#### ABSTRACT

Young, low-mass Brown Dwarfs orbiting early-type stars, with low mass ratios ( $q \lesssim 0.01$ ), appear intrinsically rare and present a formation dilemma: could a handful of these objects be the highest mass outcomes of "planetary" formation channels (bottom up within a protoplanetary disk), or are they more representative of the lowest mass "failed binaries" (formed via disk fragmentation, or core fragmentation)? Additionally, their orbits can yield model-independent dynamical masses, and when paired with wide wavelength coverage and accurate system age estimates, can constrain evolutionary models in a regime where the models have a wide dispersion depending on initial conditions. We present new interferometric observations of the 16 Myr substellar companion HD 136164 Ab (HIP 75056 Ab) with VLTI/GRAVITY and an updated orbit fit including proper motion measurements from the Hipparcos-Gaia Catalogue of Accelerations. We estimate a dynamical mass of  $35 \pm 10 \,\mathrm{M}_{\mathrm{J}}$  ( $q \sim 0.02$ ), making HD 136164 Ab the youngest substellar companion with a dynamical mass estimate. The new mass and newly constrained orbital eccentricity ( $e = 0.44 \pm 0.03$ ) and separation (22.5 ± 1 au) could indicate that the companion formed via the low-mass tail of the Initial Mass Function. Our atmospheric fit to the SPHINX M-dwarf model grid suggests a sub-solar C/O ratio of 0.45, and 3× solar metallicity, which could indicate formation in the circumstellar disk via disk fragmentation. Either way, the revised mass estimate likely excludes "bottom-up" formation via core accretion in the circumstellar disk. HD 136164 Ab joins a select group of young substellar objects with dynamical mass estimates; epoch astrometry from future Gaia data releases will constrain the dynamical mass of this crucial object further.

### 1. INTRODUCTION

The origins of low mass brown dwarf companions to stars are uncertain. These objects could form from the low mass tail of the Initial Mass Function (IMF, see e.g. Chabrier 2003), via fragmentation of a molecular cloud, and be captured into binary orbits (e.g. Padoan & Nordlund 2004; Boyd & Whitworth 2005; Bate 2009, 2012), or they could form via the gravitational instability of a circumstellar disk (Boss 1997; Stamatellos et al. 2007; Stamatellos & Whitworth 2009; Kratter et al. 2010; Forgan & Rice 2013; Forgan et al. 2015, 2018). Some even argue that a handful of these objects might form via core accretion like planets, and undergo runaway accretion (D'Angelo et al. 2010; Mollière & Mordasini 2012; Bodenheimer et al. 2013) to reach masses greater than the deuterium burning limit ( $\simeq 13 \text{ M}_{\text{J}}$ , Saumon et al. 1996; Chabrier & Baraffe 2000). Schlaufman (2018) argues to the contrary, showing that planetary mass companions with masses below 4 M<sub>J</sub> orbit stars with on average higher metallicity (associated with a larger amount of material for core accretion formation), while planetary mass companions with masses above this cutoff do not necessarily orbit metal-rich stars. This would appear to indicate there is population-level evidence for distinct formation channels for exoplanets and brown dwarf companions with masses above and below  $4~{\rm M_{\rm J}}$ .

There are a number of curious systems that blur these observational rules-of-thumb that enforce the boundaries between formation channels, for instance the HD 206893 system, where two nearly co-planar low mass companions reside within a debris disk (Milli et al. 2017; Delorme et al. 2017; Grandjean et al. 2019; Ward-Duong et al. 2021; Kammerer et al. 2021; Hinkley et al. 2023). For newly discovered low mass companions, especially low mass companions to early type stars (who have low mass ratios), this confusion is inevitable. However, further orbital characterization can provide clues to their formation (Bowler et al. 2020), and spectral characterization can provide a further line of evidence.

Additionally, evolutionary and spectral models of substellar objects (brown dwarfs, massive giant planets), like their higher mass stellar counterparts (e.g. Rodet et al. 2018; Dieterich et al. 2021), need to be tested and refined based on model independent measurements of their masses derived from orbital characterization (Dupuy & Liu 2017; Brandt et al. 2019; Fontanive et al.

<sup>\*</sup> Johns Hopkins University George Owen Fellow

2019; Rickman et al. 2020; Vrijmoet et al. 2020; Brandt et al. 2021; Rickman et al. 2022; Bonavita et al. 2022; Franson et al. 2022; Vrijmoet et al. 2022; Franson & Bowler 2023; Balmer et al. 2023). The difficulty is that substellar objects amenable to these measurements, unlike stellar binaries, appear intrinsically rare (e.g. Dieterich et al. 2012; Fontanive et al. 2018; Nielsen et al. 2019; Duchêne et al. 2023), and generally substellar companions are orders of magnitude fainter than their hosts, necessitating a greater observational expense than stellar binary orbits. So far, the number of substellar objects with dynamically derived masses is low, about 20 in total, and the number of these with accurate age estimates younger than a few hundred megayears is of order unity (see Figure 4 in Franson & Bowler 2023). The youngest brown dwarf with a dynamical mass, PZ Tel b  $(27^{+25}_{-9} M_J, 24 \pm 3 Myr$  Franson & Bowler 2023), has been predicted by evolutionary models to have a higher mass on average than its dynamical mass. Older, cold brown dwarfs like HD 19467 B have been found to be under-luminous compared to evolutionary models (Brandt et al. 2021; Greenbaum et al. 2023). It remains to be seen to what extent there are systematic discrepancies between dynamical and evolutionary models with age, as more dynamical masses need to be estimated for each age category, particularly for young ages.

The sensitivity of direct imaging to higher intrinsic luminosities has revealed many faint, substellar companions to stars in young stellar associations, like the greater Scorpius-Centarus (Sco-Cen) association (Janson et al. 2012; Hinkley et al. 2015; Cheetham et al. 2018; Bohn et al. 2022). These discoveries present an excellent opportunity to determine and study the dynamical masses of young brown dwarfs.

