Abstract—Ouantum computing revolutionizes the way of solving complex problems and handling vast datasets, which shows great potential to accelerate the machine learning process. However, data leakage in quantum machine learning (QML) may present privacy risks. Although differential privacy (DP), which protects privacy through the injection of artificial noise, is a well-established approach, its application in the QML domain remains under-explored. In this paper, we propose to harness inherent quantum noises to protect data privacy in QML. Especially, considering the Noisy Intermediate-Scale Quantum (NISQ) devices, we leverage the unavoidable shot noise and incoherent noise in quantum computing to preserve the privacy of QML models for binary classification. We mathematically analyze that the gradient of quantum circuit parameters in OML satisfies a Gaussian distribution, and derive the upper and lower bounds on its variance, which can potentially provide the DP guarantee. Through simulations, we show that a target privacy protection level can be achieved by running the quantum circuit a different number of times.

Index Terms—Quantum machine learning, Quantum differential privacy, Shot noise, Incoherent noise

I. INTRODUCTION

Quantum computing, which exploits principles of quantum mechanics such as superposition and entanglement, offers a great potential for significantly faster complex calculations than classical computers. In the Noisy Intermediate-Scale Quantum (NISQ) era, variational quantum algorithms (VQAs) are considered the best for quantum computing, which heavily rely on variational quantum circuits (VQCs). VQCs are parameterized quantum circuits designed to be optimized iteratively to minimize specific cost functions, enabling the exploration of solution spaces and the identification of optimal quantum states. Based on the advance of these technologies, quantum computing is becoming a powerful alternative to conduct computing intensive machine learning or optimization tasks [1, 2].

Quantum machine learning (QML) has demonstrated advantages over classical machine learning (CML) in dealing with large datasets and complex problems [3]. Due to its high computing efficiency, QML has the potential to be used in various areas such as nanoparticle synthesis and biomedical domain. Nevertheless, the datasets used in these applications may be highly sensitive, e.g., CT scanned images of COVID-19 patients [4]. Therefore, similar to data privacy concerns in CML, privacy preservation is crucial in QML to safeguard sensitive data from potential breaches and misuse.

In CML scenarios, we integrate differential privacy (DP) techniques to protect sensitive data and mitigate privacy risks during data processing and analysis. DP is a concept in data science and statistics that aims to provide a means of statistical database privacy protection proposed by [5]. It offers a way to maximize the accuracy of queries from statistical databases while minimizing the chances of identifying information about specific individuals within the database. By introducing controlled amounts of statistical noise to the data, DP ensures that the presence or absence of specific records does not significantly affect the results, thereby safeguarding individual privacy. One of the most popular DP definitions is (ϵ, δ) -DP, where ϵ represents the maximum allowed change in output due to the addition or removal of an individual's data, and δ indicates an upper bound on the probability of the algorithm's privacy violation. Abadi et al. in [6] proposed a differentially private stochastic gradient descent (DP-SGD) algorithm, which can provide a strict privacy guarantee in machine learning by adding Gaussian noise to gradients.

Building on this foundation, research efforts have been dedicated to generalizing DP for quantum computing scenarios. Aiming to preserve the privacy of quantum data and computations, Watkins et al. in [7] proposed a method to protect the data privacy of OML models by adding artificial Gaussian noise to the gradients using the DP-SGD algorithm. However, this method largely ignores the inherent noises in quantum circuits, which could potentially offer a privacy protection guarantee in QML. Apart from them, we find that DP can also be achieved with shot noise that are inherent in quantum measurements. The shot noise are statistical fluctuations in the measurement outcomes of quantum bits (qubits) due to the discrete nature of particles. Fluctuations caused by shot noise are intrinsic to the quantum nature of particles and result from the probabilistic behavior of quantum systems. Shot noise affects the output of quantum circuits and makes it Gaussian distributed, potentially preserving the privacy of QML models.

