# NeRF-VO: Real-Time Sparse Visual Odometry with Neural Radiance Fields

Jens Naumann<sup>1</sup>, Binbin Xu<sup>2</sup>, Stefan Leutenegger<sup>1</sup>, and Xingxing Zuo<sup>1,3,\*</sup> https://xingxingzuo.github.io/nerfvo

Fig. 1: **3D** reconstruction and camera tracking results on Replica [1], [2]. Meshes rendered from optimized neural radiance fields. Scenes from left to right: room0-2, and office0-4. Quantitative evaluations of pose estimation and 3D reconstruction are reported in cm (ATE RMSE) and % (F1 score [<5cm]). NeRF-VO achieves an average ATE of 0.43 cm and F1 of 88.0 using solely RGB images as input.

Abstract-We introduce a novel monocular visual odometry (VO) system, NeRF-VO, that integrates learning-based sparse visual odometry for low-latency camera tracking and a neural radiance scene representation for fine-detailed dense reconstruction and novel view synthesis. Our system initializes camera poses using sparse visual odometry and obtains view-dependent dense geometry priors from a monocular prediction network. We harmonize the scale of poses and dense geometry, treating them as supervisory cues to train a neural implicit scene representation. NeRF-VO demonstrates exceptional performance in both photometric and geometric fidelity of the scene representation by jointly optimizing a sliding window of keyframed poses and the underlying dense geometry, which is accomplished through training the radiance field with volume rendering. We surpass SOTA methods in pose estimation accuracy, novel view synthesis fidelity, and dense reconstruction quality across a variety of synthetic and real-world datasets while achieving a higher camera tracking frequency and consuming less GPU memory.

## Index Terms—NeRF, Visual Odometry, SLAM, Dense Mapping

## I. INTRODUCTION

CCURATE pose estimation and 3D reconstruction of the environment using images are fundamental challenges in 3D computer vision and essential prerequisites for diverse applications in robotics. Neural Radiance Fields (NeRF) [3] have proven to be an excellent scene representation method for novel view synthesis tasks. The original NeRF employs large multi-layer perceptrons (MLP) to decode 3D coordinates and ray directions into volume density and color. However,

<sup>3</sup> Xingxing Zuo is also with California Institute of Technology, Pasadena, CA 91125, USA.

<sup>\*</sup> Corresponding author: Xingxing Zuo.

it fails to represent complex and large scenes, particularly those with fine detail. Both training and rendering NeRFs with deep MLPs are computationally intensive and time-consuming. Recent works [4], [5], [6] have sought to accelerate NeRFs by replacing deep MLPs with more efficient representations. For instance, Instant-NGP [6] achieves a substantial speedup by utilizing a hybrid representation that combines trainable multi-resolution hash encodings (MHE) with shared shallow MLPs. These accelerated neural implicit scene representations pave the way for real-time critical SLAM/VO.

1

NeRF-based scene representations enable high-fidelity photometric and geometric reconstructions while being very memory efficient. They enable comprehensive exploitation of information from raw images, leveraging every pixel in the optimization process. This has the potential to push the performance frontier beyond traditional direct [7], [8], [9] and indirect SLAM [10], [11], [12]. Lately, numerous works have aimed at integrating SLAM with neural implicit mapping [2], [13], [14], [15], [16], [17]. Yet, only a few focus on monocular RGB input [18], [19], [20], [21], [22], [23]. In terms of accuracy, RGB-only methods lag behind their RGB-D counterparts, especially in dense reconstruction. Further, most of these approaches are computationally expensive, lack realtime capability, and require significant GPU memory.

To address these issues, we propose a real-time capable sparse visual odometry with neural implicit dense mapping. A preview of its performance is provided in Fig. 1. We obtain the initial pose estimation and sparse 3D landmarks using low-latency learning-based sparse visual odometry. Up-toscale dense geometric cues, including monocular dense depth and normals, are inferred using a transformer-based neural network. With the initial poses, camera-captured monocular images, and dense geometric priors, we can efficiently optimize a neural radiance field that implicitly represents the 3D scene. Accurate poses and dense geometry of the scene

Fig. 2: **System architecture of NeRF-VO.** The method uses only a sequence of RGB images as input. The sparse visual tracking module selects keyframes from this input stream and calculates camera poses and depth values for a set of sparse patches. Additionally, the dense geometry enhancement module predicts dense depth maps and surface normals and aligns them with the sparse depth from the tracking module. The NeRF-based dense mapping module utilizes raw RGB images, inferred depth maps, surface normals, and camera poses to optimize a neural implicit representation and refine the camera poses. Our system is capable of performing high-quality 3D dense reconstruction and rendering images at novel views.

are recovered by minimizing the disparity of captured images and predicted dense geometric cues relative to the renderings generated from the neural radiance field. Hence, our proposed method comprises three main components: a sparse visual tracking front-end, a dense geometry enhancement module, and a NeRF-based dense mapping back-end. The system architecture is depicted in Fig. 2.