HD 136164 A (HIP 75056 A, 2MASS J15201339-3455316, GAIA DR3 6206053714943873408) is a bright  $(G_{mag}=7.75, \text{ Gaia Collaboration et al. 2022})$ , A2V type (Houk 1982) member of the Upper-Centaurus-Lupus (UCL) association (with 99.9% probability membership according to BANYAN  $\Sigma$ , Gagné et al. 2018). HD 136164 A has a Gaia DR3 parallax of 8.20  $\pm$  0.04, corresponding to a distance of 122 pc. Pecaut & Mamajek (2016) report an age for UCL of  $16\pm2$  Myr based on a multiwavelength spectroscopic and photometric evolutionary study of the association; Žerjal et al. (2023) report an age of  $15\pm3$  Myr, based purely on kinematics. For the primary mass, we adopt  $M=1.7\pm0.1\,\mathrm{M}_\odot$  from Kervella et al. (2022), based on Girardi et al. (2000).

The system has a low Gaia RUWE (1.053), but has a strong proper-motion anomaly between Hipparcos and Gaia noted in Kervella et al. (2019, 2022) and a  $\chi^2 = 15.9$  in the Hipparcos-Gaia Catalog of Accelera-

tions (HGCA, Brandt 2021), indicative of the presence of a perturbing companion. Kouwenhoven et al. (2007) and Wagner et al. (2020) identify a nearby low mass star (HD 136164 AB,  $M_B \sim 0.3~M_{\odot}$ ,  $Ks_{mag} = 11.2$ ) at a separation of 5."2 ( $\sim 650~au$ ), which cannot reproduce the observed astrometric signal (Kervella et al. 2022).

Wagner et al. (2020) first identified the substellar companion HD 136164 Ab as part of their coronagraphic survey of A-type stars in Sco-Cen (Wagner et al. 2022). At a separation of 125-150 mas, the companion is consistent with inducing the astrometric signal observed between Hipparcos and Gaia; at a separation of  $\sim 30$  au the acceleration is consistent with a substellar mass (Kervella et al. 2022). The NIR magnitudes are consistent with the companion being substellar (Wagner et al. 2020, give  $25 \pm 5$  M<sub>J</sub> based on evolutionary models from Baraffe et al. (2003)), and Wagner et al. (2020) report an estimate of the companion's spectral type (M6-L2) consistent with the observed absorption due to water in the low resolution SPHERE spectrophotometry. Only considering two epochs of astrometry, they partially constrain the separation of the companion's orbit ( $\sim 30 \pm 15$  au), and were unable to estimate the eccentricity reliably.

With a low mass ratio and close separation, Wagner et al. (2020) posit that the companion could have formed via disk fragmentation (e.g. Boss 1997; Kratter et al. 2010; Forgan et al. 2018), or even the very high end of a "planetary" core-accretion formation channel (e.g. Pollack et al. 1996; Mordasini et al. 2012) although the possibility (e.g. Emsenhuber et al. 2021a) and occurrence (e.g. Schlaufman 2018) of such high mass core-accretion planets is still heavily debated. Placing the companion's orbit in context could provide insight into this question, as recent population level studies of substellar companions indicate two populations in eccentricity (Bowler et al. 2020; Nagpal et al. 2023; Do Ó et al. 2023). It appears that low mass objects (that likely formed within a protoplanetary disk, whose gas damped their initial eccentricity) exhibit a distribution of eccentricities that is on average lower than the distribution for higher mass objects (that likely formed via core fragmentation along with the stellar population, and formed within or became captured into binary orbits). Coupling a measurement of the mass and eccentricity of the object from a Keplerian orbit could therefore inform the interpretation of its formation history. If an object forms bottom up and has a high eccentricity orbit, it appears to be an outlier; if the object forms like a "failed star," its eccentricity is less interpretable. A low mass/low mass ratio and low eccentricity could favor a "planetary" formation channel via either core accretion or disk instability,

whereas a moderate mass and lower eccentricity could likewise favor a disk instability formation, and a higher mass and/or eccentricity could favor a core fragmentation interpretation, the "failed-binary" interpretation.

Here, we present new interferometric measurements of the companion from VLTI/GRAVITY, including orbital coverage through periastron passage. GRAVITY has been used in the past few years to observe, for the first time with long-baseline optical interferometry, a handful of exoplanets and substellar companions: HR 8799 e (GRAVITY Collaboration et al. 2019), β Pic b and c,(Gravity Collaboration et al. 2020; Lagrange et al. 2020; Nowak et al. 2020; Lacour et al. 2021), HD 206893 B and c (Kammerer et al. 2021; Hinkley et al. 2023), PDS 70 b and c (Wang et al. 2021), HD 79246 B (Balmer et al. 2023), and HIP 65426 b (Blunt et al. 2023). On high contrast targets, GRAVITY consistently achieves 50-100 µas precision astrometry, while providing valuable spectral information about carbonbearing molecules in the K-band, which can be used to constrain atmospheric modeling (Gravity Collaboration et al. 2020; Kammerer et al. 2021; Blunt et al. 2023), in particular atmospheric retrievals (Mollière et al. 2020; Balmer et al. 2023). We use our new measurements of HD 136164 Ab along with the proper motion measurements of the host star from the HGCA to derive a new dynamical mass estimate. We detect absorption due to carbon monoxide in the companion's K-band spectrum. The well determined properties of this young brown dwarf companion make it an excellent prospect for future observations, and additional tests of evolutionary models.

### 2. OBSERVATIONS

## 2.1. VLTI/GRAVITY

We observed HD 136164 A and Ab four times between 2022-02 and 2023-05 using the GRAVITY instrument (Gravity Collaboration et al. 2017) at the European Southern Observatory (ESO) Very Large Telescope Interferometer (VLTI). We used the four 8.2m Unit Telescopes (UTs) in dual-field on-axis fringe tracking mode (Lacour et al. 2019), where the fringe tracking fiber was placed at the location of the host star HD 136165 A and used to track the fringe pattern, and the science fiber was placed at the predicted location of the companion and integrated to detect the shifted fringe pattern from the companion. Observations on 2022-02-19 and 2023-05-10 were taken as target visibility or bad weather backups to Program 1104.C-0651 (PI: Lacour) in Visitor or designated Visitor Mode (dVM). Observations on 2022-04-21 and 2022-06-14 were taken as part

of Program 109.237J.001 (PI: Balmer) in Service Mode (SM). Table 1 records our observing log.

