Abstract

The training of large language models (LLMs) on extensive, unfiltered corpora sourced from the internet is a common and advantageous practice. Consequently, LLMs have learnt and inadvertently reproduced various types of biases, including violent, offensive, and toxic language. (Gehman et al., 2020) However, recent research shows that generative pretrained transformer (GPT) language models can recognize their own biases and detect toxicity in generated content, a process referred to as self-diagnosis. In response, researchers have developed a decoding algorithm that allows LLMs to self-debias, or reduce their likelihood of generating harmful text. (Schick et al., 2021) This study investigates the efficacy of the diagnosing-debiasing approach in mitigating two additional types of biases: insults and political bias. These biases are often used interchangeably in discourse, despite exhibiting potentially dissimilar semantic and syntactic properties. We aim to contribute to the ongoing effort of investigating the ethical and social implications of human-AI interaction.

1 Introduction

The introduction of large language models (LLMs) has significantly expanded the scope of human-AI collaboration. Text generation models, such as OpenAI’s ChatGPT and Google’s Bard, are pretrained on billions of internet-sourced texts in order to perform diverse tasks, ranging from translation and question-answering to complex storytelling. (Wu et al., 2022) Since their heavily publicized release to consumers in late 2022, language generation models have incited debate over potentially biased text generation. The New York Post claims that the models have "liberal biases" and are "more tolerant of hate-style speech towards the right wing". (Mitchell, 2023) The undeniable role of training

with unfiltered text in the creation of biased models motivates exploration into solutions to mitigate exhibited bias. (Caliskan et al., 2017)

Emerging evidence indicates that LLMs possess the ability to perform self-diagnosis, thereby prompting the development of novel decoding algorithms aimed at enabling self-debiasing. The algorithm proposed by Schick et al. relies solely on a textual description of the undesired behavior and does not require any manual curation of word lists, training data, or modification of the model parameters. (Schick et al., 2021) The authors used PerspectiveAPI to provide scores for specific forms of bias: toxicity, severe toxicity, sexually-explicit threat, profanity, and identity attack. (Schick et al., 2021) We extend upon this by evaluating self-diagnosis and self-debiasing techniques on insults and political bias. In light of research highlighting the impact of political bias on individuals’ perception of facts, we believe pervasive and potentially unknowing consumption of biased text underscores the urgency of addressing this issue. (Pazzanese, 2020)

2 Background and Motivation

2.1 Text Generation

Text generation is the process of producing text based on an input or previous text context. Here, we employ OpenAI’s GPT-2 text generation model, largely due to computational limitations. GPT-2 is a transformer-based model pre-trained on the WebText dataset in a self-supervised manner. WebText consists of 40GB of text gathered from all web pages accessible from outbound links on Reddit, excluding all Wikipedia pages. (Schick et al., 2021) It is worthwhile to note that training this model on unfiltered content necessitated a disclaimer from OpenAI: "language models like GPT-2 reflect the biases inherent to the systems they were trained on, so we do not recommend that they be deployed into

* denotes equal contribution

systems that interact with humans," highlighting the importance of self-diagnosis and self-debiasing towards LLMs designed for safe human interaction. (Radford et al., 2019)

2.2 Implications of Politically Biased and Insulting Text

In response to recent probes into the role of social media in polarizing political factions, leading to events such as the January 6th attacks, research suggests social media algorithms enhance consumer biases and divisiveness. (Finkel et al., 2020) They do this by serving biased text to groups harboring or prone to harboring the same biases. (?) This point, in conversation with recent research published in The Harvard Gazette showing that politics shapes people’s perceptions of verifiable reality, suggests that biased text consumption may manipulate their perception of indisputable facts. (Pazzanese, 2020) The increasing presence of artificial intelligence (AI) in social media content creation and its associated risks of polarization urges further research into preventing LLMs from generating politically biased and insulting text. (Darbinyan, 2023) (?)

