#### Abstract

Many imaging science tasks can be modeled as a discrete linear inverse problem. Solving linear inverse problems is often challenging, with ill-conditioned operators and potentially non-unique solutions. Embedding prior knowledge, such as smoothness, into the solution can overcome these challenges. In this work, we encode prior knowledge using a non-negative patch dictionary, which effectively learns a basis from a training set of natural images. In this dictionary basis, we desire solutions that are non-negative and sparse (i.e., contain many zero entries). With these constraints, standard methods for solving discrete linear inverse problems are not directly applicable. One such approach is the modified residual norm steepest descent (MRNSD), which produces non-negative solutions but does not induce sparsity. In this paper, we provide two methods based on MRNSD that promote sparsity. In our first method, we add an  $\ell_1$ -regularization term with a new, optimal step size. In our second method, we propose a new non-negative, sparsity-promoting mapping of the solution. We compare the performance of our proposed methods on a number of numerical experiments, including deblurring, image completion, computer tomography, and superresolution. Our results show that these methods effectively solve discrete linear inverse problems with non-negativity and sparsity constraints.

# <span id="page-0-2"></span>1 Introduction

Inverse problems are an important class of mathematical problems with the aim to re- or uncover unobserved information from noisy data paired with an underlying mathematical or statistical model. Inverse problems are ubiquitous in modern science, from data analysis and machine learning to many imaging applications, such as image deblurring, computer tomography, and super-resolution [\[17\]](#page-20-0).

In this work, we consider the common imaging problem that is given as a discrete linear inverse problem

<span id="page-0-0"></span>
$$
\mathbf{b} = \mathbf{C} \mathbf{y}_{\text{true}} + \boldsymbol{\eta},\tag{1}
$$

where  $y_{\text{true}} \in \mathcal{Y} \subset \mathbb{R}^n_+$  is the desired solution (a vectorized representation of the image is some image space),  $\mathbf{C} \in \mathbb{R}^{m \times n}$  is a given forward imaging process and  $\mathbf{b} \in \mathbb{R}^m$  contains observed measurements. We assume these observations **b** are corrupted by additive Gaussian noise  $\eta \sim \mathcal{N}(0, \sigma^2 \mathbf{I}_m)$ . In most cases, the underlying operator C is ill-conditioned (i.e., the solution is sensitive to small perturbations in b) or underdetermined  $(m < n)$  such that the solution is not unique. In most of these common settings, prior knowledge is required for selecting a meaningful solution. One approach to embedding prior knowledge into the solution is to cast [\(1\)](#page-0-0) as a variational inverse problem of the form [\[10,](#page-20-1) [16\]](#page-20-2)

<span id="page-0-1"></span>
$$
\min_{\mathbf{y}\in\mathcal{Y}} \quad \frac{1}{2} \left\| \mathbf{C}\mathbf{y} - \mathbf{b} \right\|_2^2 + \mu \mathcal{R}(\mathbf{y}).\tag{2}
$$

<span id="page-1-2"></span>The first term measures the data fidelity between the model prediction, Cy, and observations, b, with discrepancy measured in  $\ell^2$ -norm. For  $\mu = 0$ , this corresponds to a maximum likelihood estimator with Gaussian noise distribution. The second term,  $\mathcal{R}(\cdot)$ , denotes an appropriate regularizer that promotes desirably properties in the solution, y, (e.g., small norm, smoothness). The regularization parameter  $\mu > 0$ balances the weight of the data fidelity and regularization terms, and is often chosen heuristically or based on noise estimates [\[15\]](#page-20-3).

Regularization for imaging problems is motivated by the fact that the *natural image space*  $\mathcal{Y} \subset \mathbb{R}^n_+$  is minuscule compared to the set of all images of dimension  $\mathbb{R}^n_+$ . For instance, drawing a random sample from  $\mathbb{R}^n_+$  will most likely look like noise [\[4\]](#page-19-0). In other words, natural images exhibit a high degree of redundancy and can be efficiently captured within a low-dimensional manifold. Hence, the features and the structure of natural images must be included in an inverse problem process.One common approach is to utilize an edgepreserving total variation (TV) regularization  $\mathcal{R}(\mathbf{y}) = \|\mathbf{L}\mathbf{y}\|_p$ . Here,  $\mathbf{L}\mathbf{y}$  is a finite difference approximation of the directional pixel gradients, and  $||y||_p$  denotes the  $\ell^p$ -norm [\[30\]](#page-21-0). This type of regularization has shown tremendous success in various applications. However, disadvantages of this approach include the potential over-smoothing of the reconstructed image (apart from the edges) and potential inconsistent intensity shifts in y, [\[8,](#page-19-1) [13,](#page-20-4) [38\]](#page-21-1).

An entirely different approach to regularize is to represent the solution to [\(2\)](#page-0-1) in terms of a pre-trained image data "basis" or dictionary [\[36\]](#page-21-2). Dictionaries of natural images or image elements provide an informative prior and incorporate expected image features (e.g., edges, smoothness) into y by directly. To be precise, we represent y as a linear combination of vectors (atoms)  $\mathbf{g}_k \in \mathbb{R}_+^n$  for  $k = 1, \ldots, K$ , i.e.,  $\mathbf{y} = \mathbf{G}\mathbf{x}$ , where  $\mathbf{G} =$  $[g_1,\ldots,g_K]$  is referred to as the *dictionary* and  $\mathbf{x} \in \mathbb{R}_+^K$  are appropriate non-negative selection coefficients. If  $K > n$  or even  $K \gg n$ , we say the dictionary is *overcomplete*. As a result, the coefficient vector is not unique and larger than the original image. In this setting, we desire coefficients that exhibit sparsity, i.e., many elements in x are being zero, to ensure we do not increase the storage of our solution.

To select such a suitable and sparse coefficient vector  $\bf{x}$  (and therefore a suitable  $\bf{y}$ ), we ideally minimize

<span id="page-1-0"></span>
$$
\min_{\mathbf{x} \ge \mathbf{0}} \quad \|\mathbf{x}\|_{0} \quad \text{subject to} \quad \frac{1}{2} \left\| \mathbf{C} \mathbf{G} \mathbf{x} - \mathbf{b} \right\|_{2}^{2} \le \delta^{2},\tag{3}
$$

where  $\|\mathbf{x}\|_0$  is not a proper norm and is defined as the cardinality of non-zero elements in **x**, while  $\delta$  represents the given noise level. Solving [\(3\)](#page-1-0) is NP-hard and efficient approximation approaches need to be utilized, [\[13,](#page-20-4) [40\]](#page-21-3). One approach in tackling [\(3\)](#page-1-0) is to incrementally generate non-zero elements in x by iteratively selecting and updating the element in x minimizing the remaining residual until a prescribed accuracy threshold is reached. Methods following this approach include matching pursuit and orthogonal matching pursuit, [\[25,](#page-20-5) [41\]](#page-21-4). A main disadvantage of matching pursuit approaches is that we cannot ensure optimally. Further, each iteration requires the computation of inner products with the remaining dictionary adding to the computational complexity of the algorithm.

