(Dated: April 30, 2024)

 134 Xe is a candidate isotope for neutrinoless double beta decay $(0\nu\beta\beta)$ search. In addition, the two-neutrino case $(2\nu\beta\beta)$ allowed by the standard model of particle physics has not yet been observed. With the 656-kg natural xenon in the fiducial volume of the PandaX-4T detector, which contains 10.4% of 134 Xe, and its initial 94.9-day exposure, we have established the most stringent constraints on $2\nu\beta\beta$ and $0\nu\beta\beta$ of ¹³⁴Xe half-lives, with limits of 2.8×10^{22} yr and 3.0×10^{23} yr at 90% confidence level, respectively. The $2\nu\beta\beta$ ($0\nu\beta\beta$) limit surpasses the previously reported best result by a factor of 32 (2.7), highlighting the potential of large monolithic natural xenon detectors for double beta decay searches.

Neutrinoless double beta decay $(0\nu\beta\beta)$, if discovered, would be the unambiguous evidence of the Majorana nature of neutrino and the violation of lepton number conservation [1–3]. $0\nu\beta\beta$ could only happen in isotopes decaying via two-neutrino double beta decay $(2\nu\beta\beta)$, an exceptionally rare nuclear decay process emitting two electrons and two antineutrinos simultaneously [4, 5]. $2\nu\beta\beta$ has been directly observed in multiple isotopes, with the longest half-life at approximately 2×10^{21} yr for 136 Xe [6–9]. The $2\nu\beta\beta$ of 134 Xe, with an expected half-life of $\mathcal{O}(10^{24})$ yr [10, 11], is the next promising discovery. The most stringent experimental constraint on its half-life is 8.7×10^{20} yr at the 90% confidence level (CL) from the EXO-200 experiment [12], which used xenon with approximately 19% 134 Xe (a fiducial mass of 18.1 kg) and 81% 136 Xe.

Different from the $2\nu\beta\beta$, $0\nu\beta\beta$ has no neutrinos emitted. Many experiments have searched for the $0\nu\beta\beta$ processes employing various isotopes, including ⁷⁶Ge [13, 14], ¹³⁰Te [15], and ¹³⁶Xe [16, 17]. The best constraints on the half-lives of these isotopes are on the order of 10^{26} yr. EXO-200 has reported the most stringent constraint on the $0\nu\beta\beta$ half-life of ¹³⁴Xe, 1.1×10^{23} yr at the 90% CL [12]. If discoveries are made in a pair of isotopes of the same element, such as ¹³⁶Xe and ¹³⁴Xe, it is particularly intriguing to potentially mitigate theoretical uncertainties associated with alternative $0\nu\beta\beta$ mechanisms, such as heavy Majorana neutrino exchange or gluino exchange in supersymmetry models [18].

Previously, we have reported a precise measurement of the $2\nu\beta\beta$ half-life of ¹³⁶Xe [9]. In this Letter, we present new searches for ¹³⁴Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ using the PandaX-4T natural xenon Time Projection Chamber (TPC) [19] based on 94.9 live days of data from the initial data release. Compared to searches conducted in a ¹³⁶Xe-enriched detector, a natural xenon detector such as PandaX-4T offers the unique advantage of a high ¹³⁴Xe/¹³⁶Xe ratio of 1.2. The energy region of interest (ROI) from 200 to 1000 keV includes the majority of the $2\nu\beta\beta$ events and almost all of the $0\nu\beta\beta$ events. Compared to EXO-200, our extension of the energy range to 200 keV also results in a relatively lower contribution from ¹³⁶Xe $2\nu\beta\beta$ due to the different Q values.

The PandaX-4T experiment is in the B2 hall of the recently expanded China Jinping Underground Laboratory [20]. The detector has been commissioned since late 2020. The cylindrical active volume of the PandaX-4T dual-phase TPC, operating at -94.6 °C, is enclosed within a field cage to ensure a uniform electric field along the vertical z axis. The active volume has a diameter of 118.5 cm and a height of 116.8 cm. The height is calculated as the distance between the cathode and gate meshes, considering the 1.4% polytetrafluoroethylene shrinkage caused by temperature. As a result, the total mass of natural xenon in the active volume is 3.69 tonnes, slightly different from the previously reported value [9]. The TPC is equipped with 169 and 199 threeinch Hamamatsu photomultiplier tubes (PMTs) mounted at the top and the bottom readout arrays in horizontal xy direction, respectively. For more details about the

detector configuration, please refer to Refs. [9, 19].

