Abstract

ScFe₆Ge₄ with the LiFe₆Ge₄-type structure (space group $R\overline{3}m$), which has a double-layered kagome lattice (18*h* site) of Fe crystallographically equivalent to that of a well-known topological ferromagnet Fe₃Sn₂, is newly found to be antiferromagnetic (AFM) with a high Néel temperature of $T_N \approx 650$ K, in contrast to the ferromagnetic (FM) ground state previously proposed in a literature. ⁴⁵Sc nuclear magnetic resonance experiment revealed the absence of a hyperfine field at the Sc site, providing microscopic evidence for the AFM state and indicating AFM coupling between the bilayer kagome blocks. The stability of the AFM structure under the assumption of FM intra-bilayer coupling is verified by DFT calculations.

Keywords: A. ScFe6Ge4; C. LiFe6Ge4-type; C. double-layered kagome lattice; E. NMR

Recently, a number of non-trivial quantum phases have been discovered in magnetic materials consisting of the kagome lattice [1]. One of the intensively studied materials is the ferromagnetic (FM) Fe₃Sn₂ with a double-layered kagome lattice of Fe [2], which is a well-known topological ferromagnet (see, e.g., [3]). The space group of Fe₃Sn₂ is $R\overline{3}m$ and Fe occupies a site with Wykoff symbol 18*h* [2]. The Fe site is characterized by two adjacent breathing kagome layers (bilayer block). As a family of materials with the Fe sublattice crystallographically equivalent to that in Fe₃Sn₂, RFe_6Ge_4 compounds (R = Li, Mg, Zr, Sc) with the LiFe₆Ge₄-type structure are known [4] (compare Figs. 1(a) and (b)). However, their magnetic properties are poorly understood. On the other hand, the magnetic properties of the RM_6X_6 family (R = Gd-Tm, Mg, Sc, Y, Lu, Ti, Zr, Hf, Nb; M = Fe, Mn; X = Ge, Sn), with a local structure similar to RFe_6Ge_4 , have been studied intensively [5-7] and their topological nature is also attracting attention recently (see, e.g., [8, 9]).

In *R*Fe₆Ge₄, the Fe bilayer blocks and *R*Ge₈ hexagonal bipyramidal layers (*R* is the center of the Ge dodecahedron) are alternately stacked in the *c*-direction (Fig. 1(b)) [4]. The Sn₈ bipyramidal layer in Fe₃Sn₂ is replaced by the *R*Ge₈ layer in In *R*Fe₆Ge₄. The vertices of the Sn₈ bipyramids in Fe₃Sn₂ do not penetrate the Fe kagome plane, while those of the ScGe₈ in *R*Fe₆Ge₄ slightly penetrate the kagome plane (see Figs. 1(a) and (b)). On the other hand, *R*Fe₆Ge₆ of the HfFe₆Ge₆-type (*P*6/*mmm*) has Fe monolayers (non-breathing kagome, 6*i* site) stacked in phase, with the *R*Ge₈ bipyramidal layers and the Ge honeycomb layers alternating between the Fe kagome layers (Fig. 1(c)) [10, 11]. *R*Fe₆Ge₆ is antiferromagnetic (AFM) when *R* is a nonmagnetic element [12-15], while Fe₃Sn₂ is FM [16]. The magnetic anisotropy of both Fe₃Sn₂ and *R*Fe₆Ge₆ is basically uniaxial with the *c*-axis as the easy axis: a canted component appears at low temperatures, but both show collinear structures just below the Curie and Néel temperatures (*T*_C and *T*_N), respectively [12, 15-17]. The Fe moment of Fe₃Sn₂ is ~2.0 μ_B [16], while that of *R*Fe₆Ge₆ is 1.5–2.1 μ_B [13, 15], depending on *R*. These three crystal structures have in common that they are composed of the Fe kagome lattice, but the spacing and phase between the Fe layers are different, resulting in a diversity of magnetic coupling between the layers.