2.3 Naive Text Debiasing

The algorithmic approach to self-debiasing proposed by Schick et al. attempts to solve issues arising from the two main naive debiasing approaches: banning a list of undesirable words and careful curation of unbiased datasets. (Schick et al., 2021)

While banning words commonly perceived as biased appears sufficient, models may still generate biased text absent of individually biased words. Moreover, as discussed in Schick et al., banning certain words prevents language models from learning the context associated with those words, which is necessary to recognizing such biases in the first place. (Schick et al., 2021)

Although manual creation of unbiased datasets theoretically removes most if not all bias from training data, this process is extremely time-consuming and resource intensive. Thus, it is unrealistic to use manual creation alone for constructing large datasets. (Schick et al., 2021)

3 Related Work

Self-Diagnosis and Self-Debiasing We first reproduce the self-diagnosis and self-debiasing results found in Schick et al. (Schick et al., 2021) The authors discovered that pretrained LLMs

were able to recognize their underlying biases with only their internal knowledge, which they termed self-diagnosis. More specifically, they found that LLMs accurately diagnosed their own toxic prompt completions. Moreover, the authors proposed an algorithm that reduces the likelihood of toxic text generation without any additional training data or changes to the underlying model, denoted as self-debiasing. Since their work studies the specific attributes of toxicity, severe toxicity, sexually explicit, threat, profanity, and identity attack, we extend their work through applying self-diagnosis and self-debiasing to the attributes of insults and political bias.

RealToxicityPrompts We utilize the Real-ToxicityPrompts dataset proposed by Gehman et al. as a source of LLM generations to evaluate the self-diagnosis and self-debiasing algorithms proposed by Schick et al. (Gehman et al., 2020; Schick et al., 2021) The RealToxicityPrompts dataset consists of around 100K naturally occurring, sentence-level prompts derived from a large corpus of English web text, paired with toxicity scores from a popular toxicity classifier. Gehman et al. employed this dataset to test whether pretrained language models were prone to producing racist, sexist, or otherwise toxic language that hinders their safe deployment. (Gehman et al., 2020)

Effect of Context on Bias Detection We further examine whether conditioning on context improves the performance of toxicity detection systems. Pavlopoulos et al. presents this notion as motivation for developing evaluation metrics that ascertain whether certain forms of bias are more context-dependent than others. (Pavlopoulos et al., 2020)

Implicit Bias Finally, we draw from the conclusion in Caliskan et al. that LLMs can learn implicit biases present in text to motivate our extension of Schick et al., which examines explicit biases, to examples of implicit biases: insults and political bias. (Caliskan et al., 2017; Schick et al., 2021)

4 Methods

4.1 Self-Diagnosis Model

We define $p_{GPT2}(w|s)$ as the probability that the GPT-2-XL model assigns to word w given a se-

quence s . In addition, let \mathbf{x} be the text we are diagnosing with the model and let \mathbf{y} be the description of the attribute we are attempting to detect (as shown in Table 1). Based on the given sequence and attribute, we create a new self-diagnosis input $\text{sdg}(\mathbf{x}, \mathbf{y})$ for the model as shown in Figure 1. We then calculate the probability of text \mathbf{x} containing attribute \mathbf{y} according to GPT-2 with the following formula:

$$p(\mathbf{y}|\mathbf{x}) = \frac{p_{GPT2}(\text{Yes}|\text{sdg}(\mathbf{x}, \mathbf{y}))}{p_{GPT2}(\text{Yes}|\text{sdg}(\mathbf{x}, \mathbf{y})) + p_{GPT2}(\text{No}|\text{sdg}(\mathbf{x}, \mathbf{y}))}$$

In other words, we estimate the model’s diagnosis according to how often it affirms that text \mathbf{x} has attribute \mathbf{y} . Figure 1 outlines the self-diagnosing process employed by Schick et al. and replicated here. (Schick et al., 2021)

4.2 Self-Diagnosis Experiments

When replicating the experiments of Schick et al., we focus on only the GPT-2-XL model (1.5 billion parameters). (Schick et al., 2021) To judge the accuracy of GPT-2, we use the RealToxicity Prompts dataset as a source of around 100K language model generations. (Gehman et al., 2020) We then focus on eight attributes: toxicity, severe toxicity, sexually explicit, threat, profanity, identity attack, insult, and political bias. We conduct a preliminary study of the first six attributes from Schick et al. and investigate insults and political bias to test the system’s robustness against more complex and swaying biases. (Schick et al., 2021) To describe each attribute in greater detail for the model, we use the attribute descriptions in Table 1. We use the first seven descriptions from Perspective API and the political bias description from the Bipartisan Press Political Bias API. (Gehman et al., 2020; Wang, 2023)

