotted) and without (solid) on-site dissipation at $n = n_{\text{NV}}$ $(n_{\rm NV} = 0$ here). (b) Corresponding total net polarization as a function of time from time-evolution with the Hamiltonian of Eq. $(S 80)$. The black dashed-dotted line corresponds to a simulation including dissipation. The blue and red filled circles relate to the corresponding dashed-dotted line in (a) at the indicated time. We use the dipole initial state of Fig. [S25.](#page-33-0) When dissipation is non-zero we set $\gamma_+ = \gamma_- = \gamma_z =$ |0|. Further parameters are as in Fig. [S15.](#page-28-0) *Summary.–* The total **x**ˆ-polarization is a conserved quantity in the absence of dissipation, preventing the observation of a sign inversion. In the presence of dissipation the positive polarization close to the NV is dissipated faster than the negative polarization further out leading to a sign inversion in the total **x**ˆ-polarization.

3. Polarization diffusion

There is a striking difference between the dynamics generated by the $\theta = \pi/2$ kick Hamiltonian of Eq. [\(S 80\)](#page-33-5) and the $\theta = \pi$ kick Hamiltonian from Eq. $(S 60)$: with the total net polarization conserved, besides energy, also polarization diffuses through the system. As a consequence, even when starting from an initial state with a polarization dipole, there is no experimental way to resolve this spatial structure from the total net polarization (which is constant in time). Only if dissipation induced by the NV center is sufficiently strong to reduce the polarization close to n_{NV} (here the positively polarized part), can the total net polarization change significantly over time; under these conditions, a sign inversion of the total net polarization, similar to the one discussed on Sec. [S8 B,](#page-27-1) can be observed. These two scenarios are shown in Fig. [S26.](#page-33-6) The dissipation is modeled using on-site dissipators according to Eq. $(S 78)$ with a non-zero dissipation coupling constant only for $n = n_{\text{NV}}$.

D. Comparison between energy diffusion and polarization diffusion

The employed toy models of Sec. [S8 B](#page-27-1) and Sec. [S8 C](#page-32-0) can both be used to create the characteristic sign-inverting signature of the total net polarization for the respective parameter regimes and initial states. While seemingly similar, the underlying physics is fundamentally different in both cases: The toy model of Sec. [S8 B](#page-27-1) (which corresponds to the experimental system driven at with kick angles close to π) has no globally conserved quantity other than energy. In this case, energy diffuses and, over time, a polarization gradient builds up; in particular, the boundary between negatively and positively polarized spins r_c remains constant in time. By contrast, the toy model investigated in Sec. $S8 \text{ C}$ (which corresponds to the experimental system driven with $\hat{\mathbf{x}}$ -kick angles of $\pi/2$) has the total $\hat{\mathbf{x}}$ -polarization as an additional global (quasi-)conserved quantity. Thus, in this case, polarization diffuses in the system. This, in turn, implies that any artificially designed polarization domain wall is *not* preserved in time, i.e., $r_c = r_c(t)$ changes over time. The exact functional form of $r_c(t)$, in this case, depends sensitively on the interplay of diffusion, dissipation, and the initial state.

Figure [S27](#page-35-0) shows a direct comparison between the dynamics of the different cases with and without dissipation. The right column depicts the evolution at an x-kick angle close to π (toy model of Sec. [S8 B,](#page-27-1) Hamiltonian engineering approach): Using the applied potential given in Eq. $(S 73)$, we can compute r_c (dashed vertical line in the right column of Fig. $S27$). As energy diffuses following a $\propto \sqrt{t}$ scaling, the polarization gradient builds up with r_c being constant. Instead, in the left column panels we show the dynamics generated by an x-kick angle $\pi/2$ (toy model of Sec. S⁸C, State engineering approach). In both panels (i.e., with and without dissipation) the position of the domain wall separating the positively and negatively polarized regimes depends strongly on time, as a result of polarization diffusion.