In this paper, we theoretically study the impacts of shot noise on the privacy budget of (ϵ, δ) -DP. Meanwhile, considering that QML is severely affected by incoherent noise, we propose to employ the quantum error mitigation (QEM) method to mitigate the incoherent noise, and investigate the impacts of the QEM method on the degree of privacy preservation. The methods of QEM include zero noise extrapolation, probabilistic error cancellation (PEC) [8], etc. In this study, we utilize PEC as our QEM method, since the analytic representation helps us analyze the impact of QEM method on the quantum circuit outputs. To the best of our knowledge, we are the first to utilize the inherent noises of quantum circuits to achieve DP preservation in QML. The contributions of this paper are three-fold as summarized below:

- With shot noise, incoherent noise, and the PEC method, we show that the outputs of a quantum circuit satisfy Gaussian distribution, and provide its analytical expressions.
- We further prove that the gradient of QML also satisfies Gaussian distribution, when performing a binary classification task with a modified hinge loss function and considering the inherent noise. We also give upper and lower bounds on the variance of the Gaussian distribution, which is closely related to the privacy budget ϵ and the privacy violation probability δ .
- We conduct extensive simulations on the quantum simulator, and the results demonstrate the inherent noises in quantum circuits can be harnessed to implement DP. Moreover, we show that under a certain δ, the privacy budget ε can be achieved by running the quantum circuit a different number of times.

The rest of the paper is organized as follows. Section II introduces the background knowledge of DP and DP-SGD algorithm. We give analyze the effect of shot noise, incoherent noise, and the PEC method on the gradient of QML and further discuss the relationships between the distribution of the gradient and the privacy budget of DP in Section III. Then, we present the experiment study in Section IV. Finally, we conclude our paper in Section V.

II. DIFFERENTIAL PRIVACY AND DP-SGD ALGORITHM

In this section, we introduce the basic concept of DP and the DP-SGD algorithm proposed by Abadi *et al.* in [6] achieving DP of machine learning models.

A. Differential Privacy

DP [9] is a method for preserving the privacy of a sensitive dataset while maintaining statistical information of the dataset. Intuitively, given a private dataset, a DP mechanism can protect individual data privacy even though statistics of the dataset are published. The formal definition of (ϵ, δ) -DP is shown as follows.

Definition 1 (Differential Privacy). A randomized algorithm \mathcal{M} satisfies (ϵ, δ) -DP if for any two adjacent datasets \mathcal{D} and \mathcal{D}' that differ in only a single record, and for all $S \subseteq Range(\mathcal{M})$, we have

$$\mathbf{P}[\mathcal{M}(\mathcal{D}) \in S] \le e^{\epsilon} \mathbf{P}[\mathcal{M}(\mathcal{D}') \in S] + \delta.$$
(1)

 (ϵ, δ) -DP ensures that for all adjacent datasets \mathcal{D} and \mathcal{D}' , the absolute value of the privacy loss will be bounded by ϵ with probability at least $1 - \delta$, and the privacy loss is defined as:

$$\mathcal{L}^{x}_{\mathcal{M}(\mathcal{D})||\mathcal{M}(\mathcal{D}')} = \ln(\frac{\mathbf{P}[\mathcal{M}(\mathcal{D}) = x]}{\mathbf{P}[\mathcal{M}(\mathcal{D}') = x]}).$$
 (2)

If $\delta = 0$, the randomized algorithm \mathcal{M} is said to have ϵ -DP. A generic method of achieving (ϵ, δ) -DP is the Gaussian mechanism that adds Gaussian noise from the distribution $\mathcal{N}(0, \sigma^2)$, calibrated to the sensitivity. The sensitivity captures the maximum difference in the output of the dataset caused by a single record in the worst case. We define sensitive more formally below and then we describe the Gaussian mechanism.

Definition 2 $(l_p$ -sensitive). Let f be a query mapping from the space of datasets to \mathbb{R}^m , Let N be the set of all possible pairs of neighboring datasets. For a fixed positive scalar p, the l_p -sensitivity of f is defined by

$$s(f;p) = \max_{D,D' \in N} \|f(D) - f(D')\|_p.$$
 (3)

Gaussian mechanism. Given the output of the query $f(D) \in \mathbb{R}^m$, the Gaussian mechanism adds noise sampled from the Gaussian distribution to each of the *m* dimensions in the output, with the variance of the noise calibrated to the l_p -sensitivity. The Gaussian mechanism cannot guarantee pure ϵ -DP but can instead ensure approximate (ϵ, δ)-DP. The Gaussian mechanism is commonly used in machine learning [10], e.g., it is the main mechanism behind DP-SGD, which we are going to explain in Section II-B.