A common alternative approach to provide a non-negative and sparse x is based on convex relaxation. We approximate [\(3\)](#page-1-0) by

<span id="page-1-1"></span>
$$
\min_{\mathbf{x} \ge \mathbf{0}} \quad \frac{1}{2} \left\| \mathbf{A} \mathbf{x} - \mathbf{b} \right\|_{2}^{2} + \lambda \left\| \mathbf{x} \right\|_{1},\tag{4}
$$

where  $\mathbf{A} = \mathbf{C}\mathbf{G}$  and  $\lambda > 0$  is an appropriate regularization parameter [\[6\]](#page-19-2). When **x** is unrestricted, the optimization problem [\(4\)](#page-1-1) is the so-called least absolute shrinkage and selection operator (LASSO) problem. Methods such as basis pursuit, Alternating Direction Method of Multipliers (ADMM), and Variable Projected Augmented Lagrangian (VPAL) have been shown to efficiently solve an unconstrained version of  $(4)$ ; see [\[3,](#page-19-3) [9,](#page-19-4) [11\]](#page-20-6). Additionally, Krylov subspace methods are a major tool for large-scale least squares problems [\[34\]](#page-21-5). However, none of these approaches are directly applicable in this setting because they do not inherently enforce non-negativity or promote sparse solutions. Consequently, alternative approaches have been developed to address these constraints. Here, we follow another approach, we propose to use a method designed for non-negative least squares and extend these approaches to also provide sparse solutions.

Our work is structured as follows. In Section [2](#page-2-0) we provide details on the modified residual norm steepest descent methods which have been developed to solve least squares problems with non-negativity constraints and we further provide a background on patch dictionary learning. In Section [3](#page-4-0) we discuss our proposed <span id="page-2-2"></span>methods to solve non-negative least squares problems with sparsity priors. We demonstrate the effectiveness of our approaches with various numerical experiments in Section [4](#page-6-0) including deblurring (Section [4.2\)](#page-7-0), image completion (Section [4.3\)](#page-9-0), and computer tomography (Section [4.4\)](#page-12-0). We close up our investigations with some conclusions and further outlook in Section [5.](#page-18-0)

# <span id="page-2-0"></span>2 Background

Because images are inherently non-negative, we are interested in the constrained optimization problem

<span id="page-2-1"></span>
$$
\min_{\mathbf{x} \ge \mathbf{0}} \quad f(\mathbf{x}) \equiv \frac{1}{2} \left\| \mathbf{A} \mathbf{x} - \mathbf{b} \right\|_{2}^{2}.
$$
 (5)

While standard constrained optimization techniques may be employed for [\(5\)](#page-2-1), they often suffer from poor computational efficiency [\[29\]](#page-21-6). To address this issue, specialized methods like the expectation-maximization (EM) algorithm or modified residual norm steepest descent (MRNSD) have been proposed. These methods have shown great success by directly handling the linear least squares fitting term with non-negativity constraints [\[21,](#page-20-7) [26\]](#page-21-7).

### 2.1 Modified Residual Norm Steepest Descent (MRNSD)

The main idea behind MRNSD is to enforce non-negativity by introducing an implicit, element-wise exponential variable transformation and performing a gradient descent update directly on x with appropriate step size selection. Let us introduce the element-wise variable transformation  $x_i = e^{z_i}$ , for  $i = 1, ..., K$ , short we write  $\mathbf{x} = e^{\mathbf{z}}$ . This mapping ensure  $\mathbf{x} \geq \mathbf{0}$  and the optimization problem [\(5\)](#page-2-1) reduces to

$$
\min_{\mathbf{z}} \quad \hat{f}(\mathbf{z}) \equiv \frac{1}{2} \left\| \mathbf{A} e^{\mathbf{z}} - \mathbf{b} \right\|_2^2. \tag{6}
$$

Note the gradient of  $\hat{f}$ , the objective function over **z**-space, is given as

$$
\nabla_{\mathbf{z}} \hat{f}(\mathbf{z}) = \text{diag}(e^{\mathbf{z}}) \mathbf{A}^{\top} (\mathbf{A} e^{\mathbf{z}} - \mathbf{b}) = \text{diag}(\mathbf{x}) \nabla_{\mathbf{x}} f(\mathbf{x}). \tag{7}
$$

MRNSD performs a steepest descent direction update with respect **x** using the gradient of  $\hat{f}$ , i.e.,

$$
\mathbf{s} = -\nabla_{\mathbf{z}} \hat{f}(\mathbf{z}) = -\text{diag}(\mathbf{x}) \mathbf{g},\tag{8}
$$

where  $\mathbf{g} = \nabla_{\mathbf{x}} f(\mathbf{x}) = \mathbf{A}^\top (\mathbf{A}\mathbf{x} - \mathbf{b})$  is the gradient of the f, the objective function in x-space. We note that s is a descent direction in **x**-space, i.e.,  $\mathbf{s}^\top \mathbf{g} < 0$ , because of the assumed positivity of **x**. This ensures diag(**x**) is a positive definite matrix, which in turn ensures we move in a descent direction. Further note that an optimal step size can be computed, i.e.,

$$
\alpha = \frac{-\mathbf{s}^\top \mathbf{g}}{\mathbf{s}^\top \mathbf{A}^\top \mathbf{A} \mathbf{s}}.\tag{9}
$$

However, since MRNSD updates  $x$  directly (and not the surrogate variable  $z$ ), there may exist a selected step length  $\alpha > 0$  for which the update  $x + \alpha s$  can have negative elements. Hence, thresholding must be performed to maintain non-negativity in x which is provided by

$$
\alpha = \min \left\{ -\mathbf{s}^{\top} \mathbf{g} / (\mathbf{s}^{\top} \mathbf{A}^{\top} \mathbf{A} \mathbf{s}), \min_{s_i < 0} \{-x_i / s_i\} \}_{i=1}^K \right\}.
$$
 (10)

The MRNSD method is summarized in Algorithm [1.](#page-3-0)

Note that MRNSD only performs a surrogate variable transformation implicitly but never constructs nor updates z. While MRNSD has been shown to effectively address non-negativity constraints, the utilized exponential mapping prevents values of  $x$  from becoming zero and hence does not naturally promote sparsity in the solution. Achieving sparsity requires ad hoc threshholding in postprocessing, and motivates our exploration of efficient methods that enforce both non-negativity and sparsity during optimization.

Figure 1: Illustration of image patchification. For simplicity, we illustrate non-overlapping patches that exactly partition the image with  $r = (M/p)(N/q)$  total patches. In MATLAB, this operation is given by im2col(Y,[p,q],'distinct') and is reversible.