Overall, we introduce NeRF-VO, a neural SLAM system that employs sparse visual odometry for efficient pose estimation, and a NeRF scene representation for highly accurate dense mapping. It showcases superior geometric and photometric reconstruction in comparison to SOTA methods while maintaining the lowest tracking latency and GPU memory consumption among competing works. The main contributions of our work can be summarized as follows:

- We propose NeRF-VO, a monocular RGB SLAM system that utilizes sparse visual odometry for pose tracking and an implicit neural representation for mapping. This enables highly accurate camera tracking, promising 3D reconstruction, and high-fidelity novel view synthesis.
- We present a novel paradigm for optimizing a NeRF scene representation and camera poses by incorporating dense depth and surface normal supervision. Utilizing a monocular transformer-based network, we predict dense depth and surface normal priors. To align their scale with the sparse visual odometry, we propose a dedicated sparse-to-dense scale alignment procedure.
- NeRF-VO demonstrates SOTA performance in camera tracking, 3D dense reconstruction, and novel view synthesis across various synthetic and real-world datasets.

#### II. RELATED WORK

For brevity, this section covers only the related work most relevant to our approach. Please refer to the survey by Tosi et al. [24] for a more detailed overview of recent advances in NeRF- and GS (Gaussian Splatting)-based SLAM.

Learning-Based Visual Tracking. Our work centers on monocular visual odometry using RGB image sequences from a calibrated camera. This technique estimates the camera positions and orientations of each incoming frame. Unlike SLAM, visual odometry focuses on local coherence among consecutive frames and does not include SLAM's loop closure optimization or global bundle adjustment. Recently, VO methods have advanced from traditional handcrafted feature detection and matching to deep learning-based approaches, enhancing accuracy and robustness [25], [26], [27], [28], [29]. Among all of them, DROID-SLAM [28] and DPVO [29] are two noteworthy works that leverage neural networks to predict the optical flow between consecutive images and iteratively update camera poses. DPVO [29] serves as the foundation for our system's front-end since it is highly efficient and accurate.

**Dense Visual SLAM.** Dense visual SLAM aims to construct a dense 3D representation of the environment instead of sparse 3D landmarks. Following the first real-time dense visual work DTAM [30], many approaches have been proposed, primarily those exploiting monocular depth prediction [31], [32], [33]. The scene representations selected in these works have also progressed from volumetric representations [30] to low-dimension latent representations [34], [31], [35] and the integration of pre-trained depth estimators [25], [36], [37]. In this work, we choose a volumetric NeRF as the representation due to its superior photometric and geometric accuracy.

**NeRF-Enabled SLAM.** Recently, many works have been proposed to integrate NeRF-based [3] scene representations into SLAM. In general, existing methods can be differentiated into *one-stage* and *two-stage* approaches. *Two-stage* approaches use an existing SLAM algorithm as a tracking module to estimate depth and camera poses, and then use these estimates as supervisory signals to optimize an implicit neural representation as part of a mapping module. Early approaches such as Orbeez-SLAM [21] and NeRF-SLAM [18] demonstrated the effectiveness of this combination. Recent advances

in this direction have further introduced view-centric implicit functions [38], global loop closure [22], [23], and monocular depth priors [23] to improve pose estimation accuracy and dense mapping quality. In contrast, one-stage approaches use a single implicit neural function for both tracking and mapping. iMAP [2] and NICE-SLAM [13] set the groundwork for this direction using RGB-D data. Subsequent works aimed at enhancing the scene representation [14], [15], [16], introducing implicit semantic encoding [17], and integrating inertial measurements [39]. Among these, NICER-SLAM [19] and DIM-SLAM [20] perform dense SLAM only using monocular images. NICER-SLAM prioritizes scene reconstruction and novel view synthesis through heavy optimization with various losses, while DIM-SLAM focuses on accurate camera tracking, but shows suboptimal performance in dense reconstruction. However, both methods are not suitable for real-time applications.