PandaX-4T has developed a dedicated analysis pipeline for MeV-scale signals and performed calibration campaigns in the energy range, allowing for the study of double beta decays of 136 Xe [9]. Following a similar procedure, the search for the $2\nu\beta\beta$ and $0\nu\beta\beta$ of ¹³⁴Xe was performed with the same data set and fiducial volume (FV). Energy deposition in liquid xenon (LXe) produces prompt scintillation light S1 signals and ionization electrons. The ionization electrons drift toward the liquidgas interface in the applied electric drift field. The electric field in the gaseous region is more than 1 order of magnitude stronger at 5-6 kV/cm, resulting in the emission of S2 photons through electroluminescence. The distribution of S2 photons, collected by the top PMT array $(S2_T)$, is utilized to reconstruct the horizontal xyposition. The time delay between the S1 and S2 signals determines the vertical z position. Event energy is determined by combining the S1 and S2 detected by the bottom PMT array $(S2_B)$.

One improvement in this analysis is the usage of the "rolling gain" of PMTs, which is determined based on the single photoelectron peaks in physics data. PMT gains were calculated with weekly calibration using lightemitting diodes (LEDs) in previous analyses. The rollinggain method does not suffer from uneven illumination and has large samples of single photoelectron, which improves the accuracy of gain calibration. The gains of all PMTs calculated from the LEDs exhibit an average offset of +1.7% with a 4.5% variation compared to the rolling-gain results. The difference introduces a negligible difference in the final spectrum but may impact the energy and and position reconstruction of individual events. The event selection and spectrum fit procedures are developed with LED-gain data and then applied to the analysis of rolling-gain data. The stepwise approach minimizes possible bias in the analysis.

In this analysis, we also improve the photonacceptance-function-based position reconstruction algorithm, which characterizes the anticipated charge detected by a specific PMT as a function of the event's position [21]. The xy position of an event is determined by comparing the observed $S2_T$ charge distribution with photon acceptance functions derived from optical Monte Carlo (MC) simulation. Compared to the previous analysis [9], we use a more realistic model with multiple layers of image PMTs to simulate light reflection on side polytetrafluoroethylene panels. The $S2_T$ charge is calculated with the desaturation algorithm to mitigate PMT saturation of large signals. Both improvements lead to a more accurate position reconstruction in the xy plane. The boundary of the detector is reconstructed within 1.8 cm of the physical position, while an inward offset of 6.0 cm is observed in the previous analysis.

The detector is calibrated with gamma sources deployed outside the active volume (including 232 Th,

FIG. 1: Relative energy resolution σ/E as a function of energy. The black line represents a fit of the experimental data with the function $0.41/\sqrt{E \text{ [keV]}} + 2.6 \times 10^{-6} \text{E [keV]} + 0.008.$

⁶⁰Co, and ¹³⁷Cs) and internal sources (including ^{83m}Kr, ^{131m}Xe, ¹²⁷Xe, and ^{129m}Xe). Energy is calculated from the S1 signal and $S2_B$ signal:

$$E = 13.7 \text{ eV} \times \left(\frac{S1}{\text{PDE}} + \frac{S2_B}{\text{EEE} \times \text{SEG}_B}\right), \qquad (1)$$

in which PDE, EEE, and SEG_B are the photon detection efficiency for S1, electron extraction efficiency, and the single-electron gain for $S2_B$, respectively. The 13.7 eV is the work function in liquid xenon [22]. The $S2_B$ signal is desaturated following the previous analysis [9].

The nonuniformity of detector response is corrected in three dimensions. Along the z direction, electron lifetime correction is applied to $S2_B$ to correct electron loss along the drift path. The electron lifetime measured with the 164 keV energy peak from ^{131m}Xe spans from 800.4 to 1288.2 μ s, depending on the xenon purity [19]. The nonuniformity of detector response is mapped out by injecting 83m Kr [23] with the improved position reconstruction. Nonuniformity in the xyz (xy) space for $S1 (S2_B)$ is mapped out, and corresponding corrections are applied. Additional third-order polynomial-function corrections are applied to the energy spectrum based on observed gamma peaks to account for the residual nonlinearity after the position-dependent correction. The polynomial correction reduces deviations of gamma peak energies from about 40 keV to less than 10 keV, which is taken as the systematic uncertainty of energy reconstruction.

Figure. 1 shows the energy resolution of physics data in the FV and is fitted with the parametrization function $a/\sqrt{E} + bE + c$. The energy resolution reaches 2.4% for single-site (SS) events at 825.8 keV, the Q value of ¹³⁴Xe double beta decay. The signal response model is used to

FIG. 2: Event distributions of the physics data in the energy range of [200, 1000] keV in z vs. \mathbb{R}^2 coordinates, with the color bar indicating counts in each bin. The orange rectangle represents the cylindrical FV.

generate probability density functions (PDFs) of signals and backgrounds in the MC.