During the first observation of the companion with GRAVITY on 2022-02-19, its position was relatively uncertain. The fibre placement was made based on a preliminary orbit fit to the two previous SPHERE observations (Wagner et al. 2020) taken 2 years before the initial GRAVITY observation, and therefore the first GRAVITY observation suffered from fiber injection losses on the companion (with a theoretical coupling efficiency of  $\gamma = 0.88 < 1$ , as opposed to  $\gamma > 0.95$  for subsequent observations).

We determined the complex visibilities on the host and the companion, which were phase-referenced with the metrology system, using the Public Release 1.5.0 (1 July 2021<sup>1</sup>) of the ESO GRAVITY pipeline (Lapeyrere et al. 2014). We proceeded to decontaminate the science fiber flux due to the halo from the host star by simultaneously fitting the stellar contamination as a low-order polynomial, and the companion as a point source. This pipeline is described in detail in Appendix A of Gravity Collaboration et al. (2020).

We determined the relative astrometry of the companion by analysing the phase of the ratio of coherent fluxes. We calculate a  $100 \times 100 \chi^2$  periodogram power map over the fiber's field-of-view (Figure 1), and take the minimum of the  $\chi^2$  map as the preliminary companion position. We then calculate another  $100 \times 100 \chi^2$ grid with a range restricted to  $\pm 10 \,\mathrm{mas}$  around the initial  $\chi^2$  grid minimum, and we estimate the uncertainty and co-variance of the measurement by computing the RMS of the  $\chi^2$  minima for each exposure. Because HD 136164 Ab is relatively bright we only observe 3 exposures per epoch. In order to estimate our errors, we divide each exposure into four subsections, each 4 detector integrations long, for a total of 12  $\chi^2$  grid computations, except for 2023-05-10, where we only have 2 exposures with 3 detector integrations each, and 6  $\chi^2$ grid computations. We find the typical precision from this technique is on the order of  $\sim 100 \,\mu as$ , greater than  $16.5 \,\mu as$  (the theoretical limit of VLTI/GRAVIY), due to systematic phase errors<sup>2</sup> Once the astrometry is determined, we extract the ratio of the coherent flux between the two sources at the estimated position of the companion, calculating the "contrast spectrum" of the companion.

 $<sup>^{1}\; \</sup>rm https://www.eso.org/sci/software/pipelines/gravity/$ 

 $<sup>^2</sup>$  In future work we intend to explore the cost/benefit of using a dynamic nested sampler, as opposed to a  $\chi^2$  grid, to estimate the astrometry.

Figure 1. Detections of HD 136164 Ab with VLTI/GRAVITY. Each panel visualizes the  $\chi^2$  map calculated after subtracting the stellar contamination. Each epoch in Table 1 is presented chronologically, left to right. The dashed grey circle indicates the fiber field-of-view. The origin is the placement of the science fiber on-sky for a given observation, a prediction based on the previous available orbit fit, and the units are in  $\Delta$  RA and Dec, e.g. the displacement of the fiber with respect to the host star HD 136164 A. The strongest peak in the  $\chi^2$  map (indicated with a blue arrow) reveals the position of the companion, with characteristic interferometric side-lobes whose shape and distribution depend on the u-v plane coverage.

**Table 1.** Observing log. NEXP, NDIT, and DIT denote the number of exposures, the number of detector integrations per exposure, and the detector integration time, respectively, and  $\tau_0$  denotes the atmospheric coherence time. The fiber pointing is the placement of the science fiber relative to the fringe tracking fiber (which is placed on the central star),  $\gamma$  is the coupling efficiency at the position of the companion (see Table 2).

Date	UT time		NEXP/NDIT/DIT		Airmass	$ au_0$	Seeing	Fiber pointing	$\gamma$
	Start	End	HD 136264 Ab	HD 136264 A				$\Delta {\rm RA}/\Delta {\rm DEC}$	
2022-02-20	08:50:14	09:25:14	4/12/30 s	4/64/1 s	1.03-1.06	9.5-12.3 ms	0.37 - 0.99''	11/-117	0.878
2022-04-21	05:16:58	05:55:48	4/12/30  s	4/64/1  s	1.03 - 1.06	$1.8\text{-}2.9~\mathrm{ms}$	0.95 - 1.53''	-8/-103	0.999
2022 - 06 - 15	03:36:41	04:16:26	4/12/30  s	4/64/1  s	1.05 - 1.12	$1.8\text{-}3.1~\mathrm{ms}$	0.95 - 1.37''	-17/-101	0.979
2023-05-10	04:24:53	04:40:20	2/6/30  s	2/48/1  s	1.02 - 1.03	7.9 - 11.1  ms	0.40 - 0.53''	-32/-97	0.999

Observations from 2022-02-19, 2022-04-21, and 2022-05-10 yield robust detections of the companion. Due to a metrology glitch during the 5th DIT in the observing sequence on 2022-06-14, the baselines for UT1 are unrecoverable for about half of the observing sequence, and we neglect these baselines in our extraction. We nevertheless recover the companion's signal in this data, albeit with larger astrometric uncertainties (of the same magnitude as the original SPHERE observations). Figure 1 illustrates the detections of HD 136164 Ab within the fiber field-of-view.

We transformed our contrast spectrum of the companion into a flux calibrated spectrum using a synthetic spectrum of the host star. We scaled a BT-NextGen (Allard et al. 2011) spectrum with  $T_{\rm eff}=8100\,{\rm K}$  and  $\log(g)=4.2$  (Bochanski et al. 2018) to archival photometry from Gaia (Gaia Collaboration et al. 2022), Tycho2 (Høg et al. 2000), and 2MASS (Cutri et al. 2003) using species (Stolker et al. 2020). We broadened the spectrum with specutils (Astropy Collaboration et al. 2013, 2018, 2022) using a Gaussian kernel with a FWHM of 2 Å to match the rotational broadening of the star, and then sampled the broadened spectrum

on the SPHERE and GRAVITY wavelength grids using spectres (Carnall 2017). The spectrum and stellar photometry is shown in Figure 2.