**GS-Based SLAM.** Recently, 3D Gaussian Splatting (3DGS), introduced by Kerbl et al. [40], has attracted attention for its superior ability to model novel view synthesis using differentiable 3D Gaussian-shaped primitives. Recently, this novel paradigm has inspired a variety of SLAM approaches: Analogous to the NeRF-based *one-stage* approaches, Gaussian Splatting SLAM [41], GS-SLAM [42], and SplaTAM [43] all track the camera using a dense photometric error, while Photo-SLAM [44] uses ORB-SLAM3 [11] for tracking, similar to the NeRF-based *two-stage* approaches. However, 3DGS does not explicitly model geometry, which hinders its use in robotic tasks that require geometric space awareness.

**Our work** follows a *two-stage* design. We use a sparse visual tracking method, DPVO [29] to get initial poses at high frequency and obtain dense depth and surface normals priors from a monocular prediction network. These initial poses and dense geometry cues are used to train our mapping back-end employing a nerfacto-based neural radiance field [45]. Our system yields high-frequency pose estimations and promising dense reconstruction after neural scene optimization, all achieved at a low memory footprint.

#### **III. SPARSE VISUAL POSE TRACKING**

We employ the Deep Patch Visual Odometry (DPVO) [29] algorithm as our tracking front-end. DPVO is a sparse, monocular, learning-based algorithm that estimates camera poses and sparse depths for a set of patches per keyframe.

**Patch Graph.** Given a sequence of RGB frames, DPVO randomly samples a set of *K* square patches of size  $s \times s$  pixels per keyframe and adds them to a bipartite patch graph that connects patches and frames. For instance, the *k*-th square patch from frame *i* represented by  $\mathbf{P}_k^i = [\mathbf{u}^T \quad \mathbf{v}^T \quad \mathbf{1}^T \quad \mathbf{d}^T]^T$  is connected via edges to all frames within temporal vicinity of frame *i*.  $\mathbf{u}, \mathbf{v}$  represent the pixel coordinates and  $\mathbf{d}$  the inverse depths with  $\mathbf{u}, \mathbf{v}, \mathbf{d} \in \mathbb{R}^{1 \times s^2}$ . **1** is a vector filled with ones. The patch graph builds a trajectory for each patch, incorporating all of its reprojections  $\mathbf{r}_k^{ij}$ , where  $j \in \mathcal{N}$ , and  $\mathcal{N}$  is the array of frames temporally adjacent to *i*. Assuming uniform depth across each patch, the reprojection is defined by:

$$\mathbf{r}_{k}^{ij} \sim \mathbf{K} \mathbf{T}_{j} \mathbf{T}_{i}^{-1} \mathbf{K}^{-1} \mathbf{P}_{k}^{i}, \qquad (1)$$

where **K** is the 4×4 camera calibration matrix, and  $\mathbf{T}_i \in \mathbb{SE}(3)$  represents the world-to-camera transformation of frame *i*. For simplicity, we omit the normalization operation of the third dimension in the above equation.

**Differentiable Bundle Adjustment.** The key component of DPVO is its differentiable pose and depth update operator. A recurrent neural network operates on the patch graph with a set of edges  $\mathscr{E}$ , while maintaining a hidden state for each edge  $(k, i, j) \in \mathscr{E}$  (patch-frame pair), and predicting a 2D correction vector  $\boldsymbol{\delta}_{k}^{ij} \in \mathbb{R}^{2}$  for the reprojection of the patch center  $\mathbf{\bar{r}}_{k}^{ij}$  with a corresponding confidence weight  $\boldsymbol{\psi}_{k}^{ij} \in \mathbb{R}^{2}$ . Bundle adjustment is performed using the optical flow correction as a constraint to iteratively update frame poses and patch depths via nonlinear least-squares optimization. The cost function for bundle adjustment is:

$$\sum_{(k,i,j)\in\mathscr{E}} \left\| \mathbf{K}\mathbf{T}_{j}\mathbf{T}_{i}^{-1}\mathbf{K}^{-1}\bar{\mathbf{P}}_{k}^{i} - \left[\bar{\mathbf{r}}_{k}^{ij} + \boldsymbol{\delta}_{k}^{ij}\right] \right\|_{\boldsymbol{\psi}_{k}^{ij}}^{2},$$
(2)

where  $\|\cdot\|_{\psi}$  denotes the Mahalanobis distance. The bundle adjustment step of DPVO is differentiable, the recurrent neural network is trained on a set of ground truth poses, together with the corresponding ground truth optical flow to supervise pose estimation and optical flow correction.