E. Summary

Using two numerically tractable one-dimensional short-range models akin to the three-dimensional long-range Hamiltonians present in the experiment, we have explored two different diffusion effects. While our toy model resembling the experimental regime of kick angles $\sim \pi$ only has energy as a globally conserved quantity, the corresponding toy model for kick angles $\sim \pi/2$ additionally has the total **x**ˆ-polarization as a conserved charge. This additional constant of motion changes the diffusive behaviour: polarization diffuses through the system and domain-walls are not stable – neither in space nor in time. In contrast, if energy is the only globally conserved quantity, polarization domain walls can build up in the system as energy diffuses. Such domain walls are then stable in space and time (within the duration of the prethermal plateau). We analyze this effect in detail by means of numerical and analytical methods: Assuming an initial state with a finite amount of energy whose density is located around the NV-center, which induces a spatially dependent on-site potential on 13 C nuclei, we show that the total net polarization can undergo a sign inversion while energy diffuses through the system. Depending on the initial state and the asymptotic value of the on-site single particle potential, the late-time steady-state polarization can either take a negative or positive value. Importantly, for the single-particle potentials considered here, there is always a finite range of asymptotic single-particle potentials for which a sign-inversion of the total net polarization is obtained.

Locally, the polarization of individual spins is proportional to the value of the single on-site potentials. For space-dependent on-site potentials, this implies polarization gradients, where the sign-inversion of the total net polarization might serve as a global indicator for the latter. To arrive at this result, we only assume diffusion of energy as well as a local Gibbs approximation of a given late-time state. Hence, it can straightforwardly be transferred to a three-dimensional model (as present in the experiment).

Model-specifically, we find that in our theoretically tractable one-dimensional short-range toy model, energy remains bound in regions with strong on-site potentials and diffusion slows down significantly. Some aspects that underlie this behaviour can be transferred over to the actual three-dimensional system with long-range couplings – such as a spatially-dependent diffusion constant; however, diffusive (or non-diffusive) properties of the experimental system cannot be deduced from this analysis, since localization effects are known to display a severe dependence on the dimensionality of the system and the range of interactions. Including dissipation – which is expected to appear in the experimental system as well – enhances the diffusive behaviour of the theoretical one-dimensional short-range model. The expected late-time value of the total \hat{x} -polarization is then reduced by a factor accounting for the continuous loss of energy.

S9. ROLE OF DIMENSIONALITY AND INTERACTION RANGE

Numerically simulating long-range three-dimensional quantum systems with a non-vanishing linear extent is notoriously hard. However, the essential physics is often captured already by simpler models. In order to gain a qualitative understanding of the experimental system we therefore study simplified versions of the long-range three-dimensional system. In particular, we restrict ourselves to exact quantum dynamics of long-range onedimensional small systems (Sec. [S7\)](#page-20-0) and approximate quantum dynamics of a short-range one-dimensional quasi-infinite system (Sec. [S8\)](#page-25-0).

In general, one cannot expect that these simplifications lead to *qualitatively* similar results. Therefore, in this section we summarize possible caveats of the simplifications and which behaviour is expected to generalize to three dimensions.

A. Floquet dynamics beyond the prethermal plateau

Let us briefly comment on the Floquet prethermalization of the considered models. It was found experimentally before [\[74\]](#page-39-21) that the three-dimensional long-range interacting model has a stable prethermal plateau which is algebraically long-lived in the driving period, i.e., the prethermal lifetime $T_{\text{prethermal}} \propto 1/\omega^2$. This is in contrast to the exponential lifetime of a short-range interacting system, $T_{prethermal} \propto \exp(-\omega/\text{const})$. However, the effective Hamiltonian analysis in Sec. [S7](#page-20-0) only relies on the existence of a prethermal plateau and not on its parametric scaling.

