Abstract

Biased enhanced sampling methods utilizing collective variables (CVs) are powerful tools for sampling conformational ensembles. Due to high intrinsic dimensions, efficiently generating conformational ensembles for complex systems requires enhanced sampling on highdimensional free energy surfaces. While methods like temperature-accelerated molecular dynamics (TAMD) can adopt many CVs in a simulation, unbiasing the simulation requires accurate modeling of a high-dimensional CV probability distribution, which is challenging for traditional density estimation techniques. Here we propose an unbiasing method based on the score-based diffusion model, a deep generative learning method that excels in density estimation across complex data landscapes. We test the score-based diffusion unbiasing method on TAMD simulations. The results demonstrate that this unbiasing approach significantly outperforms traditional unbiasing methods, and can generate accurate unbiased conformational ensembles for simulations with a number of CVs higher than usual ranges.

Enhanced Sampling, Machine Learning, Scorebased Diffusion Model, Molecular Dynamics Simulation

Molecular Dynamics (MD) simulations have emerged as a primary computational tool for studying the thermodynamic and kinetic properties of complex systems in chemistry, biology, and material science.^{[1](#page-7-0)} With the assistance of supercomputers, $2,3$ $2,3$ it is now possible to perform milliseconds of all-atom MD simulations for medium-sized proteins. To extend MD simulations to broader time and length scales, multiple enhanced sampling methods have been designed to increase MD sampling efficiency. 4^{-14} 4^{-14} 4^{-14} Among all enhanced sampling methods, CVbased enhanced sampling methods focus on several important degrees of freedom that capture systems' essential dynamics. By biasing the probability distribution along CVs, CV-based enhanced sampling methods encourage systems to cross high energy barriers and explore different regions of the energy landscape more efficiently.

A critical assumption behind CV-based enhanced sampling methods is the manifold hypothesis, $15-17$ $15-17$ which posits that highdimensional all-atom configurations often lie along a low-dimensional latent manifold, and such a low-dimensional manifold can accurately describe the important features of the highdimensional systems. Traditionally, physicsbased CVs are chosen from experimentally measurable properties, geometric descriptors and order parameters with important underlying physics, such as end-to-end distance, [18](#page-8-3) radius of gyration, [19](#page-8-4) or backbone torsion angles of proteins. [20](#page-8-5) Recently, machine-learningbased methods that utilize dimensionality reduction techniques have been applied to design CVs.[21–](#page-8-6)[32](#page-9-0) Regardless of CV categories, it is challenging to fully describe a complex system in biochemistry and material science with one or two parameters, a typical number of CVs used in many enhanced sampling simulations. For example, following Two Nearest Neighbors method,^{[33](#page-9-1)} we estimate the intrinsic dimension (minimum numbers of parameters) to accurately describe Amyloid-beta $42 \; (\text{A}\beta_{42})^{34}$ $42 \; (\text{A}\beta_{42})^{34}$ $42 \; (\text{A}\beta_{42})^{34}$ to be 7.13, as shown in Fig.[\(1\)](#page-1-0). A number of CVs below 7 will not fully describe this system.

For most enhanced sampling methods [35–](#page-9-3)[38](#page-9-4) that utilize biasing potentials to assist cross-

Figure 1: (a) The Two Nearest Neighbors method calculates the ratio μ between the nearest and the second nearest neighbour distance for each data point (red dots). $F(\mu)$ is the accumulative distribution of μ . The slope (black fitting line) of $-\log(1 - F(\mu))$ as a function of $log(\mu)$ is an estimation of the intrinsic dimension of $A\beta_{42}$ (see the Supporting Information for details of the Two Nearest Neighbors method). (b) The molecular structure of $A\beta_{42}$.