The only experimental study of the magnetic properties of the *R*Fe₆Ge₄ series is for ScFe₆Ge₄ [18]. From magnetization measurements of polycrystalline ScFe₆Ge₄, the authors claimed that ScFe₆Ge₄ is FM with $T_{\rm C}$ = 491 K and a spontaneous magnetization $M_{\rm s}$ of ~0.5 µ_B per formula unit (at 3 K), *i.e.* ~0.1 µ_B/Fe. Mössbauer spectroscopy revealed an internal magnetic field at the Fe site |*H*_{hf}(Fe)| of 191 kOe (common at room temperature (RT) and 5 K). Assuming a standard hyperfine coupling of for 3d transition metal elements (~ -100 kOe/µ_B), the magnitude of the Fe moment µ_{Fe} is estimated to be ~1– 2 μ_B . This value is an order of magnitude larger than M_s . In other words, M_s is unusually small, making it unlikely that ScFe₆Ge₄ is in a simple ferromagnet. Furthermore, they argued from DFT calculations that the spin-polarized state is stable, but at the same time they stated that the FM state is more stable than AFM states. Assuming a FM structure, they estimated $\mu_{Fe} \approx 1.8 \ \mu_B$. This is in agreement with $|H_{hf}(Fe)|$ observed by Mössbauer spectroscopy, but not with M_s .

In this study, we newly found that $ScFe_6Ge_4$ is not FM but AFM with $T_N \approx 650$ K. ⁴⁵Sc nuclear magnetic resonance (NMR) shows that the internal field at the Sc site $H_{hf}(Sc)$ is canceled in its magnetically ordered state, which microscopically proves that $ScFe_6Ge_4$ is not FM and indicates that the magnetic coupling between the Fe bilayer blocks is AFM. We also show by DFT calculations that the AFM state is more stable than the FM state.

We have synthesized ScFe₆Ge₄ from Sc (Johnson Matthey, 99.9% purity), Fe (Johnson Matthey, 99.95%), and Ge (Rare Metallic, 99.999%) by arc melting in an argon atmosphere. Powder X-ray diffraction measurements at RT showed that the sample has the LiFe₆Ge₄-type structure with lattice constants a = 5.071 Å and c = 20.053 Å, which are in good agreement with the literature values a =5.066 Å and c = 20.013 Å [4], a = 5.079 Å and c = 20.009 Å [18]. Magnetization was measured using a Quantum Design SQUID magnetometer MPMS in the temperature range 5-700 K and magnetic field range 0–70 kOe. ⁴⁵Sc NMR experiments were performed by the conventional spin-echo method using a Thamway PROT-II spectrometer. The sample was powdered and fixed with paraffin to ensure random orientation of the particles. The parameters of the ⁴⁵Sc nucleus were nuclear spin I = 7/2, nuclear gyromagnetic ratio $\gamma = 1.0343$ MHz/kOe, nuclear quadrupole moment $Q = -0.220 \times 10^{-24}$ cm², and natural abundance ratio 100%. DFT calculations were performed using the Vienna ab initio simulation package (VASP) [19-22]. We used the projector augmented wave (PAW) pseudopotentials [23, 24] with the generalized gradient approximation (GGA) scheme following the Perdew, Burke and Ernzerhof (PBE) functional [25]. The conjugate gradient algorithm was used to relax the atoms. The Methfessele-Paxton scheme [26] was used for both geometry relaxation and total energy calculations. All atoms were relaxed until the forces on the atoms were less than of 10⁻² eV/Å and the energy difference between two successive electronic steps was less than 10^{-7} eV. The unit cell was doubled along the c-axis and the k-point mesh was set to $35 \times 35 \times 5$ when spin-orbit coupling was not considered and $17 \times 17 \times 3$ when it was considered.

The inset of Fig. 2 shows examples of isothermal magnetization curves (5 and 300 K). They vary linearly through the origin, indicating no M_s at the temperatures, contrary to what was reported in [18].