B. Equilibration and thermalization dynamics within the prethermal plateau

In contrast to the discussion in Sec. [S8,](#page-25-0) the experimental system is described by a three-dimensional long-range Hamiltonian (instead of a short-range one-dimensional one). While the

Fig. S27. **Comparison of the dynamics of the different toy models** – *Left column:* Dynamics generated by the toy model of Sec. [S8 C](#page-32-0) using a domain wall initial state identical to the one used in Fig. [S25.](#page-33-0) *Right column:* Dynamics generated by the toy model of Sec. [S8 B](#page-27-1) with a uniformly
notatively state with $N_a = 11$ and $n = 0.6$; the lattice generate is $a = 0$ polarized initial state with $N_p = 11$ and $p = 0.6$; the lattice constant is $a = 0.2/\sqrt[3]{\pi}$. The vertical dashed line corresponds to $r_c = 1/(a\sqrt[3]{\delta\theta}) + n_{\text{NV}}$ where $n_{\text{NV}} = 0$ and $\delta\theta = 0.05\pi$. Dissipation is applied in the form of on-site dissipators at $N = n_{\text{NV}}$ with $\gamma_+ = \gamma_- = \gamma_z = |J_0|$. Moreover, we use $\phi_{\text{max}} = 0.2\pi$. The diagonal dashed line indicates the expected diffusive scaling with $\propto \sqrt{t}$, and serves as a guide to the eye. Further parameters in all panels are the same as in Fig. $S15$. The colors are chosen such that values > 0 appear in red colors and values < 0 appear in blue, on a logarithmic scale. The grey area indicates the region where no polarization is present. *Summary*.– Time evolution with respect to H_{π} qualitatively unaffected with a sign-inversion of polarization and a fixed zero crossing in both cases. For $\mathcal{H}_{\pi/2}$ the zero crossing is not fixed over time and is strongly affected by the presence of absence of dissipation.

results derived in Sec. [S8](#page-25-0) are independent of the dimensionality of the problem Hamiltonian, they rely on the locality of the Hamiltonian.

In the three-dimensional experimental system, the locality of the Hamiltonian may be violated as spin-spin interactions decay with a critical exponent. However, as far as expectation values are concerned, most of the energy is still stored on local scales. To see this, let us decompose the long-range Hamiltonian into two parts

$$
H = H_{r \le \ell_c} + H_{r > \ell_c},\tag{S 81}
$$

where $H_{r \leq \ell_c}$ contain all dipolar coupling terms of spins with a distance up to ℓ_c , while $\hat{H}_{r>\ell_c}$ covers the rest. At late times, when the (diffusive) spread of information has reached the system size, the state of the system becomes thermal $\rho(t \to \infty)$ = Z^{-1} exp($-\beta H$) with the partition function $Z = \text{Tr}[\exp(-\beta H)]$ and non-zero inverse temperature β . Using $\rho(t \to \infty)$, the energy found on scales larger than ℓ_c is given by

$$
\langle H_{r>\ell_c}\rangle(t\to\infty) = \text{Tr}\left[H_{r>\ell_c}\rho(t\to\infty)\right] \approx \frac{-\beta}{D} \text{Tr}\left[H_{r>\ell_c}^2\right] \text{ 82}
$$

with D being the dimension of the Hilbert space. Note that, the mixed term $\text{Tr}\left[H_{r>\ell_c}H_{r\leq \ell_c}\right] = 0$ vanishes as $H_{r>\ell_c}H_{r\leq \ell_c}$ contains strings with at least two non-trivial Pauli-operators and all non-trivial Pauli-strings are traceless, see Eq. [\(S 46\)](#page-24-6). The remaining trace evaluates to

$$
\text{Tr}\Big[H_{r>\ell_c}^2\Big] = D \sum_{\substack{i\ell_c}} J_{\text{exp}}^2 \frac{(3\cos^2(\vartheta_{ij})-1)^2}{r_{ij}^6}.
$$
 (S 83)

Assuming uniform ¹³C density and ℓ_c to be much larger than the average inter-spin distance we can replace the sum with an integral. This results in

$$
\langle H_{r>\ell_c} \rangle (t \to \infty) \approx -2\pi \beta \frac{4J_{\text{exp}}^2}{5} \sum_i \int_{r>\ell_c} \frac{\text{dr}}{r^4} = \frac{-8N\pi \beta J_{\text{exp}}^2}{15\ell_c^3}
$$
\n(S 84)

with N the total number of spins. Up to corrections of order $O(1/\ell_c^3)$ the energy is thus located on scales < ℓ_c .