### 2.2 Dictionary Learning

Before we turn our attention to sparsity-promoting alternatives to MRNSD, we next provide some details on patch dictionary learning and the resulting sparse representations [\[36,](#page-21-2) [37\]](#page-21-8). Suppose we have a set of t training  $M \times N$  images  $\{Y_1, \dots, Y_t\}$  with  $\text{vec}(\mathbf{Y}_j) \in \mathcal{Y} \subset \mathbb{R}_+^{MN}$ , where  $\text{vec}(\cdot)$  vectorizes the image columnwise. We collect (overlapping) patches of size  $p \times q$  with  $p \times M$  and  $q \times N$ , "patchify" the images in our training set, and vectorize those patches and store them as columns of a matrix  $\mathbf{Y}^{\text{patch}} \in \mathbb{R}_{+}^{pq \times tr}$  where r is the number of patches per image; see Figure [1](#page-3-1) for an illustration.

A goal in dictionary learning is to construct an appropriate non-negative patch dictionary  $\mathbf{D} \in \mathbb{R}^{pq \times s}_{+}$ with a corresponding set of non-negative, column-wise sparse coefficients  $\mathbf{X}^{\text{patch}} \in \mathbb{R}_+^{s \times r}$  such that  $\mathbf{Y}^{\text{patch}} \approx$ DX<sup>patch</sup>. The desired properties of the decomposition ensure that each patch of our training set will be constructed using only a few dictionary atoms, producing a "parts-of-the-whole" type of basis [\[23\]](#page-20-8).

Following the presentation in [\[36\]](#page-21-2), we form this non-negative matrix factorization by solving the optimization problem

<span id="page-3-3"></span><span id="page-3-2"></span>
$$
\min_{\mathbf{D}\in\mathcal{D}, \mathbf{X}^{\text{patch}} \in \mathbb{R}^{s \times r}_{+}} \frac{1}{2} \left\| \mathbf{Y}^{\text{patch}} - \mathbf{D} \mathbf{X}^{\text{patch}} \right\|_{\text{F}}^{2} + \beta \sum_{j=1}^{r} \|\mathbf{x}_{j}^{\text{patch}}\|_{1},\tag{11}
$$

where  $\mathbf{x}_{j}^{\text{patch}} \in \mathbb{R}^{s}$  is the j-th column of  $\mathbf{X}^{\text{patch}}$ ,  $\beta > 0$  is the regularization parameter for the sparsitypromoting  $\ell_1$ -regularization, and D restricts the values of the dictionary to lie between 0 and 1. In our experiments, we use box constraints

$$
\mathcal{D} := \left\{ \mathbf{D} \in \mathbb{R}^{pq \times s} \mid 0 \le d_{ij} \le 1 \text{ for } i = 1, \dots, pq \text{ and } j = 1, \dots, s \right\}. \tag{12}
$$

The dictionary learning problem [\(11\)](#page-3-2) is non-convex with respect to  $(D, X^{\text{patch}})$  jointly, but is convex with respect to each variable separately. This motivates the use of an alternating optimization strategy. To this end, we consider the alternating direction method of multipliers (ADMM) approach proposed by [\[36\]](#page-21-2), which

<span id="page-4-3"></span><span id="page-4-2"></span>

(a) Flower dictionary patches from a subset of images resized to  $64 \times 64$ from [\[39\]](#page-21-9). The dictionary has 400 atoms, meaning  $\mathbf{D}_{\text{flower}} \in \mathbb{R}_+^{256 \times 400}$ .

(b) Earth dictionary patches from a single high-resolution image of the earth of size  $675 \times 1,200$  [\[22\]](#page-20-9). The dictionary has 400 atoms, meaning  $\mathbf{D}_{\text{earth}} \in \mathbb{R}_+^{256 \times 400}$ .

Figure 2: Sample of 10 patches from dictionaries generated from two different sources. For training, we collect overlapping patches of size  $16 \times 16$ . The patches share similar binary-looking patterns because of the box constraints [\(12\)](#page-3-3).

reformulates [\(11\)](#page-3-2) as

<span id="page-4-1"></span>
$$
\min_{\mathbf{D}, \mathbf{X}^{\text{patch}}, \mathbf{U}, \mathbf{V}} \quad \frac{1}{2} \left\| \mathbf{Y}^{\text{patch}} - \mathbf{U} \mathbf{V} \right\|_{\text{F}}^2 + \beta \sum_{i=1}^t \left\| \mathbf{x}_j^{\text{patch}} \right\|_1 + \chi_{\mathcal{D}}(\mathbf{D}) + \chi_{\mathbb{R}_+^{s \times r}}(\mathbf{X}^{\text{patch}}), \tag{13a}
$$

subject to 
$$
\mathbf{D} = \mathbf{U}
$$
 and  $\mathbf{X}^{\text{patch}} = \mathbf{V},$  (13b)

where  $\chi_{\mathcal{Z}}$  is the characteristic function over the set Z such that  $\chi_{\mathcal{Z}}(z) = 0$  if  $z \in \mathcal{Z}$  and  $\chi_{\mathcal{Z}}(z) = +\infty$ if  $z \notin \mathcal{Z}$ . Introducing the auxiliary U and V ensures that the function is separable over the optimization variables, a necessary condition for ADMM. We solve [\(13\)](#page-4-1) using the augmented Lagrangian approach [\[3\]](#page-19-3); for further details, see [\[28,](#page-21-10) [36,](#page-21-2) [37\]](#page-21-8). Examples of generated dictionary patches are shown in Figure [2.](#page-4-2)

The patch dictionary presentation is related to the original global dictionary formulation in Section [1.](#page-0-2) Let  $X_i \in \mathbb{R}^{pq \times r}_+$  be the coefficients of the patches drawn from training image  $Y_i$  and assume the patches are non-overlapping. Then,

$$
\text{vec}(\mathbf{Y}_i) = \mathbf{P}\text{vec}(\mathbf{D}\mathbf{X}_i) = \underbrace{\mathbf{P}(\mathbf{I} \otimes \mathbf{D})}_{\mathbf{G}}\text{vec}(\mathbf{X}_i),\tag{14}
$$

where ⊗ denotes the Kronecker product, I is the r×r identity matrix, and P is a permutation matrix mapping patches to linear indices [\[32\]](#page-21-11). We require the permutation matrix because  $vec(\mathbf{X}_i)$  stacks vectorized patches column-wise, but vec( $Y_i$ ) concatenates the columns of the image vertically, which order the pixels differently.

# <span id="page-4-0"></span>3 Non-negativity and Sparsity-Promoting Mappings

We consider two alternative approaches based on MRNSD to promote sparse solutions. In the first approach, we introduce an  $\ell_1$ -regularization term following the presentation [\[28\]](#page-21-10). In the second approach, we modify the implicit non-negativity mapping to allow for entries to be set equal to zero. In both cases, choose an optimal step size based on the new iterations.