**Keyframing Strategy.** DPVO optimizes the keyframes' patch depths and camera poses in a sliding optimization window, adding each incoming frame. This sliding window keeps a constant array of the most recent keyframes and removes old ones to maintain bounded computational complexity ensuring runtime efficiency. The three most recent frames are always considered to be keyframes, but the fourth most recent keyframe is only kept if the optical flow to its predecessor is sufficiently high, otherwise, it is removed. We use this keyframe selection for our downstream geometry enhancement and mapping modules. To stabilize NeRF optimization, the last three keyframes are not propagated yet, as they are likely to be removed later by the keyframing scheme described above. Each time the fourth most recent keyframe is secured, it is passed to our dense geometry enhancement module and NeRF optimization, including all camera poses and patches in the current sliding window. Since only certain keyframes are involved in our dense geometry enhancement and NeRF optimization, the computational and memory footprint of NeRF-VO are bounded.

#### IV. NEURAL IMPLICIT DENSE MAPPING

As indicated in the system overview in Fig. 2, the keyframes from the visual tracking front-end are subsequently processed by our dense geometry enhancement and incorporated into our NeRF optimization back-end.

#### A. Dense Geometry Enhancement

Since the sparse patch depths  $D_s$  from the visual tracking module cover only a tiny portion of the image, we incorporate a dense geometry enhancement module that predicts a dense depth map  $D_d$  based solely on the monocular RGB input. We then align this dense depth prediction to the sparse patch depths using a dedicated scale alignment procedure. Monocular depth prediction is performed using the off-theshelf network [46] based on the Dense Prediction Transformer (DPT) architecture [47], [48].

Scale Alignment. Since both sparse and dense depths are predicted solely based on RGB input, their depth distributions are skewed relative to the metric depth and each other. However, downstream dense mapping necessitates depth maps and camera poses at a unified scale. Therefore, we introduce a dense-to-sparse scale alignment procedure to align the predicted dense depth map of each keyframe to the sparse patch depth. Assuming that the sparse depth  $\mathbf{D}_s$  and the dense depth  $\mathbf{D}_d$  follow a Gaussian distribution with  $\mathbf{D}_s \sim \mathcal{N}(\mu_s, \sigma_s^2)$  and  $\mathbf{D}_d \sim \mathcal{N}(\mu_d, \sigma_d^2)$ , we compute the aligned dense depth by:

$$\mathbf{D}_d' = \alpha \mathbf{D}_d + \beta \mathbf{1},\tag{3}$$

where  $\alpha$  and  $\beta$  are a scale and shift value defined as:

$$\alpha = \frac{\sigma_s}{\hat{\sigma}_d}, \ \beta = \mu_d \left( \frac{\mu_s}{\hat{\mu}_d} - \alpha \right), \tag{4}$$

where  $\hat{\mu}_d$  and  $\hat{\sigma}_d$  are the mean and standard deviation of the sparsified dense depth map  $\hat{\mathbf{D}}_d$  extracted from  $\mathbf{D}_d$  at the pixel coordinates of  $\mathbf{D}_s$ . Since the patches are sampled randomly, given a sufficiently large sample size per frame, one could assume that  $\mu_d \approx \hat{\mu}_d$ . This would lead to a relaxed formulation of  $\beta$  with  $\beta = \mu_s - \alpha \hat{\mu}_d$ . We have empirically evaluated this relaxed alignment scheme along with several other alignment strategies and found that the standard formulation in Eq. 4 performs best (see Sec. V-H).

**Surface Normal Cues.** To improve the accuracy of the neural implicit representation for fine-grained dense mapping, we introduce surface normal constraints by matching against surface normals predicted from the RGB input using the same off-the-shelf monocular predictor from [46].

## B. Mapping with Neural Scene Representation

**Neural Radiance Field.** Our dense mapping back-end reconstructs the scene by optimizing a neural radiance field built on the nerfacto model [45]. The neural scene representation comprises multi-resolution hash encodings similar to [6], spherical harmonics encoding, and two multi-layer perceptrons (MLPs) for density and color recovery. The NeRF scene representation is optimized using the camera poses, captured RGB images as well as inferred depth maps and surface normals of all keyframes.