$$
\langle H \rangle (t \to \infty) = \langle H_{r \le \ell_c} \rangle (t) + O(1/\ell_c^3). \tag{S 85}
$$

Similarly, at early times, for the initial state with finite polarization close to the NV-center (and featureless anywhere else), we have $\langle H_{r>\ell_c}\rangle(t) = 0$. Assuming diffusive transport the late time value of Eq. [\(S 84\)](#page-35-1) poses an upper bound on the energy found on scales $> \ell_c$. Thus, as far as we are not interested in correlation functions that exceed the scale ℓ_c , we can neglect the energy stored at scales $> \ell_c$ and approximate the full Hamiltonian of the system using only terms up to ℓ_c

$$
H \approx \sum_{n} h_{V_n^{\ell_c}},\tag{S 86}
$$

where $h_{V_n^{\ell_c}}$ is the ℓ_c -local Hamiltonian density in the volume $V_n^{\ell_c}$ with center *n* and diameter ℓ_c . Similar arguments were derived in Ref. [\[103\]](#page-39-41) in the context of Floquet heating.

Equation $(S 86)$ allows to repeat the steps outlined in Secs. $S8 B 3 - S8 B 6$ $S8 B 3 - S8 B 6$. In analogy to Eq. [\(S 69\)](#page-29-6) This yields local inverse temperatures of the form

$$
\beta_n(t) \approx \frac{\text{Tr}[H\rho_{\text{init}}]}{\text{Tr}\left[h_{V_n^{f_c}}H\right]} p_E(n,t). \tag{S 87}
$$

where $\text{Tr}\left[h_{V_n^{\ell_c}}H\right]$ takes a non-zero positive value depending on n and ℓ_c . Following similar steps as derived in Secs. [S8 B 3](#page-27-0) -[S8 B 6,](#page-30-0) we obtain the local polarization of a given spin n

$$
I_n^x(t) = \frac{\phi_n}{4} \frac{\text{Tr}[H\rho_{\text{init}}]}{\text{Tr}\left[h_{V_n^{f_c}}H\right]} p_E(n, t). \tag{S 88}
$$

Finally, let us point out that interactions in the three-dimensional long-range system depend on the angle ϑ between the lattice position vector and the applied magnetic on-site potential. This leads to an angular dependence in the couplings and the spatially inhomogeneous on-site potential ϕ_n induced by the NV electron spin, which cannot be equivalently modeled in one dimension. Moreover, the radial dependence of the exact profile does not follow a simple $1/r^3$ -dependence, see effective Hamiltonian analysis around Eq. $(S 41)$ and Fig $S10$ (b) for the exact form.

The angular dependence in the spin-spin couplings has no qualitative impact on the observed dynamics. Nevertheless, it does change the details of the above analysis. For instance, the key results of diffusion and the fact that the effective potential profile will also be imprinted in the local polarization profile, Eq. [\(S 88\)](#page-36-2), remain unchanged. However, angular-dependent spatially inhomogeneous on-site potentials lead to a quantitatively different local polarization profile following the local on-site potential, which is also found in the classical three-dimensional simulation, Sec. [S10.](#page-36-1)

S10. THREE-DIMENSIONAL CLASSICAL SIMULATIONS ON A DIAMOND LATTICE

In this section we complement the observations from the previous Secs. [S7](#page-20-0) and [S8](#page-25-0) performed for few spin or infinite 1D systems, with a classical simulation on a finite 3D long-range system on a diamond lattice of $L = 1000$ randomly placed spins.

Performing a classical simulation allows us to reach considerably larger system sizes of hundreds of spins, enabling the study of 3D systems with a finite linear extent. At the same time, however, a classical simulation comes at the expense of neglecting all quantum correlations. The thermalization analysis in Sec. [S7 C](#page-23-1) and the approximate dynamics in Sec. ([S8\)](#page-25-0) indicate that the system starts in an high-temperature state and remains close to a high-temperature state. This suggests that the dynamics may be described well classically.