ing of energy barriers, it is challenging to use many CVs, primarily due to the difficulty of constructing accurate biasing potential for a high-dimensional FES. Other methods like driven-adiabatic free energy dynamics/temperature accelerated molecular dynamics $(TAMD)$, $6,7,35,39$ $6,7,35,39$ $6,7,35,39$ $6,7,35,39$ which enhance MD sampling by rising the temperature of certain degrees of freedom, are capable of adopting many CVs in enhanced sampling simulations, since biasing potential is not required. However, when handling many CVs, the task of unbiasing TAMD trajectories to produce unbiased conformational ensembles becomes increasingly complex. This complexity arises from the need for accurate modeling of the high-dimensional, often multimodal CV probability distribution. Traditional density estimation techniques, such as histogram methods, kernel Density Estimation (KDE), [40](#page-9-6) Nearest Neighbor Density Estimation, [41](#page-9-7) and Gaussian Mixture Model (GMM) , ^{[42](#page-9-8)} often struggle to accurately capture the nuances of such intricate distributions. For instance, KDE suffers in high-dimensional spaces as it may produce overly smooth or distorted estimates due to the lack of data across the expansive highdimensional space. On the other hand, GMM suffers from scalability, initialization sensitivity, and a trivial model selection process. In this paper, we leverage the score-based diffusion model $(SBDM)^{43}$ $(SBDM)^{43}$ $(SBDM)^{43}$ for accurate unbiasing of enhanced sampling simulations with many CVs. In our study, we evaluate the performance of the SBDM-based unbiasing method in TAMD simulations. We will demonstrate that SBDM excels in constructing CV probability distributions, and can adapt to non-Euclidean CV such as torsion angles, with minor changes to the model architecture.^{[44](#page-9-10)} These capacities endow the SBDM-based unbiasing method with superior performance and versatility.

We will first introduce the TAMD method and its unbiasing formula. For a system of N particles, we denote its Cartesian coordinates by $\mathbf{r} \equiv (\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)$, and n collective variables by $\mathbf{q} \equiv (q_1(\mathbf{r}), \ldots, q_n(\mathbf{r}))$. In TAMD, q are coupled with extended variables $z \equiv (z_1, \ldots, z_n)$ with stiff harmonic potentials $\sum_i \kappa_i/2(q_i(\mathbf{r})-z_i)^2$. **z** typically shares the same topology as q. It has been proved that the free energy surface $A(q)$ can be approximated with the free energy surface of extended variables $A_{\kappa}(\mathbf{z})$ when $\kappa_i \to \infty$ for all κ_i . TAMD introduces a high temperature $T_h \gg T$ for z, and maintains \bf{r} at desired temperature T. To keep the thermodynamic properties of the system, z are adiabatically decoupled from r by assigning each z_i a fictitious mass $\mu_i \gg 1$. By defining $\beta_h = 1/k_B T_h$ where k_B is the Boltzmann constant, the joint probability distribution of r and **z** from a TAMD simulation satisfies^{[35](#page-9-3)}

$$
P_{\text{TAMD}}(\mathbf{r}, \mathbf{z}) \approx P_{T_h}(\mathbf{z}) P(\mathbf{r}|\mathbf{z}) \quad , \tag{1}
$$

where $P_{T_h}(\mathbf{z}) \propto \exp\{-\beta_h A_{\kappa}(\mathbf{z})\}$ is the marginal probability distribution of **z** and $P(r|z)$ is the Boltzmann distribution at the physical temperature T conditional on z . Eq.[\(1\)](#page-2-0) is exact if all $\mu_i \to \infty$. The free energy of collective variables $A_{\kappa}(\mathbf{z})$ can be easily obtained from TAMD with $A(\mathbf{z}) \approx -k_{\rm B}T_h \log P_{T_h}(\mathbf{z}).$

We are often interested in intuitive features

Figure 2: The free energy profiles generated from the unbiasing method of using Eq.[\(2\)](#page-2-1) are shown as solid lines with an "inaccurate" estimation of the high-temperature probability. The blue, orange, and green lines correspond to unbiasing results from $k_BT_h =3$, 6, and 9, with $k_BT = 1$ in all three cases. The black dashed line is the ground truth with accurate estimation of the high-temperature probability.