We generate ray bundles  $\mathscr{R}$  inside the camera frustums of the keyframes and sample 3D coordinates along these rays  $t \in \mathscr{R}$  by using a proposal sampler, which is optimized jointly with the rest of the architecture. Each sampled 3D coordinate is mapped to a set of learnable embeddings in the multi-resolution hashmap. These embeddings are processed by the first MLP to predict the volume density. The resulting density is fed into the second MLP together with the spherical harmonic encoded view direction and appearance embeddings to compute the color. The surface normals per sample are obtained by computing the gradient over the first MLP with respect to the hashed 3D coordinate. Finally, the color, depth, and surface normal for the entire ray are obtained using volumetric rendering similar to [3].

**Joint Optimization of Poses and Neural Scene.** Since the keyframe camera poses  $T_C$  are involved in ray sampling, they can be optimized jointly with the NeRF scene representation. Hence, we optimize the learnable parameters  $\Theta$  of the scene representation and the MLPs jointly with the camera poses  $T_C$  using a weighted sum of four losses.

Our color loss is defined as the mean squared error between the rendered color image and the ground truth RGB input, analogous to [3]:

$$L_{\text{rgb}}(\mathbf{T}_{C},\boldsymbol{\Theta}) = \sum_{(u,v)\in\mathscr{B}} \left\| \mathbf{C}[u,v] - \check{\mathbf{C}}[u,v](\mathbf{T}_{C},\boldsymbol{\Theta}) \right\|_{2}^{2}, \quad (5)$$

where  $\check{\mathbf{C}}[u,v]$  and  $\mathbf{C}[u,v]$  are the rendered and ground truth color, and (u,v) are the pixel coordinates of the ray bundle.

To counter noise and bias in our depth estimation and alignment procedures, we employ the uncertainty-aware depth loss [49], which aims to minimize the Kullback-Leibler divergence between the assumed Gaussian distributed depth values of all samples along each ray and our aligned dense depth map  $\mathbf{D}'_d$ :

$$L_{d}\left(\mathbf{T}_{C},\boldsymbol{\Theta}\right) = \sum_{(u,v)\in\mathscr{B}} \sum_{t\in\mathscr{R}[u,v]} \log\left(\mathscr{T}_{t}\left(\mathbf{T}_{C},\boldsymbol{\Theta}\right)\right) \cdot \exp\left(-\frac{\left(d_{t}-\mathbf{D}_{d}'\left[u,v\right]\right)^{2}}{2\hat{\sigma}^{2}}\right) \Delta d_{t}, \quad (6)$$

where  $t \in \mathscr{R}[u, v]$  is the *t*-th sample along the ray  $\mathscr{R}[u, v]$ ,  $d_t$  is the distance of the sample *t* from the camera center along ray  $\mathscr{R}[u, v]$ ,  $\Delta d_t$  is the distance between the sampling distances  $d_{t+1}$  and  $d_t$  with  $\Delta d_t = d_{t+1} - d_t$ ,  $\hat{\sigma}$  is the estimated variance of the depth  $\mathbf{D}'_d[u, v]$  (we use 0.001 empirically) and  $\mathscr{T}_t(\mathbf{T}_C, \Theta)$  is the accumulated transmittance along the ray  $\mathscr{R}[u, v]$  up to sample *t* computed by:

$$\mathscr{T}_{t}(\mathbf{T}_{C},\boldsymbol{\Theta}) = \exp\left(-\sum_{s < t} \boldsymbol{\rho}_{s}(\mathbf{T}_{C},\boldsymbol{\Theta}) \Delta d_{s}\right), \tag{7}$$

where  $\rho_s(\cdot)$  is the estimated density at the sample *s*.

The normal supervision is guided by the normal consistency loss proposed in [50], which integrates the L1 distance and cosine distance between the rendered surface normals  $\check{\mathbf{N}}[u,v] \in \mathbb{R}^3$  and the normals predicted from the monocular prediction network  $\mathbf{N}[u,v]$  at pixel (u,v):

$$L_{n}(\mathbf{T}_{C},\boldsymbol{\Theta}) = \sum_{(u,v)\in\mathscr{B}} \left\| \mathbf{N}[u,v] - \check{\mathbf{N}}[u,v](\mathbf{T}_{C},\boldsymbol{\Theta}) \right\|_{1} + \left\| 1 - \mathbf{N}[u,v]^{\top} \check{\mathbf{N}}[u,v](\mathbf{T}_{C},\boldsymbol{\Theta}) \right\|_{1}, \quad (8)$$

where  $\mathbf{N}[u,v]^{\top} \mathbf{\breve{N}}[u,v]$  indicates the cosine similarity.