In our experiments, when the sample was synthesized with excess Fe, a small M_s was observed. This is most likely due to FM impurities based on the hexagonal Laves phase ScFe₂ with $T_c = 542$ K [27]. The temperature dependence of the susceptibility χ measured in a temperature range up to 700 K and a field of 10 kOe is shown in Fig. 2. χ is small at low temperatures, decreases slightly with increasing temperature up to ~400 K, increases at higher temperatures, reaches a maximum at ~650 K, and decreases at higher temperatures. Another small hump was observed at ~570 K (denoted by T^*). Except for the hump at T^* , this behavior is typical for AFM materials, suggesting that ScFe₆Ge₄ is AFM below $T_N \approx 650$ K.

The Mössbauer spectrum of our sample at RT (not shown) was the same as reported in [18] (see Fig. 7 in [18]); the spectrum was practically a single sextet component with $|H_{hf}(Fe)| \approx 191$ kOe. Assuming a standard hyperfine coupling for the 3d transition metal elements, μ_{Fe} is estimated to be $\sim 1-2 \mu_B$. The observed $|H_{hf}(Fe)|$ is nearly identical to the RT value for Fe₃Sn₂ (199–200 kOe) [28, 29], suggesting that the μ_{Fe} of ScFe₆Ge₄ is comparable to that of Fe₃Sn₂; the reported M_s in Fe₃Sn₂ is $\sim 2 \mu_B/Fe$ [16].

It is also interesting to note that the T_N of ScFe₆Ge₄ (≈ 650 K) is almost the same as the T_C of Fe₃Sn₂, indicating that the magnetic interaction strength in ScFe₆Ge₄ and Fe₃Sn₂ is almost the same and differs only in sign. The sign difference can be attributed to the different medium driving the interbilayer interaction: ScGe₈ in ScFe₆Ge₄ and Sn₈ in Fe₃Sn₂ (see Figs. 1(a) and (b)). Note also that the T_N of ScFe₆Ge₆ (≈ 500 K) in the absence of the bilayer blocks is significantly lower than that of ScFe₆Ge₄ (≈ 650 K), indicating that the intra-bilayer interaction is stronger than the inter-monolayer interaction. In ScFe₆Ge₄, the in-plane Fe-Fe bond length is 2.48 Å or 2.60 Å, and the inter-plane Fe-Fe bond length in the bilayer block is 2.97 Å, suggesting that the Fe-3d electrons hybridize directly in the bilayer block. On the other hand, the bilayer blocks are separated by more than 4 Å, suggesting an indirect magnetic coupling between the bilayer blocks. Considering that the same bilayer block is common to both FM and AFM materials, it is reasonable to assume that the magnetic coupling within the bilayer block is FM both in-plane and inter-plane.

To investigate the field dependence of the susceptibility humps observed at high temperatures, the temperature dependence of M/H (M is the magnetization) was measured at several different fields H (inset of Fig. 3). Two humps corresponding to T^* and T_N were observed in the range of measured fields. T_N changed little with field, while T^* decreased slightly with increasing field. Considering that T^* tentatively corresponds to a certain phase transition, a magnetic phase diagram is shown in Fig. 3.

There are two distinct AFM phases. The low-temperature phase appears to be slightly destabilized by the application of the field. The change in the spin structure of Fe₃Sn₂ pointed out by Fenner *et al.* [17] is suggestive; Fe₃Sn₂ undergoes a transition from the paramagnetic phase to a *c*-axis collinear FM state at $T_{\rm C}$, but at 520 K the moments begin to tilt from the *c*-axis to the *c*-plane, *i.e.*, a non-trivial magnetic state with a non-collinear component begins to appear below the temperature close to T^* of ScFe₆Ge₄. It is very likely that the same phenomenon occurs in ScFe₆Ge₄ as in Fe₃Sn₂.