While the classical simulation scales only linearly in the number of spins L , the number of spins in a three-dimensional system scales cubic $L \propto r^3$ in the linear dimension r. Thus, studying quasi infinite systems, i.e., systems with a linear extension far exceeding the support of the initial state, is beyond the scope even for the classical simulation. Therefore, we cannot study free diffusion in these systems. Hence, we restrict the study of three-dimensional systems to test the predictions from the ETHanalysis in Sec. [S7 C](#page-23-1) about the formation of spatially inhomogeneous local polarization starting from a homogenous polarized state in three dimensions.

As discussed before, it is sufficient to consider the Hamiltonian time evolution generated by the effective Hamiltonian [\(S 54\)](#page-25-4) for intermediate times, since we are only interested in the prethermal properties.

A. Classical simulation algorithm

Equations of Motion. – Notice that the effective Hamiltonian analysis in Sec. [S7](#page-20-0) was performed for a quantum system. However, the same analysis and arguments of the Floquet prethermal plateau are expected to remain valid also in the classical limit [\[104,](#page-39-42)[105\]](#page-39-43). The starting point for the classical equations of motion is the quantum Heisenberg equation of motion for the expectation values of the spin operators with respect to the three-dimensional Hamiltonian, Eq. [\(S 55\)](#page-25-3),

$$
\frac{\mathrm{d}}{\mathrm{d}t} \langle \mathbf{I}_k \rangle(t) = \langle i \left[\mathcal{H}_{\mathrm{eff}}^{\theta \approx \pi}, \, \mathbf{I}_k \right] \rangle(t) = \langle \mathbf{I}_k \times \nabla_{\mathbf{I}_k} \mathcal{H}_{\mathrm{eff}}^{\theta \approx \pi} \rangle(t) \tag{S 89}
$$

where $I_k = (I_k^x, I_k^y, I_k^z)^T$ and spin index k and \times denotes the vector (outer) product in 3D. In the second line of Eq. [\(S 89\)](#page-36-3) we used the spin-algebra $[I_k^{\alpha}, I_l^{\beta}] = i \delta_{kl} \sum_{\gamma} \epsilon_{\alpha\beta\gamma} I_k^{\gamma}$ χ^{γ} , with the fully anti-symmetric Levi-Civita symbol $\epsilon_{\alpha\beta\gamma}$. The classical approximation amounts to a mean potential approximation $\left\langle I_{k}^{\alpha}I_{l}^{\beta}\right\rangle$ $\langle I_k^{\alpha} \rangle \langle I_l^{\beta} \rangle$ $\binom{\beta}{l}$. Therefore, the classical equations of motion for the spin expectation values $I_k^{\alpha} = \langle I_k^{\alpha} \rangle$ read

$$
\frac{\mathrm{d}}{\mathrm{d}t} \boldsymbol{I}_k(t) = \boldsymbol{I}_k(t) \times \boldsymbol{\nabla}_{\boldsymbol{I}_k} \mathcal{H}(\boldsymbol{I}_k(t)), \qquad (S \, 90)
$$

where $H = H_{\text{eff}}^{\theta \approx \pi} (I_k)$ is a quadratic function in the spin expectation values and is obtained from $\mathcal{H}_{\text{eff}}^{\theta \approx \pi}$ by replacing $I_k \rightarrow I_k$.

Notice, that Eq. $(S 90)$ only contains 2L independent degrees of freedom instead of 2^L for a quantum system of L spins, thus, leading to an exponential reduction of degrees of freedom. Therefore, the classical simulation enables us to study much larger systems compared to the quantum simulation ($L \approx 1000$). Further notice that Eq. [\(S 90\)](#page-36-4) is a non-linear equation of motion as the right-hand-side is quadratic in I_k and must thus be solved iteratively. The classical chaotic dynamics renders time evolution up to very long times harder compared to the linear quantum equations.