Finally, we use two regularization terms for the volume density. The distortion and proposal losses introduced by [51] serve to prevent floaters and background collapse and guide the optimization of the proposal sampler:

$$L_{\rm reg} = L_{\rm prop} + 0.002 L_{\rm dist},\tag{9}$$

Overall, the complete loss for our NeRF optimization is:

$$L = L_{\rm rgb} + 0.001L_d + 0.00001L_n + L_{\rm reg}$$
(10)

# C. System Design

The sparse tracking, dense geometry enhancement, and dense mapping modules run asynchronously on separate threads. Information is propagated in a feed-forward fashion through the three components sequentially. Communication occurs each time a new keyframe is secured in the visual tracking module. It is then processed by the enhancement module and included in the training database of the mapping module. Separated from this process, the mapping module continuously optimizes the implicit representation jointly with the camera poses. With this multi-threaded architecture, our system can run in real-time, with the visual tracking running at low latency, while the enhancement and mapping run at a relatively low frequency, which does not block the data streaming in from the sensor. Due to its asynchronous architecture, our system has the potential to be run on multiple GPUs, leading to improved runtime efficiency.

#### V. EXPERIMENTS

We evaluate our method qualitatively and quantitatively against the state-of-the-art monocular SLAM methods using neural implicit representations on a variety of real and synthetic indoor datasets and present an extensive ablation study of the key design choices of our method.

## A. Evaluation Datasets

We evaluate our method on four datasets. Replica [1]: a synthetic dataset that contains high-quality reconstructions of indoor scenes, where we use the eight trajectories generated by [2]. ScanNet [52]: a real-world dataset where the RGB-D sequence is captured using an RGB-D sensor attached to a handheld device and the ground truth trajectory is computed using BundleFusion [53]. 7-Scenes [54]: a real-world dataset that provides a trajectory of RGB-D frames captured by Kinect sensors where the ground truth trajectories and dense 3D models are computed using KinectFusion [55]. We also evaluate our method on a self-captured dataset consisting of a set of four RGB-D trajectories captured with the RealSense sensor in a meeting room. The ground-truth trajectories are computed using the visual-inertial SLAM system OKVIS2 [56] based on synchronized stereo images and IMU data, while the 3D model is obtained using TSDF-Fusion [55] on the captured depth maps.

# B. Baselines

We compare our method against the SOTA SLAM method NeRF-SLAM [18], which also uses neural implicit representations for mapping. Additionally, where applicable, we report results from the contemporary methods DIM-SLAM [20], NICER-SLAM [19], Orbeez-SLAM [21], GO-SLAM [22] and HI-SLAM [23]. To evaluate the benefits of our back-end, we compare the camera tracking accuracy against DPVO [29] as well as the visual odometry version of DROID-SLAM [28] (DROID-VO), which is used as the tracking module in NeRF-SLAM.

TABLE I: Camera tracking performance (ATE RMSE [cm]) on the Replica [1] dataset.

Model	rm-0	rm-1	rm-2	of-0	of-1	of-2	of-3	of-4   Avg.
DIM-SLAM [20] NICER-SLAM [19]								
DROID-VO [28] NeRF-SLAM [18] DPVO [29] <b>Ours</b>	0.50 0.40 0.49 <b>0.28</b>	0.70 0.61 0.54 <b>0.33</b>	<b>0.20</b> 0.54	<b>0.21</b> 0.77	0.45 0.36	0.59 0.57	<b>0.33</b> 0.46	1.530.701.300.510.570.540.47 <b>0.43</b>

## C. Metrics

We evaluate our method on three tasks: camera tracking, novel view synthesis, and 3D dense reconstruction. For camera tracking, we align the estimated trajectory to the ground truth using the Kabsch-Umeyama [57], [58] algorithm and evaluate the accuracy using the absolute trajectory error (ATE RMSE) [59]. For novel view synthesis, we assess the quality of the rendered RGB images using peak signal-to-noise ratio (PSNR), structural similarity (SSIM) [60], and learned perceptual image patch similarity (LPIPS) [61]. To compute these metrics, we select 125 equally spaced RGB frames along the trajectory. To render the exact view of these evaluation frames, we transform the ground truth camera poses to the coordinate system of the implicit function. For 3D reconstruction, we consider accuracy, completion, and recall. We render the predicted mesh from our neural implicit representation. Analogous to [18], [20], [19], [22], [23] we exclude regions not observed by any camera from the evaluation. We align both meshes using the Iterative Closest Point (ICP) algorithm. To ensure statistical validity, we report the average of 5 independent runs.