The FV, as shown in Fig. 2, is defined by a cylinder with a radius of 34.6 cm and a height of 61.2 cm at the geometrical center of the detector. The mass of natural xenon within the FV is 656 kg, calculated by scaling 83m Kr percentage and improved position reconstruction. Taking into account the isotopic abundance of 10.47%, the FV contains 68.7 kg of 134 Xe. The total isotopic exposure is 17.9 kg yr.

The criteria for selecting physical events are developed with calibration data, validated with 9.6 days of rollinggain data, and then applied to the entire physics dataset. Quality cut variables to remove noise and select electron recoil events are adopted from the previous analysis [9] but adjusted according to events extended down to 200 keV. The overall cut efficiency is $(99.94\pm0.03)\%$, and consistent results are calculated from calibration data and the 9.6-day dataset.

The discrimination between SS and multisite (MS) events is improved in this analysis. Most of the $2\nu\beta\beta$ and $0\nu\beta\beta$ signals are SS events, which can be discriminated from MS gamma background events using the temporal profile of the summed $S2_B$ signal. Energy depositions at different positions along the z axis correspond to different timings in the $S2_B$ signal. Because of electron diffusion during drifting, the $S2_B$ signal is broadened, and the z position information is smeared. Instead of a constant time window, $S2_B$ peaks separated by more than a dynamic time window ranging from ± 0.16 to $\pm 1.6 \ \mu$ s, are classified as MS events. The width of the dynamic window depends on the drift distance and is determined by the 1σ width of the highest $S2_B$ waveform.

The SS/(SS+MS) ratio for $2\nu\beta\beta$ ($0\nu\beta\beta$) events is

99.89% (98.23%) within the ROI. The efficiencies are calculated based on BambooMC, a Geant4-based MC framework developed by PandaX [24]. The ¹³⁴Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ events are simulated based on theoretical calculations described in Ref. [25]. The SS signal and background PDFs are generated from MC data with the SS criteria identical to those in the physics data. The 232 Th gamma calibration data are used to study the systematic uncertainty of SS cut efficiency, as illustrated in Fig. 3. The difference in SS/(SS+MS) ratio between data and MC (in absolute value) averaged over the energy range is 6.4%, which is conservatively adopted as a systematic uncertainty for all PDFs. Since the majority of events in the ROI are β -like events, which are almost entirely SS events, the systematic uncertainty from ²³²Th calibration is a conservative choice.

We search for ¹³⁴Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ by fitting the energy spectrum of the SS events with a binned likelihood method. Similar to Ref. [9], the likelihood function is constructed as

$$L = \prod_{i=1}^{N_{\text{bins}}} \frac{(N_i)^{N_{i,\text{obs}}}}{N_{i,\text{obs}}!} e^{-N_i} \cdot \prod_{j=1}^{N_{\text{G}}} G(0,\sigma_j) \cdot \mathscr{G}(a,b,c,\sigma_{a,b,c}) ,$$
(2)

where $N_{i,\text{obs}}$ and N_i are the observed and expected numbers of events in the *i* th energy bin, with

$$N_{i} = (1 + \epsilon_{\text{eff}}) \left[(1 + \eta_{\text{Xe}}) \sum_{s}^{2\nu,0\nu} n_{s} S_{s,i} + \sum_{b=1}^{N_{\text{bkgs}}} (1 + \eta_{b}) n_{b} B_{b,i} \right]$$
(3)

Here, n_s and n_b are the counts for the signal $(2\nu\beta\beta)$ or $0\nu\beta\beta$ and the background component b, respectively, and $S_{s,i}$ and $B_{b,i}$ are the corresponding PDF values in the *i* th bin. ϵ_{eff} , η_{Xe} , and η_b are the constrained parameters to represent the systematic uncertainties from the overall efficiency, xenon target mass, and different background contributions. The constraints are implemented as Gaussian penalty terms in the likelihood function in Eq.(2) with the 1σ variation defined in the text. The shapes of signal and background PDFs are modeled with energy resolution function with the parameters a, b, and c (Fig. 1) with their correlated uncertainties included in the penalty term $\mathscr{G}(a, b, c, \sigma_{a,b,c})$.