that are different from CVs used in an enhanced sampling to understand properties of the simulated system. Unbiasing enhanced sampling trajectories is necessary to project biased simulation data onto intuitive features. Assuming $Y(r)$ is a set of low dimensional intuitive features of interests, the equilibrium probability of $Y(r) = y$ can be written as

$$
P(\mathbf{y}) = \int \delta(\mathbf{y} - \mathbf{Y}(\mathbf{r})) \omega(\mathbf{z}) P_{\text{TAMD}}(\mathbf{r}, \mathbf{z}) \text{d} \mathbf{r} \text{d} \mathbf{z},
$$
\n(2)

where $\omega(\mathbf{z}) = P_{T_h}(\mathbf{z})^{T_h/T-1}$ is the unbiasing weight. If $\mathbf Y$ can be written as a function of CVs, Eq.[\(2\)](#page-2-1) can be reduced to $P(\mathbf{y}) = \int \delta(\mathbf{y} \mathbf{Y}(\mathbf{z}))\omega(\mathbf{z})P_{T_h}(\mathbf{z})\mathrm{d}\mathbf{z}.$

A good estimation of $P_{T_h}(\mathbf{z})$ is crucial for obtaining an accurate $\omega(\mathbf{z})$ in TAMD. Errors in estimating $P_{T_h}(\mathbf{z})$ magnify errors in $\omega(\mathbf{z})$ at a high T_h , leading to inaccurate $P(\mathbf{y})$. We design a toy problem to demonstrate the importance of accurately modeling $P_{T_h}(\mathbf{z})$ in unbiasing TAMD. In this example, a one dimensional probability density $P(\mathbf{z})$ at $k_{\text{B}}T = 1$ is constructed with a mixture of Gaussians. The probability is scaled

Figure 3: (a) The mechanism of denoising SBDM. During the diffusion process, the data (in this demonstration a picture) is gradually perturbed to an isotropic Gaussian noise via a forward SDE. (b) The flow chat of unbiasing TAMD with SBDM. We perform TAMD simulation at a high temperature T_h , and construct SBDM for z. The time-dependent score function, squared in orange, is used to perform density estimation of CV, $P(\mathbf{z}) \equiv P_{T_h}(\mathbf{z})$, from a simple distribution, as shown above the red line. The weight $\omega(\mathbf{z})$ of configurations is evaluated from the estimated CV probability $P(\mathbf{z})$. The weight is used to compute the unbiased distribution of features of interest $P(\mathbf{y})$.

to different T_h followed by convolution with a Gaussian kernel to "perturb" the high temperature probability $\tilde{P}_{T_h}(\mathbf{z})$. $\tilde{P}_{T_h}(\mathbf{z})$ is used to calculate weight $\omega(\mathbf{z})$. The "unbiased" distribution of $\mathbf{z}, P_{\text{ub}}(\mathbf{z})$, is then calculated with Eq.[\(2\)](#page-2-1) (see the Supporting Information for details of the toy problem). Fig.[\(2\)](#page-2-2) demonstrates that the error in $P_{\text{ub}}(\mathbf{z})$ is more sensitive to errors in $\tilde{P}_{T_h}(\mathbf{z})$ when T_h is higher.

We then briefly review the SBDM framework and its usage in density estimation. The SBDM perturbs data to noise prior with a diffusion process over a unit time by a linear stochastic differential equation (SDE):

$$
d\mathbf{z} = f(\mathbf{z}, t)dt + g(t)d\mathbf{w}, \ t \in [0, 1], \quad (3)
$$

where $f(\mathbf{z}, t)$, $q(t)$ are user-defined drift and

diffusion functions of the SDE and w denotes a standard Wiener process. In this paper, an SDE with the drift term $f(\mathbf{z}, t) = 0$ is used. With carefully designed $q(t)$, the marginal probability of z at diffusion time t , $P_t(z)$, changes from the data distribution at $t = 0$ to approximately a simple Gaussian distribution at $t = 1$.