B. DP-SGD Algorithm

DP-SGD is a privacy-preserving optimization algorithm designed to train machine learning models while ensuring individual data point privacy. The algorithm achieves this by incorporating DP directly into the stochastic gradient descent optimization process. Mathematically, DP-SGD modifies the gradient computation step by adding carefully calibrated noise, ensuring that the impact of any single data point on the model parameters remains statistically indistinguishable. The updated gradient computation can be expressed as:

$$\tilde{\nabla}\ell(w) = \frac{\nabla\ell(w)}{\max(1, \frac{||\nabla\ell(w)||_2}{C})} + \mathcal{N}(0, \sigma^2 C^2 I), \qquad (4)$$

where $\nabla \ell(w)$ is the gradient of the loss with respect to the model parameters for the data point. *C* is the clipping norm, which bounds the influence of each example on the gradient and $\mathcal{N}(0, \sigma^2 C^2 I)$ represents the added noise following a Gaussian distribution with mean 0 and covariance $\sigma^2 C^2 I$. The privacy cost is typically quantified using the (ϵ, δ) -DP definition. DP-SGD achieves DP by bounding the ratio of probabilities of any two adjacent datasets. Incorporating these modifications into the standard stochastic gradient descent update rule, the DP-SGD algorithm provides a robust and privacy-preserving approach to training machine learning models on sensitive datasets. The current method for realizing DP in QML was proposed by Watkins *et al.* in [7], they artificially add Gaussian noise to the gradient like DP-SGD. In the next section, we additionally consider shot noise and incoherent noise, and we prove that the gradient satisfies a Gaussian distribution in a binary classification task using a modified hinge loss function, which can potentially achieve (ϵ, δ) -DP.

III. NOISY GRADIENTS OF QUANTUM CIRCUIT PARAMETERS

In this section, we consider the binary classification task with modified hinge loss function on classical dataset. We leave the case of arbitrary loss functions for multiclassification tasks in the future work. The binary classification task takes $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{y}_i) \in \mathcal{X} \times \mathcal{Y} : i = 1, 2, ..., m\}$ as input training data which consists of *m* data-label pairs, where the data space $\mathcal{X} = \mathbb{R}^d$ and the label set $\mathcal{Y} \in \{-1, 1\}$. We would like to train a classifier $\mathbf{g} : \mathcal{X} \to \mathcal{Y}$. We measure the quality of our classifier on the training data via a loss function $\ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$. In empirical risk minimization (ERM), we choose a classifier \mathbf{g} that minimizes the empirical loss:

$$J(\mathbf{g}, \mathcal{D}) = \frac{1}{m} \sum_{i=1}^{m} \ell(\mathbf{g}(\mathbf{x}_i), \mathbf{y}_i),$$
(5)

where $g(\mathbf{x}_i)$ is the output of the QNN (i.e. the expectation of an observable) under classical input data \mathbf{x}_i and is parameterized by $\boldsymbol{\theta} = \{\theta_1, \theta_2, \cdots\}$. We will show that partial derivatives of the loss function $\nabla_{\theta} \ell$ satisfy the Gaussian distribution under the effect of shot noise, incoherent noise and the PEC method. Therefore, it can potentially achieve DP in QML.

A. The Impact of Shot Noise and Incoherent Noise on the Output in Quantum Circuits

Given a QNN, the output has an expectation value of $Tr(\mathcal{A}\rho)$, where ρ is the output state of the quantum circuit, $Tr(\cdot)$ is the trace function of a matrix and \mathcal{A} is the observable of interests, whose eigenvalues are $\lambda_1, \lambda_2, ..., \lambda_{2^q}$. Here, q is the number of qubits to be observed. Assuming that after running the quantum circuit n times, we can get the observation that $\mathcal{O}^n = \{\mathbf{o}_1, \mathbf{o}_2, ..., \mathbf{o}_n\}$, where $\mathbf{o}_1, \mathbf{o}_2, ..., \mathbf{o}_n$ are independently and identically distributed random variables. The probability that $\mathbf{o}_n = \lambda_k$ is p_k , which depends on the output state ρ . Consequently, the expectation value obtained by running the quantum circuit can be expressed as a random variable $O = \frac{\sum_{i=1}^{n} o_i}{n}$, where o_i denotes the value of the random variable o_i . According to the Lindeberg-Lévy central limit theorem [11], we assume that O follows Gaussian distribution. It implies that each time a quantum computation is performed, the output value $\mathbf{g}(\mathbf{x}_i)$ is a random variable that follows Gaussian distribution.