Sparsity-Promoting MRNSD We consider a sparsity-promoting MRNSD that minimizes the nonnegativity-constrained lasso problem as introduced in  $(4)$ . The  $\ell_1$ -norm promotes sparsity when the solution switches from positive to negative entries. However, because unregularized MRNSD imposes the implicit mapping that enforces strict positivity of the solution, the  $\ell_1$ -regularization will not promote sparsity. In response, we slightly modify the implicit mapping as  $x = e^z - \varepsilon$  where  $\varepsilon > 0$  to allow for small negative values. Following proximal operator theory [\[31\]](#page-21-12), the resulting sparsity-promoting MRNSD iteration is

$$
\mathbf{x} \leftarrow S_{\alpha\lambda}(\mathbf{x} + \alpha \mathbf{s}),\tag{15}
$$

<span id="page-5-4"></span>where the soft-thresholding operator  $S_{\alpha\lambda}$  is applied entry-wise and given by the piecewise function<sup>[1](#page-5-0)</sup>

<span id="page-5-3"></span><span id="page-5-1"></span>
$$
(S_{\gamma}(\mathbf{x}))_i = \begin{cases} x_i + \gamma, & \text{for } x_i < -\gamma, \\ 0, & \text{for } |x_i| \le \gamma, \\ x_i - \gamma, & \text{for } x_i > \gamma, \end{cases} \quad \text{for } i = 1, \dots, K. \tag{16}
$$

In this work, we choose the optimal step size for the soft-threshold-updated solution by solving

$$
\alpha^* \in \min_{\alpha \in [0, u]} \frac{1}{2} \|\mathbf{A} S_{\alpha \lambda}(\mathbf{x} + \alpha \mathbf{s}) - \mathbf{b}\|_2^2, \qquad \text{where} \quad u = \min_{s_i < -\lambda} \{-x_i / (s_i + \lambda)\}_{i=1}^K \tag{17}
$$

at each iteration. Solving the scalar optimization problem [\(17\)](#page-5-1) can be performed efficiently utilizing nonlinear solvers for single variables such as golden section search with parabolic interpolation [\[1\]](#page-19-5). We summarize sparsity-promoting MRNSD (spMRNSD) in Algorithm [2.](#page-5-2) We note that in practice we can pre-apply the operator A before solving [\(17\)](#page-5-1), significantly reducing the computational cost.

Note that the upper bound u in  $(17)$  is slightly different from the boundary for the original MRNSD step size (Algorithm [1,](#page-3-0) Line [5\)](#page-3-4). Specifically, when we step in x-space in MRNSD, we adjust the step size  $\alpha$  to ensure that the step  $x_i + \alpha s_i$  does not violate the non-negativity constraint. Similarly, for spMRNSD, we must ensure that the smallest value in  $S_{\alpha\lambda}$  remains non-negative; that is, whenever  $x_i + \alpha s_i < -\alpha\lambda$  or rewritten  $x_i + \alpha(s_i + \lambda) < 0$  is satisfied. Because  $x_i, \lambda$  and  $\alpha$  are assumed to be non-negative, this condition arises when  $s_i$  is negative and sufficiently smaller than  $-\lambda$ . Thus,  $\alpha$  cannot be larger than  $-x_i/(s_i + \lambda)$ , which completes the upper bound of [\(17\)](#page-5-1).

The original sparsity-promoting MRNSD from [\[28\]](#page-21-10) used the optimal MRNSD step size in Algorithm [1,](#page-3-0) Line [5.](#page-3-4) Instead of the optimal step size for the soft-thresholding operator. We note that the MRNSD step size is acceptable for spMRNSD in the sense that it will not introduce negative values in x, but may produce inferior updates. However, an optimal step size based on the soft-thresholding operator could potentially be larger because it allows for negative search directions up to the level of  $-\lambda$ . Additionally, a larger step size will make the middle region of [\(16\)](#page-5-3) wider, potentially yielding sparser solutions. This being said, the MRNSD step size may be larger or yield sparser solutions for certain problems, but these cases are difficult to predict and further analysis will be considered for future directions.

#### <span id="page-5-2"></span>Algorithm 2 Sparsity-Promoting MRNSD (spMRNSD) [\[28\]](#page-21-10)

1: Solve  $\min_{\mathbf{x} \geq 0} \frac{1}{2} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{x}\|_1$ 2: while not converged do 3:  $\mathbf{g} = \mathbf{A}^\top (\mathbf{A}\mathbf{x} - \mathbf{b})$ 4:  $\mathbf{s} = -\text{diag}(\mathbf{x})\mathbf{g}$ 5: compute  $\alpha^*$  solving [\(17\)](#page-5-1) 6:  $\mathbf{x} \leftarrow S_{\alpha^* \lambda} (\mathbf{x} + \alpha^* \mathbf{s})$ 7: end while

Sparsity-Promoting Non-negative Mapping As a competing approach to spMRNSD, we focus on adapting the non-negativity MRNSD mapping. The core of MRNSD is to represent the solution via the *implicit* non-negative mapping  $x = e^z$ . Here, we consider a broader class of point-wise, non-negativity mappings  $w: \mathbb{R}^K \to \mathbb{R}^K_+$  and solve

$$
\min_{\mathbf{z}} \quad \frac{1}{2} \left\| \mathbf{A} w(\mathbf{z}) - \mathbf{b} \right\|_{2}^{2}.
$$
 (18)

There are two key differences between our approach and traditional MRNSD. The first is that MRNSD performs all of the updates in x-space, potentially yielding small step sizes near the boundary of the nonnegative domain. In comparison, our approach will take steps in z-space, which is unconstrained and can

<span id="page-5-0"></span><sup>&</sup>lt;sup>1</sup>In MATLAB, we write softThreshold(y,c) = sign(y)  $.*$  max(abs(y) - c, 0).

<span id="page-6-2"></span>

Figure 3: Consider the toy problem  $\min_{\mathbf{x} \geq 0} \|A\mathbf{x} - \mathbf{b}\|_2^2$ , with  $\mathbf{A} = \begin{bmatrix} 20 & 5 \\ 5 & 20 \end{bmatrix}$  and  $\mathbf{b} = \begin{bmatrix} 2 \\ 23 \end{bmatrix}$ . The unconstrained minimizer is at  $\mathbf{x}^* = 1/10 \begin{bmatrix} -2 & 12 \end{bmatrix}^\top$  (purple), while the minimizer of the constrained optimization problem is obtained at  $\hat{\mathbf{x}} = \begin{bmatrix} 0 & 1.1059 \end{bmatrix}^{\top}$  (dark red). We illustrate the different steepest descent paths in the x-space. Let the current iteration start from  $\mathbf{x} = \begin{bmatrix} 0.15 & 0.13 \end{bmatrix}^{\top}$ . We depict various choices for MRNSD (line search in x, dashed lines) and spNNGD (line search in z, solid lines), with four different functions for w, i.e.,  $w(\mathbf{z}) = \mathbf{z}^2$  (blue),  $w(\mathbf{z}) = e^{\mathbf{z}}$  (red),  $w(\mathbf{z}) = |\mathbf{z}|$  (yellow),  $w(\mathbf{z}) = w_{1,0}(\mathbf{z})$  from [\(19\)](#page-6-1) (green). Note that with optimal step size selection, spNNGD with the  $w_{1,0}(\mathbf{z})$  would find the minimizer in just one iteration.