For any diffusion process in Eq. (3) , it has a corresponding reverse-time SDE^{45} SDE^{45} SDE^{45} :

$$
d\mathbf{z} = [f(\mathbf{z}, t) - g^2(t)\nabla_{\mathbf{z}}\log P_t(\mathbf{z})]dt + g(t)d\bar{\mathbf{w}},
$$
\n(4)

with \bar{w} a standard Wiener process in the reverse-time. The trajectories of the reverse SDE have the same marginal densities as the forward SDE. Thus, the reverse-time SDE can gradually convert noise to data. The SBDM parameterizes the time-dependent score function $\nabla_{\mathbf{z}} \log P_t(\mathbf{z})$ in the reverse SDE with a neural network $\mathbf{s}_{\theta}(\mathbf{z}(t), t)$. To estimate $\nabla_{\mathbf{z}} \log P_t(\mathbf{z}),$ a time-dependent score-based model $s_{\theta}(\mathbf{z}(t), t)$ can be trained via minimizing a denoising score matching loss:

$$
M(\theta) = \left\| \mathbf{s}_{\theta}(\mathbf{z}(t), t) - \nabla_{\mathbf{z}(t)} \log P(\mathbf{z}(t)|\mathbf{z}(0)) \right\|_{2}^{2}
$$

$$
J(\theta) = \arg\min_{\theta} \mathbb{E}_{t} \left\{ \mathbb{E}_{\mathbf{z}(0)} \mathbb{E}_{\mathbf{z}(t)|\mathbf{z}(0)} M(\theta) \right\},
$$
(5)

with t uniformly sampled between $[0, 1]$. We note that $\nabla_{\mathbf{z}(t)} \log P(\mathbf{z}(t)|\mathbf{z}(0))$ is not explicitly required in the score matching loss while samples following $P(\mathbf{z}(t)|\mathbf{z}(0))$ are needed.

Finally, SBDM defines a deterministic way to compute the data distribution $P_0(\mathbf{z})$ as follows, with $f(\mathbf{z}, t) = 0$:

$$
\log P_0(\mathbf{z}(0)) = \log P_1(\mathbf{z}(1))
$$

$$
-\frac{1}{2} \int_0^1 g^2(t) \nabla_{\mathbf{z}} \cdot \mathbf{s}(\mathbf{z}(t), t) dt. \quad (6)
$$

CVs can be defined in spaces with different topologies. For example, n torsion angles are defined on a hypertorus space \mathbb{T}^n , and quaternions which representing rigid-body rotation are defined on a 3D unit sphere \mathbb{S}^3 . Therefore, extending the SBDM to different topologies is important. In this study we will focus on SBDM on a hypertorus space. The theory behind SBDM holds for compact Riemannian manifolds, with subtle modifications. For $z \in M$, a Riemannian manifold (such as hypertorus \mathbb{T}^n , w being the Brownian motion on the manifold, and $f(\mathbf{z}, t) \in T_{\mathbf{z}}M$, a tangent space, Eq.[\(4\)](#page-3-1) still holds. 44

As shown in Eq.[\(5\)](#page-4-0), training a denoising score matching model requires sampling from the perturbation kernel $P(\mathbf{z}(t)|\mathbf{z}(0))$ of the forward diffusion defined by Eq.[\(3\)](#page-3-0). We consider the perturbation kernel on \mathbb{T}^n with wrapped normal distribution:

$$
\mathbf{U}_{\mathbf{d}}(t) = \frac{\|\mathbf{z}(0) - \mathbf{z}(t) + 2\pi \mathbf{d}\|^2}{2\sigma^2(t)}, \ \mathbf{d} \in \mathbb{Z}^n
$$

$$
P(\mathbf{z}(t)|\mathbf{z}(0)) \propto \sum_{\mathbf{d}} \exp(-\mathbf{U}_{\mathbf{d}}(t)), \tag{7}
$$

 $\sqrt{\mathrm{d}\sigma^2(t)/\mathrm{d}t}$. The rest of the terms in the loss where $q(t)$ and $\sigma(t)$ are related by $q(t)$ = function in Eq. [\(5\)](#page-4-0) remain the same. Note

Figure 4: Molecular structure of alanine dipeptide is shown in (a). (b, c) FES w.r.t backbone dihedral angles of alanine dipeptide are presented, obtained by metadynamics (b) and SBDM-TAMD (c). The red/black points represent the location of important minima and saddle points on the FES. (d-f) The absolute free energy difference between metadynamics and SBDM-TAMD, KDE-TAMD, and GMM-TAMD.

that density estimation in $Eq.(6)$ $Eq.(6)$ is applicable to both variables in Euclidean and hypertorus space. The architecture of an SBDM model is highly flexible. For example, an SBDM model can use Residual neural network (ResNet), [46](#page-10-1) U-Net,[47](#page-10-2) Graph Neural Network (GNN), [48](#page-10-3) etc.