In addition to shot noise, there is also inevitable incoherent noise in quantum circuits, which affects the variance of the output O. The wide variety of incoherent noise, coupled with the different specific forms of quantum circuits, makes it difficult to study the effect of such noise on the output O. Therefore, we approximate the incoherent noise in quantum circuits using the global depolarizing noise. It has been proven that global depolarizing noise successfully captures the effects of realistic noise and can serve as a phenomenological model [12]. The global depolarizing noise can be expressed as:

$$\mathcal{E}_{\mathsf{Dep}}^{\otimes q}(\rho) = (1 - p_t)\rho + p_t \frac{I^{\otimes q}}{2^q},\tag{6}$$

where p_t is the effective total error probability and can be obtained by solving a quadratic equation [13]:

$$\operatorname{Tr}[\rho^2] = (1 - p_t)^2 + \frac{p_t(1 - p_t)}{2^{n-1}} + \frac{p_t^2}{2^n}.$$
 (7)

The value of $\text{Tr}[\rho^2]$ can be measured directly on the device. Because p_t affects the output quantum state, it affects the probability p_k that λ_k occurs. Therefore, the variance of the noise output \hat{O} can be expressed as a function of the global depolarizing noise error rate p_t , the noiseless output quantum state ρ and the number of executions n of the quantum circuit:

$$\operatorname{Var}[\hat{O}] = h(p_t, \rho, n). \tag{8}$$

Without dealing with incoherent noise, the quantum circuit output results will be highly biased, which can have serious implications for the performances of QML. It will be shown in Section IV-A. To address the effect of incoherent noise on QML, in the next section we consider the use of the PEC method and analyze its effect on the Gaussian distributed output \hat{O} .

B. Analyzing the Variance of the Gaussian Distributed Output with Probabilistic Error Cancellation

The main idea of PEC is to represent each ideal gate G_i of the quantum circuit as a linear combination of noisy implementable operations $\{U_{\alpha}\}$:

$$\mathcal{G}_i = \sum_{\alpha} \eta_{i,\alpha} \mathcal{U}_{i,\alpha},\tag{9}$$

where $\eta_{i,\alpha} \in \mathbb{R}$, and $\sum_{\alpha} \eta_{i,\alpha} = 1$. The real coefficients $\eta_{i,\alpha}$ form a quasi-probability distribution. We can obtain the ideal expectation value as a linear combination of noisy expectation values:

$$\langle \mathcal{A} \rangle_{\text{ideal}} = \sum_{\vec{\alpha}} \eta_{\vec{\alpha}} \text{Tr}[\mathcal{A} \Phi_{\vec{\alpha}}(\rho)]$$

$$= \sum_{\vec{\alpha}} \eta_{\vec{\alpha}} \langle \mathcal{A}_{\vec{\alpha}} \rangle_{\text{noisy}},$$
(10)

where $\vec{\alpha} = (\alpha_1, \alpha_2, ..., \alpha_t)$ is the multi-index, $\Phi_{\vec{\alpha}} = \mathcal{U}_{t,\alpha_t} \circ \cdots \circ \mathcal{U}_{2,\alpha_2} \circ \mathcal{U}_{1,\alpha_1}, \ \eta_{\vec{\alpha}} = \prod_{i=1}^t \eta_{i,\alpha_i}$. The noise expectation values $\langle \mathcal{A}_{\vec{\alpha}} \rangle_{\text{noisy}}$ can be measured directly. By combining all the noise expectation values, the desired result $\langle \mathcal{A} \rangle_{\text{ideal}}$ can be calculated.