allow for larger steps. The second difference is the broader choice of mapping. MRNSD restricts itself to the exponential mapping. However, any other non-negativity mapping may be viable as well, e.g.,  $\mathbf{x} = w(\mathbf{z}) = \mathbf{z}^2$ , or  $\mathbf{x} = w(\mathbf{z}) = |\mathbf{z}|$ . Here, we propose the following,

<span id="page-6-1"></span>
$$
w_{a,c}(z) = \begin{cases} e^{a(z-c)} - a(z-c) - 1, & \text{for } z > c, \\ 0, & \text{for } z \le c, \end{cases}
$$
 (19)

where  $a > 0$  controls the steepness of the mapping and c controls where the mapping switches from exponential to zero. The mapping is continuously differentiable and allows for the solution  $\mathbf{x} = w(\mathbf{z})$  to have entries equal to zero. An illustrative toy example of how different mappings perform is provided in Figure [3.](#page-6-2)

This new method provides sparsity while ensuring non-negativity in x, hence we refer to this method as Gradient Descent with a Sparsity-Promoting Non-negative Mapping (spNNGD). We summarize the proposed approach in Algorithm [3.](#page-7-1)

This approach shares some similarities with sparsity-promoting MRNSD. First, the sparsity pattern will not change during the iterations; that is, once a zero appears in the search direction, we do not change the value of  $z$ , so the zero remains throughout the iterations. This is because  $w'(z)$  will have the same pattern of zeros as  $w(\mathbf{z})$ . Second, the implicit vertical shift defined by  $\varepsilon$  plays a similar role to a and c in that it enables zero values to exist in the mapping.

## <span id="page-6-0"></span>4 Numerical Experiments

#### 4.1 Experiment Setup

In the following, we discuss four experiments comparing the effectiveness of our two proposed methods. Specifically, we investigate an image deblurring, an image completion, a medical tomography, and a super-

resolution problem. For reproducible science, we made the experiments and code available at [https://](https://github.com/elizabethnewman/DL4IP) [github.com/elizabethnewman/DL4IP](https://github.com/elizabethnewman/DL4IP).

Metrics and Presented Results We consider three metrics that measure (relative) accuracy and sparsity, respectively, given by

rel. residual = 
$$
\frac{\|\mathbf{Ax} - \mathbf{b}\|_2}{\|\mathbf{b}\|_2}
$$
, rel. error =  $\frac{\|\mathbf{y}_{\text{true}} - \mathbf{Gx}\|_2}{\|\mathbf{y}_{\text{true}}\|_2}$ , and rel. sparsity =  $\frac{\text{nnz}(\mathbf{x})}{\text{nnz}(\mathbf{y}_{\text{true}})}$ , (20)

where  $nnz(\cdot)$  computes the number of nonzero entries for the given array. For all metrics, lower values indicate better performance. While the relative residual and the relative error are common measures of quality, the relative sparsity metric, storing the cost of the coefficients  $\bf{x}$  relative to storing the original image,  $\bf{y}_{true}$ , is a critical measure in dictionary learning. The image's storage cost is reduced when the relative sparsity is below 1. For every experiment and each algorithm, we present the reconstruction results using the above metrics and the convergence results, including the relative residual, a proxy for the relative sparsity, and the optimal step sizes for each iteration.

Operators. Each experiment in this section relies on a specific linear operator C. The shapes and sparsity patterns vary significantly for each application. For completeness, we illustrate the sparsity patterns of the operators in Figure [4a.](#page-8-0) In every problem, we incorporate a generalized Tikhonov regularization on the approximation  $\mu \mathcal{R}(\mathbf{y}) = \mu \|\mathbf{L}\mathbf{y}\|_2^2$ . We utilize different regularization operators **L** depending on the problem. All of the operators we consider promote smoother approximations, and hence are variations of two-dimensional finite difference operators. By a "finite difference" operator, we mean that each row of L contains a single 1 and a single −1 to compute the difference between pixels. The three finite differencing operators we consider are the following: the difference between (1) all adjacent pixels, (2) adjacent pixels at the boundary of patches, and (3) adjacent patches. The sparsity patterns of the three operators are depicted in Figure [4b.](#page-8-0)

#### <span id="page-7-0"></span>4.2 Deblurring

Capturing digital images can often introduce noise, blur, and other distortions that hide the true representation. Image deblurring has been a long-studied technique to remove unwanted artifacts in and enhance digital images [\[19\]](#page-20-10). Here, we consider applying the Gaussian blurring operator to an  $N \times N$  image. To be precise, we construct the blurring operator  $\mathbf{C} \in \mathbb{R}^{N^2 \times N^2}$  as a banded, Toeplitz matrix with exponentially decaying bands<sup>[2](#page-7-2)</sup>. We use a bandwidth of  $b = 3$  and an exponential decay rate of  $\sigma = 4$ . Given a vectorized true image  $y_{true} \in \mathbb{R}^{N^2}_+$ , we construct a blurred, noisy image  $b = Cy_{true} + \eta$  where each entry of the noise

<span id="page-7-2"></span><sup>&</sup>lt;sup>2</sup>In MATLAB, we write  $C1 = \text{toeplitz(exp(-(0:b-1) / (2 * sigma * sigma)), zeros(1, n - b)); C = kron(C1, C1);$ to construct this blurring operator.

<span id="page-8-0"></span>

(a) Model operators  $C$  where  $numel(\cdot)$  returns the total number of elements in the given array.

(b) Finite differencing regularization operators L

Figure 4: Sparsity patterns of operators. The operators are illustrated with the correct proportions based on their row and column dimensions. The width of the operators is correctly scaled (e.g., the superresolution operator has twice as many columns as the deblurring operator).

<span id="page-9-2"></span>vector  $\eta$  is drawn from a Gaussian distribution  $\mathcal{N}(0, \beta||\mathbf{C}\mathbf{y}_{\text{true}}||_2^2\mathbf{I}_{N^2})$  with noise level  $\beta = 10^{-4}$ . We include a pixel smoothing Tikhonov regularizer term with regularization parameter  $\mu = 10^{-4}$ . We train for 100 iterations for both spNNGD and spMRNSD and report the results in Figure [5](#page-10-0) and the convergence behavior in Figure [6.](#page-11-0)

In Figure [5,](#page-10-0) we observe that both spNNGD and spMRNSD produce qualitatively good approximations to the original image for similar sparsity levels. Both sets of coefficients require less than 25% of the storage cost of the original image. Both approximations produce some blocky artifacts due to the dictionary patch representation; this is most noticeable in the spNNGD reconstruction of small vegetables, such as the garlic in the bottom right. In the bottom row, we observe similar sparsity patterns in the matricized coefficients for spMRNSD and spNNGD. In particular, the two have some rows with many nonzeros and some sparse rows, and the rows with high density are similar for both solutions. It can be observed, that the solution obtained from spMRNSD is slightly sparser than that obtained from spNNGD.