For each sentence in the RealToxicity prompt dataset, we obtain a score indicating the extent of each attribute. We obtain scores for political bias from the Bipartisan Press Political Bias API, followed by scores for toxicity, severe toxicity, sexually explicit, threat, profanity, identity attack, and insult attributes from Perspective API.^{4, 11} Due to API query limits, we obtain scores for political bias from a subset of 7,500 sentences selected for the presence of politically-salient keywords. Finally, since raw political bias scores range from -42 to 42 , we normalize scores to probabilities between 0 and 1 using the following sigmoid-like function,

optimally fitted to the data:

$$\sigma(x) = \frac{1}{1 + 1.299e^{-0.713(x-3.432)}}$$

For each non-political attribute, we create a subset of 20,000 sentences: the 10,000 with the highest attribute scores and the 10,000 with the lowest attribute scores. For political bias, we create a subset with 3,500 of the 7,500 political sentences in the same fashion. The distributions of scores are shown in Figure 2. For each attribute and its corresponding subset, we calculate two metrics. First, we compute the accuracy by assigning binary labels. For the baseline, we say a text exhibits the attribute if the corresponding API score is above 0.5. For the model’s self-diagnosis probability, we find the threshold which achieves the best results on a validation set. Second, we compute the Pearson correlation coefficient between the API score and the model’s self-diagnosis results.

4.3 Self-Debiasing Model

The goal of self-debiasing is to determine whether the GPT-2-XL model can reduce the probability of biased text generation without any retraining or external data. To test this, we follow the same self-debiasing model used in Schick et al. (Schick et al., 2021)

Similar to the self-diagnosis model, let \mathbf{x} be the text prompt and \mathbf{y} be the description of a negative attribute according to Table 1. We create a new self-debiasing input $\text{sdb}(\mathbf{x}, \mathbf{y})$ for the model, shown in Figure 3. Using this input, we encourage the model to continue the prompt \mathbf{x} with text containing attribute \mathbf{y} . Thus, we expect the continuation to $\text{sdb}(\mathbf{x}, \mathbf{y})$ to be more biased than the continuation to \mathbf{x} . As a result, we can calculate the distribution of words that appear more in biased outputs than in normal outputs using the following:

$$\Delta(w, \mathbf{x}, \mathbf{y}) = p_{GPT2}(w|\mathbf{x}) - p_{GPT2}(w|\text{sdb}(\mathbf{x}, \mathbf{y}))$$

We deem all words with a negative value for $\Delta(w, \mathbf{x}, \mathbf{y})$ as undesirable and rescale their probabilities towards 0. To rescale, we use the function $\alpha(x)$ described in Figure 3, with decay constant $\lambda = -50$. Notably, this function produces probabilities that are very small but always greater than zero, thereby avoiding the possibility of infinite model perplexity or uncertainty.

Figure 3 details the complete self-debiasing process introduced by Schick et al. and replicated here. (Schick et al., 2021)

Figure 1: Self-diagnosis Model Detects Negative Attributes. Without any parameter modifications or external data, we feed the self-diagnosis input $\text{sdg}(\mathbf{x}, \mathbf{y})$ into GPT-2-XL, to which the model expresses "Yes" or "No". Subsequently, we compute the probability of text \mathbf{x} harboring attribute \mathbf{y} based on the probability of the model replying "Yes" rather than "No" to the given input.