Inevitably, we need to investigate how PEC affects the Gaussian distribution output O of the quantum circuit. We denote \tilde{O} as the output random variable after using PEC. From Eq. (10), the error mitigated expectation value $\mathbb{E}[\tilde{O}]$ is a linear sum of the expectation values of a set of K random variables $\{X_i\}$, which are the outputs of the set of measurement circuits,

and K corresponds to the multi-index $\vec{\alpha}$. Therefore, $\mathbb{E}[\tilde{O}]$ can be expressed as:

$$\mathbb{E}[\tilde{O}] = \sum_{i=1}^{K} \eta_i \mathbb{E}[X_i] = \mathbb{E}[O], \qquad (11)$$

where η_i are real coefficients. If we estimate individual terms $\mathbb{E}[X_i]$ up to a certain precision, then combine the results, the variance of the error mitigation estimator \tilde{O} can be expressed as:

$$\operatorname{Var}[\tilde{O}] = \sum_{i=1}^{K} |\eta_i|^2 \operatorname{Var}[X_i].$$
(12)

Because the component of random variables X_i are generated from circuits that are variants of the primary circuit, they can be expected to have a similar variance as the unmitigated estimator \hat{O} [8]. This relationship can be expressed as $Var[X_i] \sim Var[\hat{O}]$, and hence we have:

$$\operatorname{Var}[\tilde{O}] = (\sum_{i=1}^{K} |\eta_i|^2) \operatorname{Var}[\hat{O}].$$
(13)

So far we have given analytical expressions for the mean and variance of a error mitigated quantum circuit's output \tilde{O} . In the next section, we will analyze how much privacy budget can be given to a quantum circuit.

C. Quantum Inherent Noise Mechanism

In this subsection, we propose a novel DP mechanism called the quantum inherent noise mechanism, which utilizes the inherent noise in the quantum circuit to achieve (ϵ, δ) -DP. The partial derivative of the loss function $\nabla_{\theta} \ell$ can often be expressed as a linear combination of two quantum circuit outputs. The two quantum circuits use the same architecture, differing only in $\pm \frac{\pi}{2}$ shift of the parameter. Here, we use parameter-shift rules [14] to compute partial derivatives of observable \mathcal{A} with respect to the parameter θ :

$$\frac{\partial \langle \mathcal{A} \rangle}{\partial \theta} = \frac{1}{2} \left[\mathbf{g}(\mathbf{x}_i; \theta + \frac{\pi}{2})) - \mathbf{g}(\mathbf{x}_i; \theta - \frac{\pi}{2})) \right].$$
(14)

If we consider using modified hinge loss function $\ell(\mathbf{g}(\mathbf{x}_i), \mathbf{y}_i) = 1 - \mathbf{y}_i \mathbf{g}(\mathbf{x}_i)$, the gradient of the parameter θ with respect to the data point $(\mathbf{x}_i, \mathbf{y}_i)$ can be expressed as:

$$\nabla_{\theta} \ell = \pm \frac{1}{2} \left[\mathbf{g}(\mathbf{x}_i; \theta + \frac{\pi}{2}) - \mathbf{g}(\mathbf{x}_i; \theta - \frac{\pi}{2}) \right].$$
(15)

We mentioned earlier that $\mathbf{g}(\mathbf{x}_i; \theta)$ is mitigated quantum circuits output satisfying Gaussian distribution. Since $\mathbf{g}(\mathbf{x}_i; \theta + \frac{\pi}{2})$ and $\mathbf{g}(\mathbf{x}_i; \theta - \frac{\pi}{2})$ are independent Gaussian random variables, their linear combination $\nabla_{\theta} \ell$ also satisfies Gaussian distribution, and we have the following Lemma.

Lemma 1. The gradient of the loss function in QML model satisfies a Gaussian distribution with the variance $Var[\nabla_{\theta} \ell]$ that is bounded by:

$$\frac{\sum_{i=1}^{K} |\eta_i|^2}{2} h_{min} \le Var[\nabla_{\theta} \ell] \le \frac{\sum_{i=1}^{K} |\eta_i|^2}{2} h_{max}, \quad (16)$$

where $h_{\min} = \min_{\rho} h(p_t, \rho, n)$ and $h_{\max} = \max_{\rho} h(p_t, \rho, n)$.