In the following section, we will demonstrate how incorporating SBDM can fulfill the strict density estimation accuracy requirement of unbiasing TAMD, thus allowing TAMD to generate correct unbiased ensembles. We tested

the efficiency and accuracy of SBDM to unbiasing TAMD simulations on three systems: (1) alanine dipeptide (2) glutamine dipeptide, and (3) met-enkephalin (see the Supporting Information for simulation details). In all three systems, we conducted TAMD with torsion angles as collective variables, with $T_h = 1200K$ in the first example while $T_h = 900K$ in the second and third examples. The physical variables were maintained at temperature $T = 300K$ in all three experiments. We then unbiased TAMD with density estimation performed by SBDM on hypertorus space (see the Supporting Information for details of training SBDM models). Unbiasing TAMD with SBDM as density estimation method is referred as SBDM-TAMD in the rest of the paper. The general framework of SBDM-TAMD is summarized in Fig.[\(3\)](#page-3-2). For a fair comparison, we unbiased the same TAMD simulations with kernel density estimation (KDE-TAMD) and Gaussian Mixture Model (GMM-TAMD) in all three systems, and Normalizing Flow on hypertorus space (NF- $TAMD)^{49,50}$ $TAMD)^{49,50}$ $TAMD)^{49,50}$ $TAMD)^{49,50}$ in the last system. We performed converged metadynamics simulations at $300K$ as the baseline results of all three systems. We will compare the unbiasing results from different density estimation methods to the baseline results.

The first proof-of-concept example is an alanine dipeptide in the aqueous solution with implicit solvent. This has been a benchmark system with well-established FES in previous studies.[51](#page-10-6)[,52](#page-10-7) In both TAMD and the baseline metadynamics, we used the Ramachandran angles (ϕ, ψ) as CVs. The accuracy of SBDM-TAMD is demonstrated in Fig.[\(4\)](#page-4-2). The SBDM capably captures the intricate free energy delineated by metadynamics, as shown in Fig. $(4)(c)$ $(4)(c)$ and Fig. $(4)(d)$ $(4)(d)$. Notably, the model accurately locates all six free energy minima, with depth of the minima quantitatively accurate $\langle \langle 1 \text{ kJ/mol} \rangle$ energy difference). Furthermore, the saddle points - representative of transitional between conformational basins, are also well reproduced. Energy errors in low free energy saddle points are less than 2 kJ/mol compared to metadynamics results. This match implies that the SBDM-TAMD is accurate for studying both

Figure 5: Molecular structure of Glutamine dipeptide is shown in (a). FES of backbone dihedral angles of Glutamine dipeptide are calculated by metadnyamics (b) and SBDM-TAMD (C). The red/black points represent the location of important minima and saddle points on the FES. (d)-(f) shows he absolute free energy difference between metadynamics and SBDM-TAMD, KDE-TAMD, and GMM-TAMD.

thermodyanmics and kinetics of alanine dipeptide conformational changes. We notice that for this two-dimensional problem, KDE and GMM perform relatively well, but still with less accuracy compared to SBDM. Both methods can locate the free energy minima but with a larger energy difference of up to 2.5 kJ/mol from the baseline metadynamics. The free energy of saddle points have even larger deviation, up to 3.5 kJ/mol . The clear disparities in free energy differences, as shown in Fig. $4(e)$ and Fig. $4(f)$, especially in regions corresponding to the annotated energy minima and saddle points, illustrate the inadequacies of KDE and GMM for precise FES calculations.