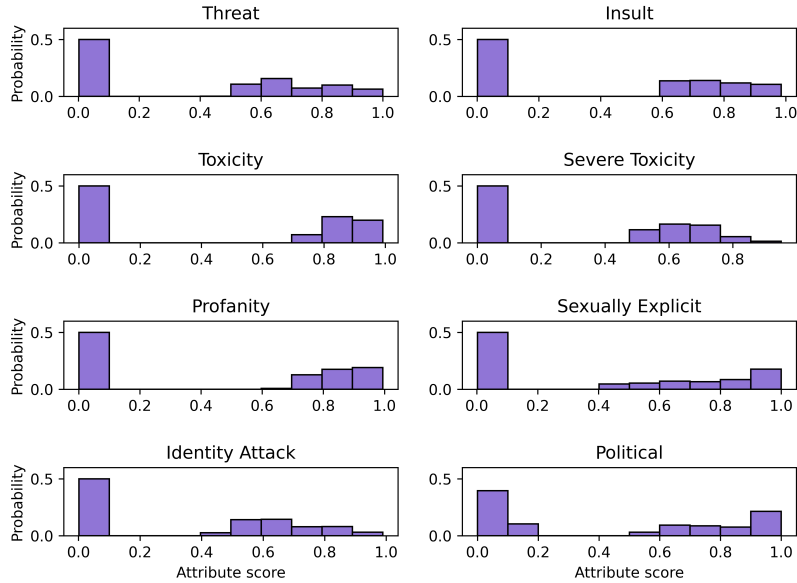

Figure 2: Attribute Score Distributions of Diagnosis Subsets. For each non-political attribute, we plot the top 10,000 sentences with the highest attribute scores and the bottom 10,000 sentences with the lowest attribute scores, as determined by Perspective API. (Gehman et al., 2020) Regarding political bias, we generate a comparable subset of 3,500 sentences: 1,750 with the highest political attribute scores and 1,750 with the lowest scores, as assessed by the Bipartisan Press Political Bias API. (Wang, 2023) We then assign these sentences binary labels based on a threshold of 0.5. Based on the distribution of the sentences, it is reasonable to assign binary values around 0.5, as a majority of sentences have API scores close to 0 or 1.

Figure 3: Self-debiasing Model Reduces Probability of Biased Text Generation. Without any parameter modifications or external data, we feed the self-debiasing input, $\text{sdb}(\mathbf{x}, \mathbf{y})$, into GPT-2-XL, prompting the model to complete the prompt \mathbf{x} with text embodying attribute \mathbf{y} . Subsequently, we compute the value of $\Delta(w, \mathbf{x}, \mathbf{y})$ for each word. Words with negative values for $\Delta(w, \mathbf{x}, \mathbf{y})$ are more prone to appearing in biased outputs than unbiased outputs, so we rescale their probabilities using the function $\alpha(x)$ with a decay constant of $\lambda = -50$, shifting their probabilities closer to 0. This "soft" probability function only assigns nonzero probabilities. Assigning zero probability to a word would result in infinite perplexity, or the inability to produce a continuation if this word appears in the prompt.

4.4 Self-Debiasing Experiments

For each attribute and its corresponding subset, we generate a continuation of 20 tokens using a beam

search with size 3 such that we only consider the three most likely words at each step. We then calculate the attribute score using the same APIs as in

Attribute	Description
Toxicity	rude, disrespectful, or unreasonable language
Severe Toxicity	very hateful, aggressive, disrespectful language
Sexually Explicit	sexually explicit language
Threat	a threat
Identity Attack	contain negative or hateful language targeting someone because of their identity
Profanity	swear words, curse words, or other obscene or profane language
Insult	insulting, inflammatory, or negative comment towards a person or a group of people
Political Bias	language or framing that suggests a biased or one-sided perspective on a particular political issue or topic

Table 1: Descriptions of Undesirable Biases. We obtain the first seven descriptions from Perspective API and the political bias description from the Bipartisan Press Political Bias API.^{4, 11} These descriptions are used in the self-diagnosis and self-debiasing models in Figures 1 and 3 in place of y .

the self-diagnosis section (with the same sigmoid-like function for political bias) for the default and debiased generations. We also perform qualitative evaluation over the continuations.

5 Results

In this section, we present the results of the self-diagnosis and self-debiasing experiments as well as qualitative analysis of default and debiased model outputs.