Proof. Using the fact $\tilde{O}^{\theta} = \mathbf{g}(\mathbf{x}_i; \theta)$ and combining Eq. (8)(13)(15), we can deduce that:

$$\begin{aligned} &\operatorname{Var}[\nabla_{\theta}\ell] \\ &= \frac{1}{4} \operatorname{Var}[\mathbf{g}(\mathbf{x}_{i}; \theta + \frac{\pi}{2})] + \frac{1}{4} \operatorname{Var}[\mathbf{g}(\mathbf{x}_{i}; \theta - \frac{\pi}{2})] \\ &= \frac{1}{4} \operatorname{Var}[\tilde{O}^{\theta + \frac{\pi}{2}}] + \frac{1}{4} \operatorname{Var}[\tilde{O}^{\theta - \frac{\pi}{2}}] \\ &= \frac{\sum\limits_{i=1}^{K} |\eta_{i}|^{2}}{4} \operatorname{Var}[\hat{O}^{\theta + \frac{\pi}{2}}] + \frac{\sum\limits_{i=1}^{K} |\eta_{i}|^{2}}{4} \operatorname{Var}[\hat{O}^{\theta - \frac{\pi}{2}}] \\ &= \frac{\sum\limits_{i=1}^{K} |\eta_{i}|^{2}}{4} h(p_{t}, \rho^{\theta + \frac{\pi}{2}}, n) + \frac{\sum\limits_{i=1}^{K} |\eta_{i}|^{2}}{4} h(p_{t}, \rho^{\theta - \frac{\pi}{2}}, n) \end{aligned}$$

Since the function h represents the noise output's variance, it is a bounded function. We can obtain the lower bounds h_{\min} and upper bounds h_{\max} on h. Bringing the minimum and maximum values into Eq. (17), we can obtain lower and upper bounds on Var $[\nabla_{\theta} \ell]$.

From Lemma 1, we can bound the variance of the Gaussian distributed gradients $\operatorname{Var}[\nabla_{\theta}\ell]$. Combining an auxiliary result in [15], we can use the lower bound on $\operatorname{Var}[\nabla_{\theta}\ell]$ to compute privacy budget ϵ and the protection failure probability δ of DP, which will be shown in Theorem 1. In our proposed quantum inherent noise mechanism, we harness the shot noise and incoherent noise as a free noise resource in the quantum circuit to achieve (ϵ, δ) -DP instead of injecting extra artificial noise into the quantum circuits.

Theorem 1. Suppose mechanism M(D) = f(D) + Z, where D is the input dataset, $f(\cdot)$ is a m-dimension function, noise $Z \sim \mathcal{N}(0, \sigma_*^2)$ and $\sigma_* = \sigma_{min}$, is (ϵ, δ) -DP, then quantum inherent noise mechanism M'(D) = f(D) + Z', where $Z' = (z_1, \ldots, z_m)^T$, $\forall i \in [m], z_i \sim \mathcal{N}(0, \sigma_i^2)$ and $\sigma_i \in [\sigma_{min}, \sigma_{max}]$ is also (ϵ, δ) -DP.

Proof. Using Lemma 1 in [15], We can introduce an equivalent σ_* which satisfies

$$\sigma_*^2 \le \min_i \sigma_i^2 = \frac{(\Delta_2 f)^2}{\frac{(\Delta_2 f)^2}{\min_i \sigma_i^2}} = \frac{(\Delta_2 f)^2}{\frac{\sum_{i=1}^m s_i^2}{\sum_{i=1}^m s_i^2}} \le \frac{(\Delta_2 f)^2}{\sum_{i=1}^m \frac{s_i^2}{\sigma_i^2}}$$

where σ_i^2 is the variance of the *i*-th gradient whose lower bound is $\sum_{i=1}^{K} |\eta_i|^2 h_{\min}/2$ from Lemma 1 and s_i is the l_2 sensitivity of the *i*-th gradient. Consequently, we can use the upper bound on σ_*^2 and Eq. (2) to compute optimal ϵ and δ .

From Theorem 1, we can determine that each step of parameter update for QML is (ϵ, δ) -DP. Using the composition theorem of DP, we can compute the final ϵ and δ like [6] and the value of the gradient clipping parameter C can take the maximum value of the l_2 norm of gradients by multiple pre-training.

Fig. 1. Quantum circuit for 2D classification of Iris dataset.