## 2.2. VLT/SPHERE

HD 136164 Ab was first detected using the Spectro-Polarimetic High contrast imager for Exoplanets REsearch (SPHERE Beuzit et al. 2019) at the ESO Very Large Telescope (VLT). We adopt the companion's 2015-06-19 and 2019-06-29 astrometry from Wagner et al. (2020) as-is, although we note that, when compared with our updated orbital fits including our GRAV-ITY observations, the observation on 2019-06-29 appears systematically biased inwards in separation, likely because the off-axis PSF becomes asymmetric due to the transmission function of the coronagraph at close separations. Because our GRAVITY observations drive the orbital fits, and the 2015-06-19 astrometry is unaffected by this systematic error, we do not correct the SPHERE astrometry in this work.

Figure 2. The SED of HD 136164 A. Archival photometry is overplotted a BT-NextGen model spectrum with  $T_{\rm eff} = 8100\,{\rm K}$  and  $\log(g) = 4.2$ . This spectrum is used to transform the companion's contrast spectra into flux calibrated spectra.

Table 2. New relative astrometry of HD 136264 Ab around HD 136264 A.

GRAVITY							
Epoch [MJD]	$\Delta RA [mas]$	$\sigma_{\Delta \rm RA} \ [{ m mas}]$	$\Delta \mathrm{Dec}\ [\mathrm{mas}]$	$\sigma_{\Delta \mathrm{Dec}}$ [mas]	ho		
59630.38	-3.92	0.07	-104.19	0.05	-0.67		
59690.24	-7.87	0.04	-103.45	0.07	-0.68		
59745.17	-11.55	0.43	-103.38	0.79	0.53		
60074.19	-32.12	0.04	-97.64	0.05	-0.69		

NOTE—The co-variance matrix can be reconstructed using  $\sigma_{\Delta RA}^2$  and  $\sigma_{\Delta Dec}^2$  on the diagonal, and  $\rho \times \sigma_{\Delta RA} \times \sigma_{\Delta Dec}$  on the off-diagonal.

We re-reduced the IFS data from 2015-06-19 in order to extract the spectrum of the companion. The data were taken in the IRDIFS-EXT mode where the IFS (Claudi et al. 2008) and IRDIS (Dohlen et al. 2008) observe in parallel. The IFS covers wavelength bands Y, J, and H1 between  $0.95-1.65 \,\mu\mathrm{m}$  and the dual band imager IRDIS covers K1 and K2 at  $2.0 \,\mu m$  and  $2.1 \,\mu m$  (Vigan et al. 2010). Because our GRAVITY data cover the Kband, we do not re-reduce the IRDIS data. The observations used the N\_ALC\_YJH\_S coronagraph, which is optimized for close inner working angles. The raw data from the ESO archive were pre-processed with vlt-sphere, an open-source pipeline (Vigan 2020), and then we performed starlight subtraction using pyKLIP (Wang et al. 2015), an open source implementation of Karhunen-Loève Image Processing (Soummer et al. 2012). We used the forward modeling capabilities of KLIP (Pueyo 2016)

to extract the spectrum of the companion using pyKLIP (Wang et al. 2016; Greenbaum et al. 2018), and applied the theoretical coronagraph transmission function to the resulting spectrum. The contrast spectrum was flux calibrated as in §2.1.

## 3. ANALYSIS

## 3.1. Orbital analysis

In order to measure the orbit of HD 136164 A and b, we use orbitize!<sup>3</sup> (Blunt et al. 2020). We use orbitize!'s parallel-tempered (Vousden et al. 2016) Affine-invariant (Foreman-Mackey et al. 2013) MCMC algorithm. This algorithm fits for the 6 parameter visual orbit (Green 1985), the system parallax, the

<sup>&</sup>lt;sup>3</sup> orbitize.readthedocs.io.

proper motions and reference epoch astrometry, and the masses of the star and companion. We used 1,000 walkers at 20 temperatures to sample our posterior distribution of orbits, with 15,000 steps of burn-in discarded, before 5,000 steps were recorded (for a total of 50,000 orbits recorded in our posterior distribution). We place a physically motivated normally distributed prior  $\mathcal{N}(1.7, 0.1) \,\mathrm{M}_{\odot}$  (Bochanski et al. 2018; Kervella et al. 2022), and a log-uniform prior on the companion mass of  $\log \mathcal{U}(1,200) \,\mathrm{M_{J}}$ , a Gaussian prior on the system parallax based on the Gaia DR3 measurement  $\mathcal{N}(8.202, 0.040)$  mas and otherwise use default priors on all orbital elements as described in Blunt et al. (2020). We fit the model to relative astrometry from SPHERE (Wagner et al. 2020), GRAVITY (this work), and absolute astrometry on the host star from the Hipparcos-Gaia Catalogue of Accelerations (Brandt 2021).

Figure 3 plots the best fit orbits to the observations of the system, and Figure 7 illustrates the posterior distribution of best fit orbits from our orbitize! MCMC. We note that the 2nd SPHERE epoch deviates by a few milliarcseconds from our orbit fits, likely because the coronagraphic transmission at the location of the companion distorts the photocenter, biasing the astrometry in separation. We find a highly eccentric orbit, with  $e = 0.44 \pm 0.03$ , and derive a companion mass of  $35 \pm 10 \,\mathrm{M_J}$ . Our derived stellar mass  $(1.87 \pm 0.07 \,\mathrm{M_\odot})$ deviates by  $1\sigma$  from our prior on the stellar mass, resulting in a mass ratio q = 0.02. Our four epochs of relative astrometry at  $< 100 \,\mu as$  precision, combined with the long time baseline information from the absolute astrometry, has strongly constrained the visual orbit of the companion.

#### 3.2. Spectral analysis

We compared the spectrum of the companion to two self-consistent, cloudless, chemical equilibrium model grids, ATMO (Phillips et al. 2020) and SPHINX (Iyer et al. 2023). We chose these model grids because they use modern opacity sources and are computed for temperature ranges (2300 – 3000 K) appropriate for the spectral type of HD 136164 Ab. In particular, the SPHINX grid accounts for spectral broadening of key molecules, a range of metallicities and C/O ratios, and has been benchmarked to observations of M-dwarfs with known bulk properties. However, it is computed for a lower resolution (R=250) than our GRAVITY data (R=500), so when fitting the grid to our data, we convolve the GRAVITY spectrum to the resolution of the grid using spectres (Carnall 2017).