The convergence behavior in Figure [6a](#page-11-0) shows that spNNGD and spMRNSD converge to similar levels of accuracy at similar rates. In comparison, the sparsity convergence plot Figure [6b,](#page-11-0) we see that spNNGD converges quickly to a sparse solution and then stagnates, whereas spMRNSD converges to a sparse solution more gradually. This behavior indicates that spNNGD fixes a sparsity pattern early and learns the best coefficients for that pattern while spMRNSD adjusts the sparsity pattern during iterations. We note that both methods are constrained by the current sparsity pattern because the search direction  $\mathbf{s} = \text{diag}(w'(\mathbf{z}))\mathbf{g}$  has the same zero entries as the approximate solution  $\mathbf{x} = w(\mathbf{z})$ . The step size plot in Figure [6c](#page-11-0) supports our original hypothesis that we take larger step sizes in z-space (spNNGD) than in x-space (spMRNSD).

Examining the relative error plot, it becomes apparent that the relative error of spNNGD is more susceptible to changes in the steepness parameter  $a$  rather than the shift parameter  $c$ . This observation is substantiated by the relatively constant rows in the relative error plot. We also observe a positive correlation between a and c, implying that increasing both parameters simultaneously results in small changes to the relative error. However, while the relative error exhibits a degree of sensitivity to the choice of parameters, the sparsity plot appears to be less sensitive to its parameter selection.

For spMRNSD, we observe that the relative error remains mainly constant across a wide range of regularization parameter  $\lambda$  values, while the sparsity undergoes drastic changes. This behavior is consistent with expectations, that larger values for  $\lambda$  will lead to poorer approximations and sparser solutions.

There are several major takeaways from our exploration of the image deblurring problem. First, the spMRNSD produced better results in terms of approximation quality and sparsity, but spNNGD is competitive. In terms of convergence, spNNGD obtains a sparser solution in fewer iterations than spMRNSD with larger step sizes, but as a result, prescribes a sparsity pattern of the solution early. In comparison, spMRNSD gradually increases sparsity which can bring benefits in the long run. In terms of sensitivity to parameters, the spNNGD parameters can drastically change the relative error, but the sparsity stays more consistent. Conversely, the regularization parameter for spMRNSD can drastically change the sparsity but does not impact the relative error as dramatically.

### <span id="page-9-0"></span>4.3 Image Completion

Matrix completion arises in numerous fields [\[7,](#page-19-6) [24\]](#page-20-11), such as collaborative filtering to predict users preferences with incomplete information [\[5\]](#page-19-7), pixels [\[2\]](#page-19-8), recovery of incomplete signals [\[12\]](#page-20-12), and digital image inpainting to restore damaged or missing information. There are similarly many different approaches to completing matrices, including forming a low-rank approximation and solving an inverse problem. In this section, we explore the inverse problem approach for digital inpainting applications.

We construct the missing pixel operator  $\mathbf{C} \in \mathbb{R}^{m \times N^2}$  with  $m \ll N^2$  that samples uniformly random pixels from an  $N \times N$  image. In practice, the rows of **C** are a subset of rows from the  $N^2 \times N^2$  identity matrix. As a result,  $\mathbf{b} = \mathbf{C} \mathbf{y}$  contains the same as the original image with a percentage of pixels randomly set to zero. In our experiment, we use Johannes Vermeer's *Girl with the Pearl Earring* painting,<sup>[3](#page-9-1)</sup> resized to

<span id="page-9-1"></span><sup>3</sup>[https://en.wikipedia.org/wiki/Girl\\_with\\_a\\_Pearl\\_Earring](https://en.wikipedia.org/wiki/Girl_with_a_Pearl_Earring)

<span id="page-10-0"></span>

Figure 5: Reconstructions for the image deblurring task. The top row (left-to-right) contains the original image, the blurred, noisy image, the reconstruction using spMRNSD, and the reconstruction using spNNGD. The middle row displays the absolute differences between the original and the reconstructions with the relative error and sparsity metrics below. Here, spMRNSD produces the best approximation in terms of both metrics of interest. The bottom row depicts the sparsity patterns of matricized solutions  $\bf{x}$  of size  $400 \times 256$  where each column corresponds to the coefficients for one vectorized dictionary patch.

<span id="page-11-0"></span>

Figure 6: Convergence behavior for the deblurring problem. The relative residual norm (left) converges at similar rates for both algorithms. The proxy for relative sparsity (middle) converges faster for spNNGD. On average, the step sizes (right) for spNNGD are larger and more consistent.

(a) spNNGD: the effect of steepness a and shift c in  $w_{a,c}(z)$  on relative error and sparsity.

(b) spMRNSD: the effect of the regularization parameter  $\lambda$  on relative error and sparsity.

Figure 7: Parameter sensitivity exploration for the deblurring problem.

<span id="page-12-1"></span> $N \times N = 128 \times 128$ , and removed 60% of the pixels in our experiments. We report the representation results in Figure [8](#page-13-0) and the convergence behavior in Figure [9.](#page-14-0)

In Figure [8,](#page-13-0) we observe that both spNNGD and spMRNSD produce qualitatively good approximations of the original image. The approximation obtained from spMRNSD is a sharper approximation to the original, particularly for the facial features in the image. Additionally, the spMRNSD-generated coefficients are notably sparser than those generated by spNNGD. The sparsity patterns of the un-vectorized coefficients reflect these metrics.

The convergence behavior in Figure [9a](#page-14-0) and Figure [9b](#page-14-0) matches that of Section [4.2.](#page-7-0) In particular, it shows that both algorithms converge to similar levels of accuracy at similar rates and spNNGD quickly reaches a sparse solution while spMRNSD converges more gradually. Notably and surprisingly, the step size plot in Figure [9c](#page-14-0) reveals that larger steps are taken in x-space (spMRNSD) than in z-space (spNNGD). The difference in behavior in terms of both relative sparsity and step size can be attributed to the image completion operator and data normalization. Specifically, C has rows from an identity matrix, the dictionary G contains entries between 0 and 1, and the right-hand side is normalized so its maximum value is 1. Thus, the approximation  $CGw_{a,c}(z)$  is more directly sensitive to values in the coefficients. For spNNGD, a large update in z could introduce unwanted zeros or could yield large values for  $w_{a,c}(\mathbf{z})$ . For this reason, we take smaller step sizes. In comparison, for spMRNSD, the soft thresholding operator reduces large values and zeroes out small values, enabling slightly larger step sizes.