The total detection efficiencies for $2\nu\beta\beta$ ($0\nu\beta\beta$) signals are the product of the data quality efficiency 99.94% (99.94%), SS cut efficiency 99.89% (98.23%), and ROI acceptance 60.56% (99.98%).

The contribution of 136 Xe $2\nu\beta\beta$ background is calculated based on the half-life measurement in Ref. [9]. The number of 136 Xe $2\nu\beta\beta$ events in the ROI is expected to be 12 372±619, used as the initial value and constraint. The spectral shape of 136 Xe $2\nu\beta\beta$ events is generated with the Decay0 package [26]. 133 Xe is generated through the deexcitation of 133m Xe, which is the product of the neutron capture process of 132 Xe. The number of 133 Xe events is

FIG. 3: Energy spectra of 232 Th calibration data and MC simulation for MS + SS and SS events.

estimated to be 3423 ± 342 , based on the data between 90 and 120keV, where the $\beta + \gamma$ shoulder of ¹³³Xe dominates. Additional contributions from short-lived xenon isotopes induced by neutron calibration are mainly from characteristic peaks in the data, including 248 keV and 276 keV from ¹²⁵Xe, 208 keV, 380 keV, and 408 keV from ¹²⁷Xe, and 236 keV from ^{129m}Xe and ¹²⁷Xe.

 $^{85}{\rm Kr}$ concentration is measured based on a sequential $\beta-\gamma$ emission through the metastable state $^{85{\rm m}}{\rm Rb}$. In comparison to Ref. [19], we optimize the coincidence selection, and the updated number of $^{85{\rm m}}{\rm Rb}$ events is $3.9\pm2.0,$ after the subtraction of possible random coincidence. The concentration of Kr/Xe is 0.52 ± 0.27 parts per trillion, assuming an isotopic abundance of 2×10^{-11} for $^{85}{\rm Kr}$ [27]. A total of 296 ± 154 $^{85}{\rm Kr}$ events is expected in the ROI.

 β decays of $^{212}{\rm Pb}$ ($^{214}{\rm Pb}$), progeny of emanated $^{220}{\rm Rn}$ ($^{222}{\rm Rn}$), are inferred from data with energy spectra taken from MC. Because of the short 55.6-s half-life of $^{220}{\rm Rn}$ [28], the alpha rate of $^{220}{\rm Rn}$ in the detector does not reflect the internal activity of $^{212}{\rm Pb}$. The $^{212}{\rm Pb}$ activity is instead constrained with daughter $^{212}{\rm Po}$ alpha decay, which is $0.11\pm0.01~\mu{\rm Bq/kg}$. The ratio between $^{212}{\rm Pb}/^{212}{\rm Po}$ of 2.5 ± 0.8 is determined from $^{220}{\rm Rn}$ calibration data. Therefore, the nominal activity of $^{212}{\rm Pb}$ is $0.28\pm0.08~\mu{\rm Bq/kg}$, resulting in 1012 ± 289 events in the ROI. The $^{222}{\rm Rn}$ level is measured with the alpha particles emitted in the decay chain and is higher than that of $^{214}{\rm Pb}$ due to progenies attaching to electrodes and the inner surface of the detector [29]. Therefore, the rate of $^{214}{\rm Pb}$ is float in the fit.

External background originates from the detector components and the lab environment. The corresponding activities of 232 Th, 238 U, 60 Co, and 40 K have been measured in Ref. [9] and used as nominal values for the fit.

The fit results are shown in Fig. 4. The fitted number of the 134 Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ events are 10 and 105 with statistical uncertainties of 269 and 48. The fitted contributions from 136 Xe $2\nu\beta\beta$, 85 Kr, and materials are all

Fig. 4: The energy spectrum for the 134 Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ search with fitted background components and the signals at the 90% CL upper limits. The background contributions of xenon isotopes except 136 Xe are grouped as one curve. The bottom panel shows the residuals.

consistent with the inputs. The fitted activity of ²¹²Pb is $0.30 \pm 0.08 \ \mu Bq/kg$, agreeing with the product of the measured ²¹²Po decay rate and the ²¹²Pb-to-²¹²Po ratio from the calibration. The fitted ²¹⁴Pb activity is $4.5 \pm 0.2 \ \mu Bq/kg$, 63% of the ²²²Rn activity.

The systematic uncertainties are listed in Table I, which include (1) target mass, (2) efficiency, (3) energy resolution, (4) background, (5) bin size, and (6) energy scale. The contributions from 1 to 4 are included in the likelihood function as Gaussian constraints [Eq.(2)] and those from 5 and 6 will be evaluated independently.