#### D. Camera Tracking

Table I reports the camera tracking results on the Replica dataset [1], [2], showing that our model achieves the lowest average ATE RMSE over all scenes. The results of DIM-SLAM [20] and NICER-SLAM [19] are taken from their original papers. While DIM-SLAM [20] and NeRF-SLAM [18] perform better on some scenes, their performance deteriorates on others, whereas our method remains relatively stable across all scenes. Table II reports the tracking accuracy on six commonly tested scenes from ScanNet [52]. Our method outperforms concurrent visual odometry methods whose tracking module only applies implicit "local loop closure" (L-LC) imposed by the scene representations (maps), such as HI-SLAM (VO), NICER-SLAM, DROID-VO, NeRF-SLAM, and DPVO. In general, we can conclude that the full SLAM methods incorporating global loop closure (G-LC) and scenewide global bundle adjustment perform better on these large scenes. Finally, Table III shows the performance of our method and NeRF-SLAM [18] as well as their respective tracking modules on our custom dataset, demonstrating the superior camera tracking performance of our model.

## E. 3D Reconstruction

Table IV demonstrates the superior 3D reconstruction performance of our model over all compared concurrent works on the Replica [1] dataset. Our method outperforms SOTA

TABLE II: Camera tracking performance (ATE RMSE [cm]) on ScanNet [52]. The methods are categorized according to whether they perform global (G) or only local (L) loop closure (LC) optimization.

	Model	0000	0059	0106	0169	0181	0207	Avg.
G-LC	Orbeez-SLAM [21]	7.2	<b>7.2</b>	8.1	<b>6.6</b>	15.8	<b>7.2</b>	8.7
	GO-SLAM [22]	5.9	8.3	8.1	8.4	8.3	n/a	n/a
	HI-SLAM [23]	6.4	<b>7.2</b>	<b>6.5</b>	8.5	<b>7.6</b>	8.4	<b>7.4</b>
	HI-SLAM (VO) [23]	14.4	26.7	10.0	15.5	9.3	9.9	14.3
L-LC	NICER-SLAM [19]	96.0	63.2	117.1	77.9	68.0	70.8	82.2
	DROID-VO [28]	14.4	<b>16.4</b>	10.9	16.3	10.8	13.6	13.7
	NeRF-SLAM [18]	14.9	16.6	10.7	16.5	12.8	13.8	14.2
	DPVO [29]	13.1	19.2	12.4	13.3	<b>8.8</b>	8.9	12.6
	Ours	<b>12.7</b>	19.0	12.4	<b>13.2</b>	9.0	<b>8.6</b>	<b>12.5</b>

TABLE III: Camera tracking performance (ATE RMSE [cm]) on our custom dataset.

Model	seq-1	seq-2	seq-3	seq-4	Avg.
DROID-VO [28]	2.58	1.37	1.81	3.05	2.20
NeRF-SLAM [18]	2.32	1.19	1.31	5.26	2.52
DPVO [29]	2.96	1.38	1.57	3.14	2.26
Ours	2.08	1.07	1.43	2.68	1.81

in accuracy, completion, and recall on four scenes and on average. The inferior performance on the office0 and office1 scenes is the result of scene-specific characteristics that complicate monocular depth predictions: these scenes have detail-rich wall paintings that lead to artifacts in monocular depth estimation. We notice that this is also the case for NICER-SLAM [19], which similarly relies on a monocular depth prediction network. A qualitative comparison of the 3D reconstruction is provided in Fig. 3. Table V reports the averaged 3D reconstruction performance of our method and NeRF-SLAM [18] on three real-world datasets: 7-Scenes [54], ScanNet [52], and our custom dataset. The results show that our model outperforms NeRF-SLAM on average on all datasets. Unfortunately, none of the concurrent papers report 3D reconstruction performance on any dataset other than the synthetic Replica [1], thus we are unable to benchmark our model against other methods besides NeRF-SLAM.

## F. Novel View Synthesis

We evaluated our model for novel view synthesis on Replica [1]. The results can be found in Table VI. They

TABLE IV: 3D reconstruction results on Replica [1].

	Rec. [<5cm %] ↑	34.0	22.5	65.0

indicate mixed performance on the different metrics. While NICER-SLAM performs best on SSIM, NeRF-SLAM and our method are almost on par. NeRF-SLAM performs best in PSNR, yet our approach is almost equal in most scenes. Considering the LPIPS metric, our model shows a significantly superior performance on all scenes, indicating a high subjective similarity for a human observer, underlining the photometric strength of our approach.