To summarize, the main takeaways from the image completion experiment are that spNNGD and spMRNSD produce approximations with similar relative errors, and spMRNSD produces a sparser solution. As before, spNNGD converges to a sparser solution more quickly, but the gradual progress of spMRNSD produces better metrics overall. The operator plays a role in determining the effectiveness of the chosen method and may inform the preferred approach.

### <span id="page-12-0"></span>4.4 Tomography

Tomography is an imaging technique that reconstructs the characteristics of an object's interior by taking cross-sectional measurements from the exterior. Tomography is widely used in a variety of applications ranging from but not limited to geophysics, atmospheric science, physics, materials science, and medical imaging. In the medical field, computer tomography (CT) is a common non-invasive technique used for diagnostic purposes and surgical planning. CT employs penetrating X-rays to pass through an object, with the amount of energy absorbed dependent on the object's properties along the X-ray path. Detectors on the opposite side measure the intensity of the X-rays emitted by the source. By rotating both the X-ray source and receiver around the object, measurements are collected in a sinogram. CT is a classic example of an inverse problem, where the goal is to deduce the object's energy absorbency from the sinogram. For illustration, we consider the 2D computer tomography [\[20,](#page-20-13) [27\]](#page-21-13). The ill-posedness of this problem requires regularization and a common regularization functional is total variation.

In this experiment, we leverage the setup from IRTools [\[14\]](#page-20-14) and AIRTools II [\[18\]](#page-20-15) to construct a parallel beam tomography problem; see Figure [10](#page-14-1) for illustration. We reconstruct the Shepp-Logan phantom of size  $N \times N = 256 \times 256$ . The model matrix **C** is constructed using  $\lfloor \sqrt{2N} \rfloor = 362$  rays and 100 rotation angles equispaced between 0 and 179 degrees. For the generalized Tikhonov regularization, we use a patch smoothing operator with  $\mu = 1$ . We train for 100 iterations, use the flower dictionary for representation. and report our results in Figure [11](#page-15-0) and Figure [12.](#page-16-0)

In Figure [12,](#page-16-0) we observe spNNGD produces the best approximation results combined with the sparsest solution. The approximation is particularly sharp in the center of the Shepp-Logan phantom, while the reconstruction obtained from spMRNSD retains many artifacts from the dictionary patches. The sparsity patterns of the solutions are slightly different for the two algorithms as well. The coefficients from spMRNSD are dense in the center while the spNNGD contain more nonzeros at the edges. We note that for both algorithms, the largest errors occur on the edges of the Shepp-Logan phantom. This is perhaps unsurprising because the dictionary elements from the flower dictionary do not contain similar curved features. A different dictionary prior could yield improved performance on the edge features, but learning the dictionaries is outside the scope of this work.

<span id="page-13-0"></span>

Figure 8: Reconstructions for the image completion task. The top row (left-to-right) contains the original image, the blurred, noisy image, the reconstruction using spMRNSD, and the reconstruction using spNNGD. The middle row displays the absolute differences between the original and the reconstructions with the relative error and sparsity metrics below. Here, spMRNSD produces the best approximation in terms of both metrics of interest. The bottom row depicts the sparsity patterns of matricized solutions  $x$  of size  $400 \times 64$  where each column corresponds to the coefficients for one vectorized dictionary patch.

<span id="page-14-2"></span><span id="page-14-0"></span>

Figure 9: Convergence behavior for the image completion problem. The relative residual norm (left) converges at similar rates for both algorithms. The proxy for relative sparsity (middle) converges faster for spNNGD. On average, the step sizes (right) for spMRNSD are larger and the step sizes for spNNGD are more consistent.

<span id="page-14-1"></span>

Figure 10: Illustration of parallel beam tomography, [\[33\]](#page-21-14).

<span id="page-15-0"></span>

Figure 11: Reconstructions for the computing tomography task. The top row (left-to-right) contains the original image, the blurred, noisy image, the reconstruction using spMRNSD, and the reconstruction using spNNGD. The middle row displays the absolute differences between the original and the reconstructions with the relative error and sparsity metrics below. Here, spMRNSD produces the best approximation in terms of both metrics of interest. The bottom row depicts the sparsity patterns of matricized solutions  $x$  of size  $400 \times 256$  where each column corresponds to the coefficients for one vectorized dictionary patch.

<span id="page-16-3"></span><span id="page-16-0"></span>

Figure 12: Convergence behavior for the computed tomography problem. The relative residual norm (left) converges faster for spNNGD and exhibits more erratic behavior for spMNRSD. The proxy for relative sparsity (middle) converges faster for spNNGD. On average, the step sizes (right) for spNNGD are larger and more consistent.

We also mention that the structure of the data motivations for using a patch smoother rather than a pixel smoother or patch border smoother. We train a dictionary on natural images, but the Shepp-Logan phantom is constructed synthetically. The Shepp-Logan patches are closer to piecewise constant than natural image patches. Using a patch smoother, we encourage patches of the images to be more similar, which leads to larger regions of almost constant pixel values.

As in the previous experiments, spNNGD converges more quickly to a smaller relative error and a sparser solution and takes larger step sizes on average. However, we observe starkly different convergence behavior in Figure [12a](#page-16-0) than in the previous experiments. The convergence of spMRNSD is erratic after approximately 30 iterations. This behavior is due to the soft-thresholding operator and the mismatch of a search direction in z-space and an update in x-space. These two factors make it possible for the algorithm to step in a non-descent direction x-space. We see this occur when the optimal  $\alpha$  is large and as the solution becomes sparser. In contrast, spNNGD, which computes search directions and steps in z-space, consistently decays.

#### <span id="page-16-2"></span>4.5 Superresolution

Superresolution is a technique to reconstruct a high-resolution image by a sequence of low-resolution images to reveal image details that are unobservable in lower resolution. This task arises in various applications, from enlarging and restoring blurry or damaged photos to improving medical imaging and enhancing surveillance footage [\[42\]](#page-21-15). For simplicity, let us assume we desire to reconstruct a high-resolution image  $\mathbf{x}_{true} \in \mathbb{R}^{N^2}$  from a sequence of low-resolution images  $\mathbf{b}_1,\ldots,\mathbf{b}_M \in \mathbb{R}^{\nu^2}$  with  $\nu^2 \ll N^2$ . We assume that the (ridged) image transformation, such as shifts, rotations, and scaling of the high-resolution image to each low-resolution image is known and denoted by  $\mathbf{S}_1,\ldots,\mathbf{S}_M \in \mathbb{R}^{N^2 \times N^2}$ . With a downsampling/restriction operator  $\mathbf{R} \in \mathbb{R}^{\nu^2 \times \tilde{N}^2}$ we state corresponding superresolution problem as

$$
\min_{\mathbf{x} \geq 0} \quad \left\| \begin{bmatrix} \mathbf{R} \mathbf{S}_1 \\ \vdots \\ \mathbf{R} \mathbf{S}_M \end{bmatrix} \mathbf{y}_{\text{true}} - \begin{bmatrix} \mathbf{b}_1 \\ \vdots \\ \mathbf{b}_M \end{bmatrix} \right\|_2^2 + \mu \left\| \mathbf{L} \mathbf{y}_{\text{true}} \right\|_2^2 \tag{21}
$$

where we selected a  $\ell_2$  regularization term, [\[35\]](#page-21-16).