We used the species<sup>4</sup> package to fit our spectra to the model grid, linearly interpolating spectra between grid points. In version 0.71 of species, we ingested the SPHINX from (Iver et al. 2022) that assumes a mixing length parameter of 1. We initialized pyMultiNest<sup>5</sup> (Feroz & Hobson 2008; Feroz et al. 2009; Buchner et al. 2014) via species to sample the interpolated grid with 500 live points. We measured the posterior distribution on the grid parameters, namely effective temperature (T<sub>eff</sub>), log(g), radius, parallax, [Fe/H] and C/O for the SPHINX grid, and included a Gaussian process parameterized by a squared-exponential kernel to account for correlated noise between wavelength channels in the SPHERE data (see §4.1 in Wang et al. 2020). When fitting the GRAVITY data, species accounts for the correlation matrix of the spectrum in the fit. We weight each spectral point across the entire SED according to its wavelength spacing so that the GRAVITY spectrum, with an order of magnitude more data points, does not completely dominate the fit. To account for an apparent offset in the flux of the two spectra, we fit for a scaling parameter on the SPHERE YJH1 spectrum, as is common in the literature (e.g. Mollière et al. 2020). We place the same parallax prior on the atmospheric fits as we do the orbital fits in §3.1.

We fit each model grid to our data twice, first with a uniform prior on the mass (related to the sampled parameters  $\log(g)$  and radius), and second with a Gaussian prior on the mass corresponding to the dynamical mass from our orbit fit in §3.1,  $\mathcal{N}(35,10)$  M<sub>J</sub>. This experiment allows the sampler to determine the log(g)and radius based solely on the spectral and parallax measurements, and then adds the additional constraint of the dynamical mass. Figure 4 plots the spectrum of the companion and the results of the ATMO model fitting. We find the median sample has  $T_{\text{eff}}$ ,  $\log(g)$ ,  $R_{\rm p}$ ,  $\log (L/L_{\odot})$  and SPHERE scale factor of 2530 K,  $3.5, 2.0 R_{\rm J}, -2.8, 0.70,$  respectively, with a uniform mass prior, and  $2600 \,\mathrm{K}, 4.3, 1.9 \,\mathrm{R_J}, -2.8, 0.71$  with the dynamical mass prior. The residuals to the fit are strongly wavelength dependent, and appear related to regions where water and iron-hydride opacity is dominant in shaping the spectral slope, especially when the dynamical mass prior is considered. This could indicate model deficiencies (non-solar abundances, reduced temperature gradients, or dis-equilibrium chemistry) or data deficiencies (improperly corrected tellurics, phase errors, or coronagraphic effects).

Table 3. Orbital parameters inferred for HD 136164 Ab in this work.

NOTE—We report the median and 68% confidence interval on each parameter derived from the posterior visualized in Figure 7. Propogating errors between both mass estimates yields  $q=0.018\pm0.005$ . †Next periastron passage after  $\tau_{\rm ref}=2020.0$ 

Figure 5 plots the spectrum of the companion and the results of the SPHINX model fitting. We find the median sample has  $T_{\rm eff}, \log(g), R_{\rm p}, [{\rm Fe/H}], {\rm C/O}, \log{\rm (L/L_{\odot})},$  and SPHERE scale factor of 2650 K, 4.6, 1.8 R<sub>J</sub>, 0.42, 0.47, 2.8, and 0.74, respectively, with a uniform mass prior, and 2640 K, 4.35, 1.9 R<sub>J</sub>, 0.39, 0.45, 2.8, and 0.74 with the dynamical mass prior. The residuals to the fit are smaller compared to the fit to the model assuming solar abundances (Figure 4), and the impact of the dynamical mass prior is more subtle. With more free parameters, the model can produce an equivalently good fit to the data with or without the dynamical mass prior, and no longer appears biased towards an implausibly low surface gravity without the dynamical mass prior.

#### 3.3. Evolutionary model comparison

As a byproduct of our spectral fits, we use species to integrate under the sampled ATMO and SPHINX spectra and determine the distributions of bolometric luminosity for both the uniform and dynamical mass prior cases. The ATMO model gives  $\log{(L/L_{\odot})} = -2.8 \pm 0.3$  for both cases, and the SPHINX model gives  $\log{(L/L_{\odot})} = -2.8 \pm 0.3$  for both cases.

For substellar objects, there is a frequently observed tension between the evolutionary and spectral effective temperatures (see, e.g. Sanghi et al. 2023, their Figure 23). We leverage our dynamical mass to compare the bolometric luminosity expected for a  $16 \pm 2\,\mathrm{Myr}$  brown dwarf according to the ATM02020 evolutionary model (Phillips et al. 2020) and the bolometric luminosity we derive from our spectral fits. The model uses the ATM0 atmospheric model as a surface boundary condition to

calculate the interior structure and evoltion of substellar objects.

We drew luminosities for a  $35\,\mathrm{M}_\mathrm{J}$  brown dwarf at 14, 16, and  $18\,\mathrm{Myr}$ , finding  $\log{(\mathrm{L/L_\odot})_\mathrm{evol}} = -2.68^{+0.08}_{-0.05}$ . Given the larger uncertainties on our spectrally derived bolometric luminosity (not to mention the potential systematic uncertainty on this estimate, given that we must rely on atmospheric models to extrapolate beyond the  $1-2.5\,\mu\mathrm{m}$  range), the evolutionary and spectral bolometric luminosities for HD 136164 Ab agree to within  $1\,\sigma$ . Increasing the wavelength coverage on the companion (especially at shorter wavelengths) will decrease the uncertainty on the spectrum-derived luminosity, and could reveal a tension if it exists. These models reveal the un-physical nature of the spectrally derived  $\log(g)$  in the absence of a dynamical mass prior.

Figure 6a plots the distributions on mass and radius from our atmospheric fits, compared to the ATM02020 mass-radius model (Phillips et al. 2020) for an age of  $16\pm 2$ , showing that these parameters are in agreement within  $1-2\,\sigma$  with expectations from the evolutionary model. Figure 6b plots the distributions on mass and effective temperature. When the dynamical mass is included as a prior in the spectral fit, the temperatures are consistent within  $1\,\sigma$ . For many brown dwarfs, there is significant tension between the evolutionary and spectral effective temperatures.