IV. EVALUATION

We conduct simulation experiments in this section to illustrate the impact of inherent noise on the privacy budget of QML across different error rates and shots. We utilize Iris dataset to generate the binary classification dataset. We choose the Petal Length and Petal Width features of the Iris Setosa and Iris Versicolour categories with corresponding labels of -1 and 1. The QNN is constructed and trained utilizing opensource software packages Qiskit and we implement PEC by *Mitiq.* The structure of the ONN we use is shown in Fig. 1. For better numerical stability and convergence, we squeeze all features onto the interval [0, 1]. The observable we use is the tensor product of pauli matrix $I \otimes Z$. What's more, we use a modified hinge loss function and the proportion of training and testing is 80% and 20%. Optimization is performed using the gradient descent method with a learning rate set to 0.01. In the simulation experiments, if not specified, we assumed an error probability of 5% for single qubit gates, 10% for two qubit controlled gates.

A. Impact of Incoherent Noise on QML

In this section we investigate how incoherent noise affects QML's test accuracy. As shown in Fig. 2, when there is unprocessed incoherent noise, QML's performance can be severely impacted, which is manifested in two-fold: (1) incoherent noise affects the speed of the model convergence, and (2) incoherent noise may cause the model fail to converge. Incoherent noise can lead to errors in the quantum computation, especially deep quantum circuits, which can propagate through the quantum circuit, affecting subsequent operations and measurements. This propagation can be particularly detrimental in complex quantum algorithms used in machine learning tasks. Therefore it is necessary to deal with incoherent noise in QML scenarios.

B. Variance of the Gaussian Distribution Gradient

According to Theorem 1, we conduct experiment to elucidate how much variance can bring to the QNN's parameter gradients in this section. First, we fix the incoherent noise to calculate the lower bound on the standard deviation that different shots can bring to the gradient. As shown in Fig. 3(a), the standard deviation of the gradient decreases as quantum circuits are executed more number of times, which is determined by Eq. (16) in Lemma 1. Next, when the quantum circuits are executed the same number of times, we consider the effect of the global depolarizing noise probability on the standard deviation's lower bound. As shown in Fig. 3(b),

Fig. 2. Comparison of test accuracy with and without the use of PEC.

when the noise probability increases, the lower bound on the standard deviation also increases, and therefore the gradient carries more noise and achieves better privacy preservation, which will be analyzed quantitatively in Section IV-C.

Fig. 3. (a) The impact of shots on the standard deviation's lower bound. (b) The impact of global depolarizing noise probability on the standard deviation's lower bound.

C. Privacy Preserving QML

In this section, We analyze how much privacy budget ϵ can be achieved to a QML model by different shots and global depolarizing noise. In this experiments the default value of the privacy violation probability δ is set to 0.01 and the default value of the gradient clipping parameter C is 0.7 based on experiments. We first analyze the relationship between shots and the privacy budget ϵ . As shown in Fig. 4(a), with iteration determined, the privacy budget ϵ increases when shots increase, this is because larger shots lead to a decrease of the gradients' standard deviation, and therefore an increase

Fig. 4. (a) The value of ϵ in different shots and iterations. (b) The value of ϵ in different global depolarizing error rates and iterations.

in privacy budget. Next, we analyze the effect of the global depolarizing noise probability p_t on the privacy budget ϵ under fixed 10 shots, which is shown in Fig. 4(b). As the probability of noise increases, the privacy budget ϵ decreases. This is because larger noise probability leads to an increase in the lower bound on the standard deviation, which can better protect the model privacy.

V. CONCLUTION AND FUTURE WORK

In this paper, we first introduce DP and the DP-SGD algorithm for preserving privacy and show that shot noise and incoherent noise can potentially achieve DP in QML. Next, we show that the output of a quantum circuit follows a Gaussian distribution under the influence of shot noise, incoherent noise, and the PEC method. What's more, we give an analytic expression for the variance of the Gaussian distribution. Finally, we prove that the gradients of the quantum circuit parameters also follow a Gaussian distribution when using a modified hinge loss function for a binary classification task, which can protect QML models' privacy.

However, we only considered PEC as a QEM method. In future work, we propose to study the achievable DP budget under different QEM methods. Moreover, we only studied QML under modified hinge loss function for the binary classification task. We will investigate how to generalize it to QML under arbitrary loss functions for multi-classification tasks. Furthermore, we used a lower bound on the variance in the privacy budget calculation, but the actual variance may depend on the specific task and quantum circuits. Given the QML task, it is worth studying how to precisely calculate the privacy budget and provide a tighter privacy bound.