The inset of Fig. 4 shows an example of a ⁴⁵Sc-NMR field sweep spectrum at 4.2 K. A sharp spectrum with satellites was observed near the field corresponding to v/ γ , where v is the experimental frequency. The resonance field, corresponding to the position of the center line of the spectrum, was measured at different frequencies and plotted in Fig. 4. Extrapolation of the data yields a straight line passing through the origin with a slope of 1.033(1) MHz/kOe, almost equal to γ of ⁴⁵Sc, thus assigning the observed signal to the ⁴⁵Sc resonance. We can also see that $H_{hf}(Sc)$ is practically negligible. An electric field gradient with asymmetry parameter $\eta = 0$ is expected at the Sc site (3*a*) with site symmetry $\overline{3}m$; the satellites observed around the center line are due to quadrupole effects. The inset of Fig. 4 also shows the simulated result of the powder pattern assuming a small negative isotropic hyperfine shift $K_{iso} = -0.3\%$ and a quadrupole frequency $v_Q = 0.76$ MHz. The agreement between experiment and calculation is good, proving that $H_{hf}(Sc) \approx 0$. This is in contrast to $|H_{hf}(Fe)| \approx 191$ kOe. These results provide microscopic and direct evidence that ScFe₆Ge₄ is not FM but AFM. Furthermore, one should consider a magnetic structure in which $H_{hf}(Sc)$ is canceled out.

Based on the magnetic structures reported for Fe₃Sn₂ and ScFe₆Ge₆ with similar stacking in their crystal structures [2, 10, 11], we consider possible magnetic structures under the constraint $H_{hf}(Sc) = 0$. Fe₃Sn₂ is FM ($T_C \approx 650$ K) [16] and ScFe₆Ge₆ is AFM ($T_N \approx 500$ K) [12]. In both compounds, the in-plane Fe-Fe bonds are FM. For simplicity, only the magnetic couplings between the Fe kagome layers are considered here, *i.e.* only up/down degrees of freedom in the moment direction are considered. In considering the model for ScFe₆Ge₄, it is reasonable to impose the following constraints. (i) The in-plane Fe-Fe magnetic coupling is FM. (ii) The interplane coupling in the bilayer block is FM. (iii) The coupling between the bilayer blocks is AFM. Assumption (i) was made for commonality with Fe₃Sn₂ and ScFe₆Ge₆. The reason for assumption (ii) is discussed above. Assumption (iii) is based on the fact that $H_{hf}(Sc) = 0$. Since the hexagonal Fe atoms are symmetrically coordinated above and below the ScGe₈ bipyramid, if the Fe moments of the kagome layers have AFM coupling with respect to the *c*-plane containing the Sc atoms, the $H_{hf}(Sc)$ (both isotropic and anisotropic) cancel at the Sc

site in terms of symmetry. This is consistent with the fact that in $ScFe_6Ge_6$, the coupling between the Fe layers sandwiching the $ScGe_8$ bipyramids is AFM. The magnetic structure satisfying (i)–(iii) is uniquely determined and shown schematically in Fig. 1(b); the stacking of in-plane FM kagome layers is -UU-DD-UU-DD-UU-DD- (the magnetic unit cell is twice the size of the crystal unit cell, hereafter denoted -UU-DD-), where U and D denote the FM layers with up and down moments, respectively, and the dash (-) corresponds to the $ScGe_8$ bipyramidal layer. Note that the discussion here does not exclude the existence of a noncollinear component or the possibility of non-uniformity in μ_{Fe} .