#### 4. DISCUSSION

#### 4.1. The formation of HD 136164 Ab

We have demonstrated that HD 136164 Ab has an eccentric orbit ( $e=0.44\pm0.03$ ), a dynamical mass of  $35\pm10\,\mathrm{M}_\mathrm{J}$ , and a mass ratio with HD 136164 A of

Figure 3. HD 136164 orbital analysis. Top left: The visual orbit of HD 136164 Ab around HD 136164 A (black star). 1,000 randomly chosen orbits from our fit using the MCMC are shown in color, with the color corresponding to the eccentricity of a given orbit. Top middle and right: The proper motion of the host star HD 136164 A over time in RA and Dec (middle and right, respectively). The proper motion of the host as predicted by the orbit fit is shown in curves colored corresponding to the mass of the companion. Observations from Hipparcos and Gaia are shown with errorbars as recorded in the HGCA. Note that the orbitize! proper motion log-likelihood function evaluates the time-averaged proper motions, and not the instantaneous proper motions that are over-plotted here (see Hinkley et al. 2023); the instantaneous measurements are shown here for visualization purposes only. Bottom: VLTI/GRAVITY measurements of the position of HD 136164 Ab across four epochs (see Table 2), plotted against the same sample of MCMC orbits as in the top left panel. The 1, 2, and 3  $\sigma$  confidence contours on each measurement are shown with decreasing transparency; the covariance of the measurement is related to the u-v plane coverage of the observation.

 $q = 0.018 \pm 0.005$  (see §3.1). This makes HD 136164 A the youngest substellar companion with a dynamical mass estimate. The dynamical mass agrees within uncertainties with the previous evolutionary model derived mass based on SPHERE spectrophotometry, and are in perfect agreement when considering the evolutionary models anchored to the SPHERE/IRDIS K-band photometry (Wagner et al. 2020). The dynamical mass and mass ratio is inconsistent with core accretion models of formation (e.g. Mordasini et al. 2009; Emsenhuber et al. 2021b,c). The good agreement with the dynamical mass, spectral effective temperature, and the ATMO isochrone with a Sco-Cen age (see Figure 6) can be interpreted as evidence for the similarity in age of the host and companion, the coevality of the two, and therefore additional evidence against core accretion.

Simulations of disk-fragment formation and fragmentfragment interactions in Forgan & Rice (2013); Forgan et al. (2015, 2018) appear to indicate the result of disk instability formation is a distribution of single giant planets/brown dwarfs near the deuterium burning limit at wide separations  $(10 - 100 \,\mathrm{au})$ , with a distribution peaking at low orbital eccentricities, but flattening towards a non-zero relative frequency between e = 0.1 - 0.8. This could tentatively support the interpretation that HD 136164 Ab formed via disk instability, since it is a widely separated companion at 22.5 au. It could be that the companion formed from disk fragmentation with an initially low eccentricity that was then increased via dynamical interactions with the outer Mdwarf HD 136164 B at 650 au, but this would take time to evolve dynamically, and the system is young. Demonstrating this would require dynamical modeling and additional orbital monitoring of B and Ab. We could interpret the slightly enhanced metallicity we derive for the companion using the SPHINX models as evidence the companion accreted a significant fraction of metals from the circumstellar environment, if it indeed formed via

Figure 4. The spectrum of HD 136164 Ab (black data points) fit to the cloudless ATMO equilibrium chemistry self-consistent model, with and without a prior on the dynamical mass of the companion (median samples are plotted as blue and red curves, respectively). 30 random samples from each posterior distribution are plotted as semi-transparent curves. In each fit, the SPHERE YJH1 data is allowed to scale by a factor, so for the fit with a dynamical mass prior, the scaled SPHERE data is shown as black circles, and without a dynamical mass prior, shifted to the right for visualization as gray squares.

Figure 5. The spectrum of HD 136164 Ab (black data points) fit to the cloudless SPHINX equilibrium chemistry self-consistent model, which varies abundance in addition to effective temperature and surface gravity, with and without a prior on the dynamical mass of the companion (median samples are plotted as blue and red curves, respectively). 30 random samples from each posterior distribution are plotted as semi-transparent curves. In each fit, the SPHERE YJH1 data is allowed to scale by a factor, so for the fit with a dynamical mass prior, the scaled SPHERE data is shown as black circles, and without a dynamical mass prior, shifted to the right for visualization as gray squares.

Figure 6. Left: Mass versus effective temperature for our atmospheric fits (contours) compared to the mass radius relationship from the ATM02020 evolutionary model (black curve). The uncertainty on the system's age is represented by gray contours to the black curve,  $16\pm 2\,\mathrm{Myr}$ . When the dynamical mass is included as a prior in the atmospheric model fit, the mass and effective temperature are consistent with the evolutionary model prediction to within  $1\,\sigma$ . Right: Mass versus radius for our atmospheric fits compared to the mass radius relationship from an evolutionary model. Without a dynamical mass prior, our spectral fits derive a  $\log(g)$  that results in a mass inconsistent with expectations from the evolutionary model. With a dynamical mass prior, the determined  $\log(g)$  is consistent with expectations to within  $1\,\sigma$ .

disk instability. For instance, it could have undergone late accretion of solids (e.g. Nowak et al. 2020). The posterior distribution on abundances from our model fits to the SPHINX grid are wide, and still encompass solar metallicity solutions at the  $2-3\sigma$  level. In Wagner et al. (2020), it was suggested that a low C/O ratio could imply an earlier period of gas accretion from the disk, because during the Class 0 stage of the star/circumstellar evolution, no CO gas would be frozen out, whereas during the Class 1 stage, CO gas would be frozen out beyond 30 au. Our best fit SPHINX spectrum has a lower C/O ratio of 0.45, although the posterior still spans a wide range of C/O encompassing the solar value at  $2-3\sigma$ , and similarly this could be loosely interpreted as evidence for formation of the companion within the circumstellar disk. The host star could also have a subsolar C/O abundance, and the lower C/O abundance for HD 136164 Ab could be reflective of a match to the stellar abundance.