The second system we studied is Glutamine dipeptide in the aqueous solution with explicit solvent. A TAMD simulation was performed with five dihedral angles on the backbone and the side chain $(\phi, \psi, \chi_1, \chi_2, \chi_3)$ as CVs to enhance the sampling of both backbone and side chain conformations. We also run a benchmark metadynamics with two backbone diheral angles as CVs. The result is demonstrated in Fig.[\(5\)](#page-5-0). Projecting unbiased SBDM-TAMD trajectory onto backbone dihedral angles quantitavely matches the bechmark FES from metadynamics. Energy errors of minima on the projected 2D FES are within 2 kJ/mol while errors of low-free-energy saddles are approximately 5 kJ/mol. As a comparison, both KDE and GMM struggle to uphold their precision with the increased CV dimensions. Both of these two methods introduce larger errors at α and α_L . This example highlights the SBDM's superior adaptability and accuracy in high-dimensional CV compared to traditional methods.

The final, more challenging system we studied is the oligopeptide met-enkephalin (Tyr-Gly-Gly-Phe-Met) in the aqueous solution with explicit water, which is a common test case for enhanced sampling techniques. [35](#page-9-3)[,53,](#page-10-8)[54](#page-10-9) For TAMD, we chose ten backbone dihedral angles $(\phi_1, \psi_1, ..., \phi_5, \psi_5)$ as CVs. The baseline metadynamics simulation was performed with a 2D stochastic kinetic embedding (StKE), a manifold learning method which serves as a low-dimensional CV representation that preserves kinetic information. [25](#page-8-7) We projected the unbiased SBDM-TAMD trajectory to features like end-to-end distance d_{ee} and the radius of gyration R_g . As a comparison, we unbiased the benchmark metadynamics simulation^{[55–](#page-10-10)[57](#page-10-11)} and projected configurations from metadynamics onto the same features. We want to emphasize that generating an optimal machinelearning-based CVs for metadynamics (StKE in this work) is non-trivial and requires extra simulation data. From Fig.[\(6\)](#page-6-0), the SBDM-TAMD exhibits high performance, demonstrating a FES that closely aligned with the metadynamics baseline. The minima and barriers on each projected one-dimensional FES predicted by SBDM is in good agreements with

Figure 6: (a) Molecular structure of metenkephalin. (b-c) Free energy of end-to-end distance and radius of gyration, with red dots indicating stable and meta-stable states.

benchmark, suggesting SBDM-TAMD is capable of modeling thermodynamics and kinetics of a polypeptide. For example, as shown in Fig. [6\(](#page-6-0)b), both metadynamics and SBDM-TAMD identify conformations with small d_{ee} as a meta-stable conformation with consistent meta-stability, while KDE and GMM fail to predict this meta-stable conformation. Also, KDE and GMM fail to predict the location of the global minimum on the FES of d_{ee} with an error of ∼3.0 Å. Although NF correctly predicts the location of the global minimum, it overestimates the stability of this minimum. Similarly, KDE ,GMM, and even NF, predict the most possible $R_{\rm g} \approx 5$ Å, while SBDM-TAMD predicts that the most stable conformations have $R_{\rm g}$ < 4 Å, which is consistent with the metadynamics' result.

In this paper, we developed an unbiasing method based on score-based diffusion model, a deep generative learning model, to generate unbiased conformational ensembles from collective-variable-based biased enhanced sampling simulations. Our method can adapt to simulations with collective variables of large amounts and different topologies. We test the unbiasing method on temperature-accelerated molecular dynamics, an enhanced sampling method that can utilize many collective variables to efficiently explore a high-dimensional free energy surface. Numerical experiments across three systems of 2,5 and 10 collective variables underscore our unbiasing method's exceptional accuracy and adaptability to highdimensional collective variables. Although biomolecules were used in the numerical experiments, the developed approach can be used to other problems like modeling material phase transitions. Looking ahead, we aim to explore the method's potential in unbiasing simulations with even larger amounts of collective variables, and form accurate high-dimensional biasing potentials for wider ranges of enhanced sampling methods.