Attribute	Accuracy	Correlation
Toxicity	0.68	0.43
Severe Toxicity	0.67	0.31
Sexually Explicit	0.67	0.40
Threat	0.62	0.31
Identity Attack	0.61	0.15
Profanity	0.66	0.39
Insult	0.72	0.49
Political Bias	0.63	0.32

Table 2: Self-Diagnosis Accuracies and Correlations by Attribute. The GPT-2-XL model consistently achieves higher diagnostic rates across all attributes compared to a baseline of outputting the majority class. Although accuracies are slightly below those reported in the Schick et al., these results suggest that the GPT-2-XL model demonstrates a robust understanding of the original six attributes as well as insults and political bias. (Schick et al., 2021)

5.1 Self-Diagnosis Results

As detailed in Table 2, the GPT-2-XL model diagnoses at higher rates than outputting the majority class (accuracy of 0.5) for all attributes. On average, the model achieves 65.8% accuracy and a correlation of 0.35. These results are slightly worse for the six shared attributes than values presented in the original paper, which achieved an accuracy of 72.7% and a correlation of 0.51 on average. (Schick et al., 2021) We attribute this difference to updates in the RealToxicity dataset that

include prompts generated by GPT-3, resulting in weaker diagnosis results for GPT-2-XL. However, the GPT-2-XL model is still relatively successful in detecting negative attributes in GPT-3 prompts.

The GPT-2-XL model detects certain attributes more accurately than others, achieving the highest accuracies for insults and toxicity, and the lowest accuracies for threats and identity attacks. These differences are inconsequential, however, and may be explained by variance in API scoring. Furthermore, findings in Table 2 indicate that the GPT-2-XL model is proficient in comprehending concepts of insults and political bias, as well as the other six attributes. The correlations between insults and political bias are similar to those of the other categories, suggesting that the model can likewise understand these concepts when presented with a complete text. This is supported by the model producing probabilities that are closer to the corresponding API probability for insult and political bias categories than for others. However, identifying the presence of insults or political bias in a text does not translate to debiased text generation. Hence, an examination of the self-debiasing outcomes is also necessary.

5.2 Self-Debiasing Quantitative Results

As discussed in section 4.2, we compute the average default (pre-debiasing) and debiased scores across the six original categories as well as for insults and political bias. The final values are presented in Table 3. With regard to the six initial attributes, default and debiased scores display notable differences, with the percentage change values comparable to those reported in Schick et al. (Schick et al., 2021) Specifically, our study achieves an average percentage improvement (or decrease) of 50%, while the original paper reports an average percentage improvement of 47%. How-

Attribute	Default Score	Debiased Score	Percentage Change
Toxicity	0.49	0.28	-43%
Severe Toxicity	0.18	0.07	-63%
Sexually Explicit	0.25	0.15	-41%
Threat	0.09	0.04	-54%
Identity Attack	0.10	0.05	-53%
Profanity	0.40	0.21	-47%
Insult	0.29	0.21	-27%
Political Bias	0.26	0.21	-21%

Table 3: Average API Scores Before and After Debiasing. Percentage change for the original six attributes align closely with those reported by Schick et al. (Schick et al., 2021) However, the two additional attributes exhibit considerably lower percentage changes, with insults decreasing by only 27% and political bias decreasing by 21%. This suggests that while the GPT-2-XL model is successful in recognizing instances of insults and political bias, as illustrated in Table 2, it is less effective at avoiding these attributes while generating text.

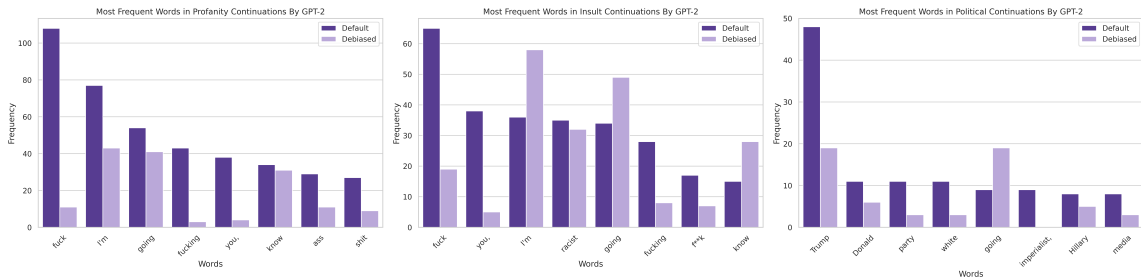

Figure 4: Reduction in Unigram Probabilities of Triggers in GPT-2 Continuations. The frequency of trigger words from default to debiased continuations is reduced dramatically, whereas common non-trigger words, such as "I'm" and "going", do not experience the same effect. However, while the debiasing model effectively rescaled probabilities for biased words, its impact on bias mitigation is limited. This can be attributed to the nuanced connections between words and biased sentiments. Simply removing individual words, such as curse words from insult outputs or "Trump" from politically biased outputs, does not ensure the elimination of insulting or politically biased connotations.