TABLE VI: Novel view synthesis results on Replica [1], [2].

TABLE VII: Runtime and max. GPU memory utilization on Replica [1]. Information on other methods is taken from the respective original papers. " $\leq$ " and " $\simeq$ " indicate missing details on maximum GPU memory usage. In such cases, we have reported the memory capacity of the device used.

Model	Tracking [fps] $\uparrow$	Mapping [fps] $\uparrow$	GPU Memory [gb] $\downarrow$
GO-SLAM [22]	8	8	18
DIM-SLAM [20]	14	3	$\simeq 11$
NICER-SLAM [19]	7	2	$\leq 40$
NeRF-SLAM [18]	15	10	$\simeq 11$
Ours	20	6	9

## G. Runtime Analysis

We have conducted a runtime and memory utilization analysis of our method. A comparison with concurrent work is presented in Table VII. The results indicate that our model achieves the highest tracking FPS while leaving the smallest GPU memory footprint. This is primarily due to our runtimeand memory-efficient sparse visual tracking module, and dense geometry enhancement paradigm. In terms of mapping runtime, our method is in the midfield of all competing works. However, it must be emphasized that the two faster methods GO-SLAM [22] and NeRF-SLAM [18] rely on the highly optimized NeRF implementation by Müller et al. [6] using custom CUDA kernels, while our work, DIM-SLAM [20] and NICER-SLAM [19] use various unoptimized Python implementations, with our model achieving twice the FPS compared to these Python-based alternatives.

## H. Ablations

**Dense Depths.** We performed an ablation to validate that using aligned dense depths from a monocular estimator does indeed improve performance over directly using the sparse depth patches from our tracking module. The results can be found in Table VIII. The substantial performance improvement from using dense depths indicates that optimizing a NeRF with only a few pixel depths per frame is not sufficient to achieve SOTA results.

**Surface Normals.** To evaluate the benefit of supervising NeRF optimization with surface normal priors, we performed an ablation by comparing our system to a baseline with

TABLE VIII: Ablation study on using dense depth, and surface normal priors for NeRF optimization. Results on the Replica [1], [2] dataset.

	ATE [cm] $\downarrow$	Acc. [cm] $\downarrow$	Com. [cm] $\downarrow$	Rec. [<5cm %] ↑
Ours	0.43	<b>2.81</b>	<b>3.59</b>	<b>86.3</b>
W/O dense depth	0.48	8.16	6.49	72.5
W/O normals	0.45	3.22	3.79	83.7

TABLE IX: Impact of various scale alignment strategies on camera tracking and 3D reconstruction on the Replica [1], [2] dataset.

	ATE [cm] $\downarrow$	Acc. [cm] $\downarrow$	Com. [cm] $\downarrow$	Rec. [<5cm %] $\uparrow$
none	0.69	9.13	7.06	66.0
min-max	0.43	8.72	9.59	65.1
least-squares [62]	0.45	3.86	4.41	77.3
ours (relaxed)	0.45	3.57	4.04	82.9
ours	0.43	2.81	3.59	86.3

the normal consistency loss weight set to zero. The results in Table VIII demonstrate an increase in 3D reconstruction performance by using normal supervision. However, enabling normal supervision slightly increases the runtime, hence one might choose to trade the accuracy gain of normal supervision for a faster runtime.

Scale Alignment. As discussed in Sec. IV, the sparse depths from our tracking module and the dense depths from the monocular estimator are skewed relative to each other, which requires an alignment strategy. In Table IX we compare five linear alignment schemes: No alignment of sparse and dense depths (none), alignment based on the minimum and maximum of each depth map (min-max), the least squares alignment method (ours) as well as its relaxed alternative (see Sec. IV). Our choice was confirmed as the probability-based alignment performs best.

## VI. CONCLUSION

We introduce NeRF-VO, a novel neural visual odometry system that combines a learning-based sparse visual odometry for pose tracking, a monocular prediction network for inferring dense geometry cues, and a neural radiance field optimization for pose and dense geometry refinement. NeRF-VO surpasses SOTA methods, demonstrating superior pose estimation accuracy and delivering high-quality dense mapping, all while maintaining low pose tracking latency and GPU memory consumption. As part of future research, it would be compelling to integrate visual or geometric constraints obtained from the neural scene representation into the pose tracking front-end. This integration has the potential to further reduce drift and improve the accuracy of initial pose tracking.