Kratter et al. (2010) show that disk fragmentation can produce brown dwarf and even planetary mass companions, but provides the additional interpretation that these systems are necessarily "failed stars," i.e. that the distribution of disk instability born companions has a low mass tail, but increases above the deuterium burning limit. They predict an increase in the occurrence of brown dwarf companions to A-type stars; as is the case here, but also appears to be the case more generally (Nielsen et al. 2019).

If it did not form from a fragmenting circumstellar disk, could HD 136164 Ab have formed via the col-

lapse of a molecular cloud, as a product of the IMF? With opacity limited minimum mass estimates as low as  $1-3 \,\mathrm{M_{J}}$  for core fragmentation (e.g. Boyd & Whitworth 2005; Bate 2009), or a derived minimum mass of around 6 – 18 M<sub>J</sub> from radiation hydrodynamical simulations (e.g. Bate 2012), the mass of HD 136164 Ab is not unprecedented for a by-product of the fragmenting core mass function. In Bate (2012), the outcome of the stellar IMF produces a handful of binaries with small mass ratios (0.01 - 0.02) with a relatively uniform distribution of eccentricities. HD 136164 Ab's high eccentricity and mass ratio of 0.02 could therefore indicate a core fragmentation formation pathway, if eccentricities are expected to be damped during formation in a disk, but not during core fragmentation. In the context of population level studies of substellar companions, this eccentricity also empirically indicates more of a "brown dwarf/failed star" nature, as directly imaged planets appear to follow a distinct eccentricity distribution with generally lower eccentricities (as their eccentricities are expected to be damped by their parent disks), whereas substellar objects produced by fragmenting cores tend to have a distribution of on average higher eccentricities (Bowler et al. 2020; Nagpal et al. 2023; Do Ó et al. 2023). Parker & Daffern-Powell (2022) use N-body simulations of star forming regions to show that early type stars can capture single brown dwarfs or even steal planets from other lower mass systems within the first 10 Myr of an association's lifetime, so it is a reasonable assumption that, even if the brown dwarf did not form directly into a binary configuration with HD 136164 A, it could have formed nearby and been subsequently captured onto a binary orbit.

It is still unclear whether this brown dwarf companion could have formed from disk fragmentation or core fragmentation, but it appears clear that the companion is a "failed star" coeval with the host, either born or captured into a binary orbit.

# 4.2. Atmospheric modeling in the context of a dynamical mass prior

In Balmer et al. (2023), we saw that the atmospheric modeling of a close separation brown dwarf companion can be strongly influenced by the inclusion of a dynamical mass prior. In that work, for a benchmark brown dwarf with a known mass and stellar abundances, the  $\log(g)$  and radius of the atmospheric model appeared strongly influenced by regions of increased systematics in the spectrum. It is necessarily the case that spectral and astrometric measurements made at such close separations will suffer, at least initially, from such systematic errors. These could be responsible for both the

wavelength dependent residuals between our data and the ATMO models. It is also the case that model deficiencies in solar abundance, chemical equilibrium, cloudless, radiative-convective equilibrium models (e.g. non-solar abundances, clouds or reduced temperature gradients, vertical mixing and disequilibrium chemistry, etc) could impact the determined physical parameters and quality of fit. The SPHINX grid, which varies abundances, can provide a better fit to the data, invoking a sub-solar C/O ratio, and an enhanced metallicity. In Figure 4, the residuals to the ATMO model occur near the edges of the instruments' respective wavelength range, and appear to strongly influence the fit  $\log(g)$ . In our fit without the dynamical mass prior, the posterior distribution was driven to unphysically low values, log(g) = 3.0. When the dynamical mass prior is considered, we find a much more reasonable  $\log(q) = 4.4$ , and a corresponding radius of 1.9 R<sub>J</sub>. It could be that a circumsecondary disk or dust extinction produces the slope to the GRAVITY data. We briefly considered including an extra blackbody term, or an extinction term, in our spectral fitting to account for these effects, and were unable to convincingly constrain its presence with our data, so we do not consider that here (the disk excess could be investigated with 3-5 µm JWST observations).

Given the good agreement between our atmospherically derived luminosity (based on our fits to the spectrum using a dynamical mass prior) and our evolutionarily derived luminosity (based on the system age and dynamical mass), for relatively cloudless late M-type substellar companions without a dynamical mass prior, it appears reasonable to adopt an evolutionary model derived mass prior based on the observed flux of the companion when fitting the spectrum with model grids. Doing so will ensure the fit is not driven to unphysical values of log(g). We note, however, that if a fit is driven to unphysical values, it could be due to a model deficiency since, in the case of HD 136164 Ab, we found a model grid that varied abundances away from solar values derived physical  $\log(g)$  values without the dynamical mass prior. As in Balmer et al. (2023), the dynamical mass prior appears most useful in determining whether there are data or model deficiencies, and what changes (to data treatment or model construction) might alleviate the tension between the two.

## 5. CONCLUSIONS

In this work we:

1. Observed the brown dwarf companion HD 136164 Ab four times with VLTI/GRAVITY dual-field interferometry. We detected the companion in all four observations despite limited field rotation and exposure time, demonstrating the power of GRAVITY to efficiently characterize brown dwarf companions.

- 2. Extracted precise astrometry of the companion (med  $\sigma=40~\mu as$ ) and a contrast spectrum at R=500 resolution from the interferometric observables. We also re-extracted the SPHERE IFS YJH1 spectrum of the companion and flux calibrated these contrast spectra using a stellar template.
- 3. Fit the orbit of the companion with a combination of relative astrometry from GRAVITY and SPHERE, and absolute astrometry from the HGCA, determining the eccentricity and dynamical mass of the companion for the first time. We leverage the moderate eccentricity ( $e=0.44\pm0.03$ ) and mass ratio ( $q=0.018\pm0.005$ ) to assess the formation of the object.
- 4. Fit the spectrum of the companion to two grids of self-consistent, cloudless atmospheric models, ATMO and SPHINX. We discussed the inclusion of the dynamical mass as a prior in atmospheric fits for this object. The SPHINX grid, which varies abundances, indicates a slightly sub-solar C/O ratio (0.45) and enriched metallicity (0.4), with uncertainties that are consistent with solar values. Deriving the luminosity from our spectral fits and comparing them to expectations from evolutionary models revealed an apparent agreement, albeit with uncertainties of 0.3 dex in luminosity.
- 5. Discussed the formation of HD 136164 Ab in the context of the new GRAVITY data and especially the dynamical mass. We rule out formation via core accretion, but present evidence that could be interpreted in favor of either disk fragmentation or cloud fragmentation.