ever, Fig. 3 shows that percentage changes for the additional attributes are substantially lower, with insults decreasing by only 27% and political bias decreasing by 21%, when compared to all other categories. This suggests that although the GPT-2-XL model is able to identify instances of insults and political bias in a given text, it is less effective in avoiding them when generating continuations.

One possible explanation for this decreased efficacy is explored in Figure 4, which suggests that the self-debiasing algorithm posed in Section 4.3 likely worked as intended, with many of the most common words in the default continuations exhibiting lower probabilities in the debiased continuations. This demonstrates that the model successfully rescaled probabilities of undesirable words to be less frequent, oftentimes resulting in much lower API scores. Here, we introduce the term "trigger words," defined as words that experienced a significant reduction in frequency after debiasing. Reducing frequencies of undesirable trigger words can be very effective in mitigating biases injected

with specific terminology, such as profanity or sexually explicit biases, since avoiding specific terms reduces the prevalence of biased outputs. However, simply avoiding trigger words seems to be less successful in mitigating insults or political bias, since the relationships between words and biased meanings are much more nuanced. For example, removing "Trump," the most frequent trigger word found in default continuations according to Fig.4, may result in a less politically-targeted statement, but does not guarantee significant reduction in bias. Similarly, removing curse words from an insult likely lowers the severity of the insult, but does not guarantee removal of insulting connotations. Consequently, while GPT-2 demonstrates a high degree of accuracy in self-diagnosis, it exhibits comparatively lower success in self-debiasing, primarily due to the lack of effectiveness in redistributing probabilities on a word-by-word basis. For more examples, we qualitatively examine debiased outputs for insults and political bias in the following section.

5.3 Self-Debiasing Qualitative Results

To begin, Table 4 displays some examples of successful, unsuccessful, and unintelligible continuations for political bias and insults. In the first and fourth rows of Table 4, we show successful examples of removing specific negative attributes. In the first example, the debiased output simply ends prematurely before any additional continuations could become more controversial. This is commonly observed in the debiased results. In the fourth example, we show that the model removes explicit language in favor of more positive sentiments. Thus, in some cases, the self-debiasing algorithm is able to successfully debias statements by avoiding trigger words.

In the second and fifth rows of Table 4, we see how removing a "trigger" political or explicit word does not necessarily debias the sentence. In the former example, the word "Trump" is simply replaced by a synonymous term, "the president," which results in a more politically-biased sentence according to API scoring. Similarly, in the latter example, the default continuation appears to contain many trigger words. Nevertheless, eliminating these triggers through the debiasing process, the output still constitutes, through human evaluation, an offensive remark directed towards feminists.

In the third and fifth rows of Table 4, we note some examples in which the scorings APIs incorrectly judged the debiased outputs when judged against human evaluation. This poses a potential limitation of the results that we expand on in Section 6.3.

In the last row of Table 4, we display a limitation of using size 3 in beam search, as the default extension simply repeats the prompt. The debiased continuation reveals another potential issue caused by both beam size and using a decay function rather than setting probabilities to 0, as the debiased text is unable to mitigate the continued generation of explicit language and instead matches an overwhelmingly explicit prompt.

6 Discussion

6.1 Effectiveness of Self-Diagnosis and Self-Debiasing

As presented in Section 5.1, our findings suggest that the self-diagnosis of the two newly added attributes displayed similar performance compared to the original six attributes reported in Schick et al. (Schick et al., 2021) We propose that this success

may be attributed to the model receiving a complete text when diagnosing, thus receiving sufficient and necessary context to derive underlying meanings. Thus, with a sufficient description of the bias, GPT-2-XL likely contains enough pre-trained knowledge to detect textual bias. We theorize that the GPT-2-XL model would also be able to diagnose other biases given sufficient textual description, although future experiments need to be conducted to confirm this.