Initial State. – The initial state in the experiment is assumed to be well described by the density matrix $\rho_0 \approx (1 + \sum_k \mu I_k^x)/Z$, where μ_k describes the local profile of the initial state and $\mu_n \ll 1$ is sufficiently small such that ρ_0 is a positive definite density matrix. Therefore, we may write $\rho_0 \approx \exp(\sum_k \mu_k I_k^x)/Z \stackrel{\mu \ll 1}{\approx}$ $(1+\sum_{k}\mu_{k}I_{k}^{x})/Z$, to have a well defined density matrix for all values of μ_n . Since this density matrix does not have any correlations between spins, i.e., $\rho_0 = \bigotimes_{k=1}^{L} \left[\exp(\mu_k I_k^x)/Z_k \right]$, it can also be used as an initial state for the classical simulation. In particular, we use the heatbath Monte-Carlo algorithm [\[106\]](#page-39-44) to sample individual classical spin configurations and average over a large number of the configurations to obtain a thermal average. The algorithm works as follows. We first draw, for each individual spin $k = 1, ..., L$, the I_k^x component with $I_k^x = \log(1 + u[e^{2\mu_k} - 1]) / \mu_k$, where u is a random variable uniformly distributed on the unit interval. Then, the $I_k^{y,z}$ $k^{y,z}$ components are drawn uniformly from a circle of radius $[1-(\mathcal{I}_k^x)^2]^{1/2}$. Finally, we compute the relevant (time-dependent) expectation values for each state (trajectory) and eventually average over many initial spin configurations. Averaging over many spin configurations the $I_k^{y,z}$ $k_k^{y,z}$ components average to zero, while the I_k^x -component is biased towards positive values, i.e. leading to a **x**ˆ-polarized ensemble.

In the experiment the initial state is generated via hyperpolarization, i.e. the NV centers are polarized via a resonant drive and due to dipole-dipole interactions this polarization diffusive through the surrounding system of 13 Catoms. Therefore, the initial state likely possesses a spatial profile with parts of the system closer to the NV being polarized more strongly. We mimic this in the classical simulation by choosing a domain-wall like state

$$
\mu_n = \begin{cases} \mu & r \le r_{\text{pol}} \\ 0 & r > r_{\text{pol}} \end{cases}
$$
 (S.91)

where spins within a given radius r_{pol} are polarized and spins beyond this radius are not polarized, see also initial state in Fig. $S28A(iii)$ $S28A(iii)$.

System geometry. – The system of interest are the nuclear spins of ¹³C-atoms which are randomly distributed on a diamond lattice with a lattice spacing $a = 0.357$ nm and a density of roughly $n = 0.5\%$ of lattice sites being occupied by ¹³C-atoms.

However, the ¹³C-spins within a radius of $r < r_c = 1.7$ nm, the so-called frozen core, are far-detuned from 13 C-spins at larger radii and cannot be detected by the measurement procedure implemented in the experiment. Therefore, we consider only spins that have a minimal distance $r_{\text{min}} > r_{\text{c}}$ from the electron. Since we cannot simulate all $\sim 10^4$ spins surrounding a single NV-center, we further restrict ourselves to a region close to the chosen crossing radius, which we choose to be $r_c \approx 6.5 \text{ nm} \cdot \sqrt[3]{|3 \cos(\theta)^2 - 1|}$ and we set $r_{\text{min}} = 3 \text{ nm}$.

Drawing the sites occupied by 13 C-atoms on the diamond lattice randomly may lead to two or more ¹³C-atoms being in close proximity of each other, leading to a strong interaction two orders of magnitude stronger than the median coupling. Such configurations can also occur in the experiment and this strong coupling will dominate the short-time dynamics. However, the long-time dynamics are hardly impacted by such rare configurations. Since we are only interested in the long-time dynamics of the system and simulating systems which possess a separation of time scales demands expensive high precision simulations, we neglect lattice configurations where 13 C-atoms are closer than some minimal distance d_{min} apart. We choose $d_{\text{min}} = 2 a$ leading to the interaction energy scales $E_{\text{interaction}}$ being comparable to the median coupling J, i.e., $E_{\text{interaction}} \leq 5 \text{ J}$. This entire procedure corresponds to an effective coarse-graining of time, neglecting short-time dynamics $tJ \ll 1$.