The uncertainties from target mass include FV, LXe density, and the isotopic abundance of 134 Xe, which are jointly modeled by a common normalization parameter. The uncertainties of FV are determined by the ^{83m}Kr calibration data. The observed difference between the geometrically calculated and linearly scaled volume from 83m Kr amounts to 1.6%, representing the uncertainty associated with the FV selection. The LXe density 2.850 ± 0.004 g/cm³ is calculated from the gas phase pressure of 2.064 ± 0.008 bar during the run period. The isotopic abundance of ¹³⁴Xe in the PandaX-4T detector is measured with a dedicated setup utilizing an SRS residual gas analyzer [30]. Considering the relative ionization efficiency of xenon isotopes, the abundance of 134 Xe is calculated to be $10.47 \pm 0.02\%$. The difference with respect to the reported value 10.44% [31] is treated as a systematic uncertainty. Its impact on both $2\nu\beta\beta$ and $0\nu\beta\beta$ is negligible.

Systematic uncertainties from efficiencies include the uncertainty of the SS fraction (6.4%) and quality cuts (0.03%), as described previously. The contribution propagates to an uncertainty of 119 events for $2\nu\beta\beta$ and 10 events for $0\nu\beta\beta$.

TABLE I: Summary of the uncertainties in the number of counts. The fitted mean values of $2\nu\beta\beta$ and $0\nu\beta\beta$ are 10 and 105 counts.

	Sources	$2\nu\beta\beta$	$0\nu\beta\beta$
Statistical		269	48
Systematic	Target mass	-	-
	Efficiency	119	10
	Energy resolution	-	-
	Background	521	19
	Bin size	85	13
	Energy scale	410	28
	Total	680	38

Systematic uncertainties of energy resolution are included by the penalty terms of a, b, and c in the likelihood function. The best-fit energy resolution function is consistent within 1σ . The change in energy resolution does not introduce noticeable systematic uncertainties to both results.

Systematic uncertainty from background constraints is a dominant term in the final fit results. Many backgrounds are not well constrained from prior measurements or other energy regions. The contributions are 521 and 19 events for $2\nu\beta\beta$ and $0\nu\beta\beta$, respectively.

Additional systematic uncertainties from bin size and energy scale are estimated manually. The bin size is varied from 1 to 20 keV. The energy scale of PDFs is shifted by up to ± 10 keV. The maximum changes of best-fit values of $2\nu\beta\beta$ and $0\nu\beta\beta$ are taken as the systematic uncertainties. The values are listed in Table I.

The final number of ¹³⁴Xe $2\nu\beta\beta$ and $0\nu\beta\beta$ events are $10\pm269(\text{stat.})\pm680(\text{syst.})$ and $105\pm48(\text{stat.})\pm38(\text{syst.})$, respectively. The systematic uncertainties are calculated by adding the respective values list in Table I quadratically. The *p* values for null results are found to be 0.99 for the $2\nu\beta\beta$ and 0.09 for $0\nu\beta\beta$, showing that there is no statistically significant evidence for nonzero signals. The lower half-life limits of 2.8×10^{22} yr and 3.0×10^{23} yr at the 90% CL are derived, respectively.

In summary, we performed the first experimental search for $2\nu\beta\beta$ ($0\nu\beta\beta$) of ¹³⁴Xe using natural xenon as a target with an isotopic exposure of 17.9 ± 0.3 kg yr. No significant excess over the expected background is observed, resulting in a 90% CL lower limit on the halflife of 2.8×10^{22} yr $(3.0 \times 10^{23} \text{ yr})$ for the $2\nu\beta\beta$ $(0\nu\beta\beta)$ of ¹³⁴Xe. The $2\nu\beta\beta$ limit surpasses the existing limit [12] by a factor of 32 and further approaches the theoretical expectation of $3.7-6.09 \times 10^{24}$ yrs [10, 11]. The limit for $0\nu\beta\beta$ is 2.7 times stronger than the previous best result in Ref. [12]. Compared to a ¹³⁶Xe enriched detector, the searches benefit from the reduced 136 Xe $2\nu\beta\beta$ background. Thanks to the low energy threshold of PandaX-4T, the fit range is extended down to 200 keV, leading to a further improvement of the 134 Xe $2\nu\beta\beta$ signal over ¹³⁶Xe background ratio.

PandaX-4T continues to take more physics data, and an upgrade plan is developed to optimize the detector performance at the MeV level. Larger statistics and higher quality data will further improve understanding of the background model and the search sensitivities. A discovery of ¹³⁴Xe $2\nu\beta\beta$ may be within reach with PandaX-4T and future large xenon TPCs.