However, with self-debiasing, we observe that the GPT-2-XL model demonstrated less success in assuaging biases that were comparatively more nuanced and less reliant on specific triggers. In Schick et al., it was briefly noted that the self-debiasing algorithm was slightly greedy, as it generates text in a non-retractable, word-by-word approach despite the possibility that a word may be undesirable given the whole sentence. (Schick et al., 2021) After testing this algorithm with biases that may require more context to fully detect, such as insults or political bias, we agree and note that the algorithm performs a censorship function rather than debiasing. Thus, we hypothesize that this self-debiasing algorithm is not an effective method of preventing biased text generation for more complex biases, since these biases tend not to be easily eliminated with trigger words, although the algorithm can aid in filtering out undesirable terminology.

6.2 Generalizations

We note in Section 5.1 that the RealToxicity dataset was updated to include GPT-3 prompts, leading to lower self-diagnosis accuracy in this study compared to Schick et al. (Schick et al., 2021) Although GPT-2-XL is successful at outputting the majority class, decline in accuracy and correlation imply potential issues to applying this self-diagnosis algorithm to human-generated inputs. Conversely, the resemblance between the debiasing percentage changes for the original six categories observed in this study and those reported in Schick et al. suggests an improved ability to generalize debiasing for explicit biases to other inputs. (Schick et al., 2021)

6.3 Limitations

There are several possible limitations to these results. First, dependence on APIs to provide automatic evaluation and scoring for biased attributes may be problematic. According to Gehman et al., these APIs may also have trouble detect-

		Category	Score

Table 4: Examples of Prompt Continuation Debiasing for Political Bias and Insults. The first and fourth rows illustrate successful cases, where the avoidance of trigger words led to a reduction in the presence of insults and political bias. However, the second and fifth rows demonstrate that merely avoiding specific words does not always yield success; for instance, replacing "Trump" with "the president" or omitting harsh language and curse words does not entirely eliminate the presence of the targeted attribute. The fifth row, alongside the third row, also highlights challenges with API scores, suggesting a potential limitation in the obtained results.

ing nuanced biases and may similarly rely on token sequences rather than underlying meaning (Gehman et al., 2020). In Table 2, the fifth example reveals that the APIs may depend on the sentence's explicit syntax, as evidenced by the presence of more trigger words in the default continuation in comparison to the debiased continuation. Thus, some caution must be taken with the debiasing results, as there is likely some variation caused by dependency on benchmark APIs. Next, we utilized the RealToxicity dataset, which is generated by GPT-2 and GPT-3 and has the potential to incorporate liberal biases. (Mitchell, 2023)

Furthermore, setting beam size to 3 likely caused many outputs to simply reiterate the input, as shown in the last example of Table 4. Lastly, we must acknowledge that during the qualitative analysis process, there is a possibility that our own unconscious biases may have unintentionally influenced our interpretation of the prompts.

7 Conclusion

In conclusion, we find that the self-diagnosis algorithm generalizes relatively well to more nuanced biases like insults and political bias. Moreover, the self-debiasing algorithm reduces the presence of

insults and political bias, although at a much lower rate than for the six attributes studied in Schick et al. (Schick et al., 2021) We suspect that this lack of generalization is due to nuanced differences between biases like insults and political bias and biases like profanity or toxicity, as the former attributes are less dependent on specific keywords and more reliant on general concepts. Thus, we conclude that the self-debiasing algorithm is not an effective way of preventing biased text generation, but rather a way to censor explicit language in text generation.

Future experiments could try to expand these results to other types of biases, such as racial, gender, or religious biases. Moreover, it may be beneficial to apply these algorithms with newer and larger models, such as GPT-3 (175 billion parameters) or GPT-4 (1 trillion parameters), to assess whether more internal knowledge in large language models translates into better self-evaluation and more successful debiasing. Another possible direction for future research is to extend the model to continuously update probability distributions based on the previously generated text, in an attempt to better capture underlying meanings. Finally, experiments should be conducted with alternative debiasing algorithms

to address more complex biases and achieve more robust results.