ScFe₆Ge₄ with a double-layered kagome lattice of Fe is shown for the first time to be an antiferromagnet with $T_N = 650$ K. The absence of the internal field at the Sc site provides microscopic evidence for the AFM state. The analogy with the magnetic structures of ScFe₆Ge₆ and Fe₃Sn₂, which contain the same substructures as ScFe₆Ge₄, and $H_{hf}(Sc) \approx 0$, suggests FM coupling within the bilayer block both in-plane and inter-plane, and AFM coupling between the blocks. The validity of the structure was confirmed by DFT calculations. Since the Fe sublattice in ScFe₆Ge₄ is crystallographically equivalent to that in Fe₃Sn₂, ScFe₆Ge₄ is of interest as an AFM alternative to Fe₃Sn₂ (FM at $T_C = 650$ K), a known topological magnetic material. We must await single crystal experiments to obtain an accurate phase diagram and neutron diffraction experiments to know the evolution of the microscopic magnetism.

The authors thank K. Midori for his help in the early stages of the study. This work was supported by JSPS KAKENHI Grant Numbers 22F22016, 22KF0206 and JST SPRING, Grant Number JPMJSP2110.

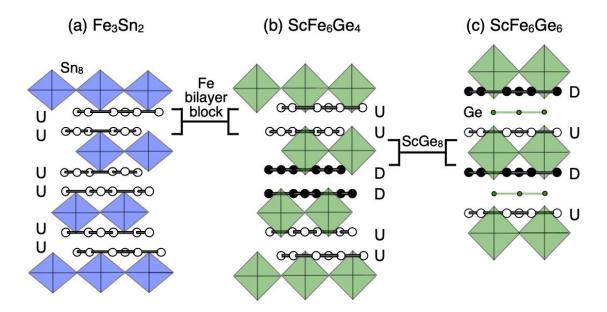

Figure 1. Interlayer magnetic couplings ([120] direction views) for Fe₃Sn₂ [16] (a) and ScFe₆Ge₆ [12] (c), and proposed magnetic coupling for ScFe₆Ge₄ (b). Open and closed circles represent Fe atoms (18*h* site in space group $R\overline{3}m$) with up and down moments, respectively. Blue and green squares represent Sn₈ and ScGe₈ hexagonal bipyramids (dodecahedrons), respectively, with Sn/Ge and Sc atoms located at the corners and center, respectively. Small dots in (c) indicate the Ge honeycomb layer. In (b), only half of the magnetic unit cell is shown; the spin directions of adjacent parts in the *c*-direction are reversed.

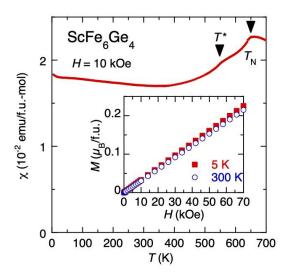

Figure 2. Temperature dependence of magnetic susceptibility measured at a magnetic field of 10 kOe for ScFe₆Ge₄. The inset shows examples of isothermal magnetization curves.

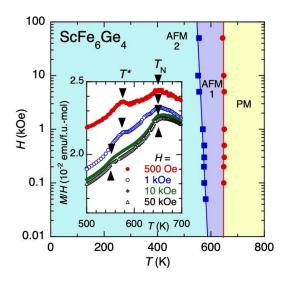

Figure 3. Magnetic phase diagram of ScFe₆Ge₄ evaluated from the susceptibility anomalies. The vertical axis is on a logarithmic scale. The inset shows temperature dependence of high-temperature part of magnetic susceptibility measured at different magnetic fields.

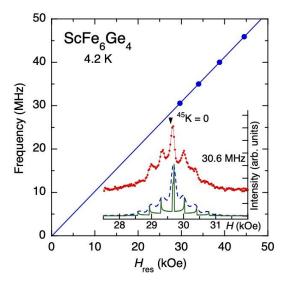

Figure 4. Frequency dependence of the resonance field of ⁴⁵Sc NMR for ScFe₆Ge₄ at 4.2 K. The inset shows an example of the field-sweep spectrum (measurement frequency 30.6 MHz) (closed circles) and powder patterns calculated assuming $K_{iso} = -0.3\%$ and $v_Q = 0.76$ MHz (solid curve: bare intensity, dashed curve: Gaussian function with full width at half maximum of 150 Oe was convoluted).