In our experiments, we consider an resized  $N \times N = 512 \times 512$  builtin MATLAB image of the moon.<sup>[4](#page-16-1)</sup> We form  $\theta = 10$  low-resolution images, downsampled by a factor of eight. Thus, the low resolution images  $B_i$  are of size  $64\times64$  and the restriction operator is a matrix  $\mathbf{R}_{+} \in \mathbb{R}^{(N/8)^2 \times N^2}$ . Poetically, we reconstruct the moon

<span id="page-16-1"></span> $4 \text{img} = \text{imread('moon.tif')};$ 

<span id="page-17-1"></span><span id="page-17-0"></span>

Figure 13: Reconstructions for the superresolution task. The top row (left-to-right) contains the original image, the blurred, noisy image, the reconstruction using spMRNSD, and the reconstruction using spNNGD. The middle row displays the absolute differences between the original and the reconstructions with the relative error and sparsity metrics below. Here, spMRNSD produces the best approximation in terms of both metrics of interest. The bottom row depicts the sparsity patterns of matricized solutions  $\bf{x}$  of size  $400 \times 1024$  where each column corresponds to the coefficients for one vectorized dictionary patch. Note that the lower right patch for both approximations has significantly more error than the other patches due to the boundary conditions of the operator.

using the earth dictionary (Figure [2\)](#page-4-2). We use 100 iterations and a patch neighbor smoothing regularizer with  $\mu = 10^{-2}$ . We report the results of the superresolution experiment in Figure [13](#page-17-0) and Figure [15.](#page-18-1)

In Figure [13,](#page-17-0) we observe that both algorithms produce similar quality approximations, and both have the same artifact in the bottom right corner. We conjecture that the cause of this artifact is twofold. First, the location of this error may be due to the operator C which rotates the images counterclockwise about the upper left corner. The second is that the initial guess plays a crucial role in the approximation, and we see this artifact appear in early iterations (see Figure [14\)](#page-18-2). In this work, we opted for sacrificing some approximation quality to promote more sparsity, and hence focus on the results with the lower right corner error.

We note in Figure [13](#page-17-0) spNNGD does not produce any sparsity. We conjecture that sparsity is harder to obtain in superresolution partially because the right-hand sides already have many nonzeros (e.g.,  $\frac{nnz(b_1)}{nume1(b_1)} \approx$  $56\%$  and overall  $\frac{\text{nnz(b)}}{\text{numel(b)}} \approx 75\%$ ) and partially because we use small patches to reconstruct a higher resolution image. Per the latter point, as shown in [\[28\]](#page-21-10), the ratio between patch size and image size can significantly affect the sparsity pattern. We have seen in previous experiments that spNNGD settles on a sparsity pattern

<span id="page-18-3"></span><span id="page-18-2"></span>

Figure 14: Superresolution approximations for first five iterations. Approximations from both algorithms contain the lower right corner due to the boundary conditions of the operator. We show the approximations on the same color scale as the original image, which can be misleading in the initial iteration. The first approximation contains values larger than 1, hence all of the pixels appear to be yellow.

<span id="page-18-1"></span>

Figure 15: Convergence behavior for the superresolution problem. The relative residual norm (left) converges at similar rates for both algorithms. The proxy for relative sparsity (middle) reaches a lower level to spMRNSD. On average, the step sizes (right) for spNNGD are larger and more consistent.

in early iterations. Fixating on one sparsity pattern while maintaining a good approximation leads to a nonsparse solution. In contrast, spMRNSD gradually promotes sparsity, and performs better along this metric.

The first iteration of Figure [14](#page-18-2) exhibits similar behavior to the previous experiments with the two algorithms converging at similar rates in terms of relative error and spNNGD promoting sparsity faster. However, we quickly see spNNGD stagnate with minuscule step sizes, eventually halting progress at about 40 iterations. As expected, the early step sizes in Figure [15c](#page-18-1) are larger for spNNGD. Interestingly, both step sizes start to decay at similar rates for iterations 20 through 30, which is the iteration at which spMNRSD stops becoming sparser in Figure [15b.](#page-18-1)

## <span id="page-18-0"></span>5 Conclusions

We have demonstrated success in solving inverse problems using patch dictionary representations to obtain non-negative, sparse solutions in image deblurring (Section [4.2\)](#page-7-0), image completion (Section [4.3\)](#page-9-0), computed tomography (Section [4.4\)](#page-12-0), and superresolution (Section [4.5\)](#page-16-2). We proposed and compared two different modifications to the modified residual norm steepest descent (MRNSD) algorithm to produce solutions with the desired structure. Motivated by [\[28\]](#page-21-10), we first introduced a sparsity-promoting MRNSD (spMRNSD) by adding  $\ell_1$  regularization and iterating with a soft-thresholding operator. Our key contribution was using the correct optimal step size based on the soft-thresholding operator update. We compared this soft-thresholding approach to a new gradient descent approach with a sparsity-promoting, non-negative mapping in spNNGD. We observed that typically spNNGD converges faster to a sparse solution than spMRNSD and takes larger step sizes. However, the sparsity pattern can be fixed after a few iterations, which can limit improvements along that metric. In comparison, spMRNSD gradually increases sparsity via the soft-thresholding operator. The performance of each algorithm can vary significantly based on the task, depending on the given operator, the algorithmic hyperparameters, and the dictionary used for the representation. In general, it seems the gradual approach of spMRNSD offers more promise than the sparsity-promoting, non-negative mapping of spNNGD, but the advantages of the latter could lead to interesting future work.

The complex relationship between all of the parameters led to our comparison of the two algorithms and motivates several exciting extensions. For spMRNSD, we can we can explore other implicit mappings. Currently, we use the exponential mapping to enable simple steps in the solution space. We could perform similar implicit mappings and solution space steps with other mappings. For example, with  $\mathbf{x} = \mathbf{z}^2$ , our search in solution space (without forming z explicitly) would use search directions  $s = diag(\frac{1}{2}\sqrt{x})g$ . For spNNGD, we can consider adaptive approaches to modify the hyperparameters as we iterate. For example, if we observe stagnation of the sparsity pattern, we may gradually shift the mapping to promote more sparsity. Additionally, we could consider accelerating the selection of the step size via linearization rather than solving a one-dimensional optimization problem explicitly. Combining the two algorithms, we could consider initializing with a few iterations of spNNGD to reach a sparser solution, and then refine with spMRNSD.