HD 136164 Ab now joins a very select group of young substellar companions with dynamical mass measurements (see Figure 4 in Franson & Bowler 2023). It is currently the youngest substellar companion with a dynamical mass estimate. Like PZ Tel B (Biller et al. 2010; Mugrauer et al. 2010; Schmidt et al. 2014; Maire et al. 2016; Stolker et al. 2020; Franson & Bowler 2023), this object will be crucial for benchmarking evolutionary models in the coming decade. HD 136164 Ab does not need to stand alone, however. We have shown that, even without stellar radial velocities, coupling GRAVITY observations with the HGCA can produce well constrained dynamical mass estimates for young companions orbiting stars that are not amenable to radial velocity

characterization. Future work should look to estimate the dynamical mass of the young substellar companions to HD 115470 (HIP 64892 B Cheetham et al. 2018),  $\mu^2$  Sco ( $\mu^2$  Sco b Squicciarini et al. 2022), HD 149274 (HIP 81208 B Viswanath et al. 2023; Chomez et al. 2023), and the planet orbiting HD 116434 (HIP 65426 b Chauvin et al. 2017; Cheetham et al. 2018; Stolker et al. 2020; Petrus et al. 2021; Blunt et al. 2023). While these might not result in dynamical masses of same precision as this result (since the aforementioned companions are on longer period orbits), a similar analysis might at the very least provide useful mass upper limits for assessing the formation histories of these objects.

For HD 136164 Ab itself, there remains a number of additional investigations that can continue to refine estimates of its bulk and atmospheric properties, to aid in the benchmarking of various models. Future observations of the companion at shorter wavelengths (e.g. z' or i' band with MagAO-X, Males et al. 2022), and longer wavelengths (e.g. with JWST/NIRCam at 3-5 μm, via GO program 1902, PI: Kammerer) will produce a precise bolometric luminosity estimate and could probe the existence of a circum-secondary disk with more certainty than our observations. High resolution spectroscopy from HiRISE (Vigan et al. 2023) could assess whether the companion is truly enhanced in metallicity. Epoch astrometry from Gaia DR4 should improve the precision of the companion's dynamical mass estimate further, and enable a comprehensive benchmarking of multiple evolutionary models at very young ages.

Thanks to our night astronomers for these observations, Thomas Rivinius, Claudia Paladini, Aaron Labdon, Abigail Frost, and Xavier Haubois. Thanks also to our telescope operators for these observations, Marcelo Lopez, Rodrigo Palominos, and Israel Blanchard. Special thanks to the Paranal and ESO staff for their support. We thank the anonymous reviewer for their constructive, encouraging report.

This work is based on observations collected at the European Southern Observatory under ESO programmes 109.237J.001 and 1104.C-0651.

S. L. acknowledges the support of the French Agence Nationale de la Recherche (ANR), under grant ANR-21-CE31-0017 (project ExoVLTI).

J.J.W., A.C., and S.B. are supported by NASA XRP Grant 80NSSC23K0280.

G-D.M acknowledges the support of the DFG priority program SPP 1992 "Exploring the Diversity of Extrasolar Planets" (MA 9185/1) and from the Swiss National Science Foundation under grant 200021\_204847 "PlanetsInTime". Parts of this work have been carried out within the framework of the NCCR PlanetS supported by the Swiss National Science Foundation.

R.G.L. acknowledges the support of Science Foundation Ireland under Grant No. 18/SIRG/5597.

This research has made use of the VizieR catalogue access tool, CDS, Strasbourg, France (DOI: 10.26093/cds/vizier).

This research has made use of the Jean-Marie Mariotti Center Aspro service.

This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation.

This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.

WOB acknowledges that the Johns Hopkins University occupies the unceded land of the Piscataway People, and acknowledges the Piscataway community, their elders both past and present, as well as future generations.

WOB acknowledges their cat, Morgoth, for her "encouragement."

#### APPENDIX

#### A. POSTERIOR DISTRIBUTIONS

This appendix includes corner plots representing the posterior distributions for the two model fits in this work. The posterior distribution of orbital parameters from our orbitize! model fit are shown in Figure 7. The posterior distribution on atmospheric parameters from our ATMO spectral fit using species is shown in Figure 8. The posterior distribution on atmospheric parameters from our SPHINX spectral fit using species is shown in Figure 9.

Figure 7. Posterior distribution of orbital elements for the orbital analysis presented in §3.1, and visualized in Figure 3. The median and  $1\,\sigma$  confidence intervals from the marginalized 1-D histograms show here, for each parameter, are recorded in Table 3. Orbital parameters with respect to HD 136164 Ab are denoted with subscript "1," and parameters with respect to HD 136164 A with subscript "0." The distribution of orbital elements is unimodal, with no obvious degeneracies present between parameters, thanks to the combination of precise relative astrometry from GRAVITY, and long time baseline absolute astrometry from the HGCA considered in the fit.

Figure 8. The posterior distribution of atmospheric model parameters from our ATMO spectral fit, in §3.2. The contours of the posterior from the fit with a uniform mass prior are plotted in red, and the contours of the posterior from the fit with a dynamical mass prior are plotted in blue. The major takeaway is that  $\log(g)$  and mass remain relatively unconstrained in the uniform prior fit, but the other parameters remain effectively the same between the two.

Figure 9. The posterior distribution of atmospheric model parameters from our SPHINX spectral fit, in §3.2. The contours of the posterior from the fit with a uniform mass prior are plotted in red, and the contours of the posterior from the fit with a dynamical mass prior are plotted in blue. The major takeaway is that, with a slightly enhanced metallicity and sub-solar C/O, the sampler is no-longer driven towards implausibly low  $\log(g)$ .