In summary, we draw L many spin positions on a diamond lattice of size L/n with inter-spin distance $r_{ij} \geq 2a$ and distance from the NV-center $r \ge r_{\min} = 3 \text{ nm} > r_{\text{c}}$. This ensures that we avoid the aforementioned large energy scales and populate a mean ratio of n^{-13} C-spins. In the experiment the observed data corresponds to an average over the environment of many NV-centers. Therefore, we also average our results over many lattice configurations.

B. Spin inversion in classical simulations

In the following, we study the spin locking regime near $\theta \approx \pi$ using the classical simulation introduced above. As already mentioned, this enables us to simulate the full three-dimensional long-range interacting system for a large, yet limited number of spins. The results are shown in Fig. $S28$.

Fig. S28. **Classical Simulation Results:** Classical simulation of spin locking around $\theta \approx \pi$, Eq. [\(S 90\)](#page-36-4), of an ensemble of 1000 spins, averaged over 100 lattice configurations and 150 initial states. **(A)** Coarse-grained polarization profile taken at different time cuts (time flowing from bottom to top) from early time (iii) to late time (i) as indicated in (C). Black squares indicate that no data exists for that parameter value. Black line indicates the ϑ -dependent crossing radius r_c . **(B)** Applied effective on-site Potential. **(C)** Time evolution of signal S normalized with respect to initial value S_0 . *Summary.*–In agreement with analytical predictions and the quantum simulation results the local polarization at late times follows the applied local potential up to an overall constant (the inverse temperature β).

Local polarization profile.– The initial state for the timeevolution is a homogeneously polarized state with a polarization of $I_n^x \approx 0.4$ per site, see Fig. [S28](#page-37-0) (A)(iii). As time progresses the state develops a spatially inhomogeneous local polarization distribution, Fig. $S28(A)(ii)$ $S28(A)(ii)$. Eventually at late times, Fig. $S28(A)(iii)$ $S28(A)(iii)$, the polarization is equal to the applied effective on-site potential, Fig. [S28](#page-37-0) (B) up to a proportionality constant given by the inverse temperature β ; this is expected from the ETH analysis in Sec. [S7 C.](#page-23-1) Therefore, the classical simulation also affirms the conjecture that the experimental observations are caused by the formation of a robust spatially inhomogeneous local polarization profile. In this case the polarization gradient around each NV encloses 1000-spins and a macroscopic distance of > 10 nm with $\approx 16\%$ negatively polarized and $\approx 84\%$ positively polarized spins. We found that the precise profile is strongly influenced by the choice of parameters, in particular the pulse duration t_p , Rabi frequency Ω, and polarization of the electron P .

Integrated polarization.– As expected (see also Sec. [S7 C\)](#page-23-1) the signal $S = \sum_{n=1}^{L} I_n^x$ is not conserved by the dynamics but decays slowly in time, see Fig. $S28(C)$ $S28(C)$. In agreement with other simulation methods the net polarization eventually inverts at late times as the energy spreads outwards and more parts of the outer region are getting negatively polarized. Notice, that the negative signal is much weaker in magnitude than the initial positive signal than observed in other simulations or the experiment. One possible explanation is the lack of dissipation such that at all times the strong positive contribution at $r < r_c(\theta)$ does not

decay and thus decreases the magnitude of the negative signal.

In summary, the classical simulation confirms in a threedimensional long-range model the analytical and numerical re-sults obtained for one-dimensional toy models in Secs. [S8](#page-25-0) and [S7.](#page-20-0) In particular, the macroscopic, stable, spatially inhomogeneous profile formed at late times reflects the profile of the effective on-site potential induced on the nuclear spins by the interaction with the NV.

- [102] Unlike Eq. [\(S 74\)](#page-29-5), Eq. [\(S 79\)](#page-32-4) is time-dependent. Therefore, in principle, depending on the initial state and the form of dissipation, Tr[$\mathcal{H}_{\pi}\rho(t)$] can change sign during the time evolution. It is thus possible to find several sign inversions of the total **x**ˆpolarization, provided that the timescales associated with dissipation are much slower than those related to diffusion. Notice that the sign inversion is only an indirect indicator for the presence of a nanoscale gradient; thus, having more than one sign-inversion process does not alter the general results.
