ABSTRACT

Only a handful of massive starless core candidates have been discovered so far, but none of them have been fully confirmed. Within the MM1 clump in the filamentary infrared dark cloud G34.43+0.24 that was covered by the ALMA-ATOMS survey at Band 3 (~ 2", 6000 au) and the ALMA-QUARKS survey at Band 6 (~ 0.3", 900 au), two prestellar core candidates MM1-C and E1 with masses of 71 and 20 M_{\odot} and radii of 2100–4400 au were discovered. The two cores show no obvious sign of star-formation activities. In particular, MM1-C is a very promising massive prestellar core candidate with a total gas mass of 71 M_{\odot} . Within MM1-C, we detected two extremely dense substructures, C1 and C2, as characterized by their high densities of $n_{\rm H_2} \sim 10^{8-9} {\rm cm}^{-3}$. Moreover, evidence of further fragmentation in C2 was also revealed. We have detected the primordial fragmentation in the earliest stage of massive star formation, and we speculate that MM1-C would be the birthplace

of a massive multiple system. However, we cannot fully rule out the possibility that the massive prestellar core MM1-C will just form a cluster of low-mass stars if it undergoes further fragmentation.

Keywords: stars: formation — ISM: kinematics and dynamics — ISM: jets and outflows

1. INTRODUCTION

Massive stars with their enormous UV radiation and large mechanical energy output, profoundly impact the surrounding interstellar medium (ISM) and play a pivotal role in the evolution of galaxies and even the Universe. However, observing the progenitors of massive stars is very challenging due to their rapid evolutionary timescale and the highly opaque molecular clouds surrounding them. Consequently, the formation of massive stars remains enigmatic, which has led to very diverse ideas on the mechanisms involved. For instance, the Turbulent Core model (e.g. McKee & Tan 2003) proposes that massive stars form in the same way as lowmass stars, by gradually accumulating gas from their natal cores (sizes $\sim 0.1 \,\mathrm{pc}$). In this case, massive prestellar cores should thus be the progenitors of massive stars. Conversely, the "clump-feed" models such as Competitive Accretion (e.g. Bonnell et al. 2001), the Inertial Inflow (e.g. Padoan et al. 2020), and the Global Hierarchical Collapse model (Vázquez-Semadeni et al. 2009, 2019) suggest that massive stars form from low-mass cores within clouds amassing through further gas accretion from their natal clumps or even clouds.

Hunting for massive prestellar cores is one of the most straightforward ways to distinguish among different scenarios. Due to their rapid evolution, only a few promising massive prestellar core candidates have been identified to date: e.g. Barnes et al. (2023, core C2c1a in the dragon cloud), Nony et al. (2018, W43-MM1#6), and Liu et al. (2017, G9.62+0.19MM9), etc. However, none of these massive starless core candidates have been fully confirmed, indicating that the search for massive prestellar core candidates warrants further observational efforts. Given that the current sample size is small, a comprehensive understanding requires persistent efforts in identifying additional samples of massive prestellar core candidates. On the other hand, surveys aiming to identify massive prestellar cores in the earliest phases of massive clumps have yielded no conclusive results in their favor (Sanhueza et al. 2017, 2019; Morii et al. 2021, 2023; Li et al. 2023). Specifically, Morii et al. (2023) reported the absence of massive prestellar cores within a substantial sample of 70 µm dark IRDCs, encompassing over 800 cores. Sanhueza et al. (2019) suggested that if massive prestellar cores do indeed exist, they are likely embedded in the more evolved environment. Recently, in an ALMA 0.87 mm survey of 11 clumps, Xu et al. (2023a) confirmed that starless cores are becoming more massive in evolved clumps as compared to early-stage clumps, through continuous gas accretion. Therefore, it might be more promising to search for massive starless cores in a protocluster environment.

Located 3.0 kpc away from the Sun (Mai et al. 2023), the filamentary IRDC G34.43+0.24 (hereafter G34) is a well studied high-mass star forming region (Garay et al. 2004; Rathborne et al. 2005; Sanhueza et al. 2010, 2012; Sakai et al. 2013; Foster et al. 2014; Xu et al. 2016; Soam et al. 2019; Liu et al. 2020a). Molecular outflows have been reported for the dense core G34-MM1 by Sanhueza et al. (2010) and Yang et al. (2018) at low resolution ($\sim 18''$). Given that molecular outflows are one of the earliest signatures of star formation activities (Yang et al. 2022), the dense core G34-MM1 in the IRDC G34 is supposed to be in the early stage of star formation. Liu et al. (2022) have extensively studied this complex using the high angular resolution ($\sim 2''$) data of the ATOMS survey (Liu et al. 2020b), and identified six dense cores in its G34-MM1 clump with masses ranging from 20 to $122 M_{\odot}^{-1}$. However, the evolutionary stages of these cores need to be explored further. The ALMA-QUARKS survey (Liu et al. 2023, see also Section 2) observed the densest kernels of the ATOMS sources at Band 6 with a much higher resolution of ~ 0.3", providing the possibility of verifying the existence of massive starless cores in G34-MM1 in a spatial resolution of ~ 1000 au. In this letter, we revisit these cores and report the discovery of the two cores MM1-C and MM1-E1, situated close to the boundary of G34-MM1 clump, as candidate massive prestellar cores containing extremely dense substructures.

2. OBSERVATIONS

G34-MM1 was observed as part of the ALMA project "ALMA Three-millimeter Observations of Massive Star-forming regions" (ATOMS, Project ID: 2019.1.00685.S; PI: Tie Liu). The observations were conducted with the 7-m array (ACA) and 12-m arrays (C43-2 or C43-3) at Band 3. The observation setup and data reduction can be found in Liu

¹ The mass in Liu et al. (2022) was estimated based on the kinematic distance (Simon et al. 2001, 2006). Those values in this paper are corrected using the parallax distance in Mai et al. (2023).

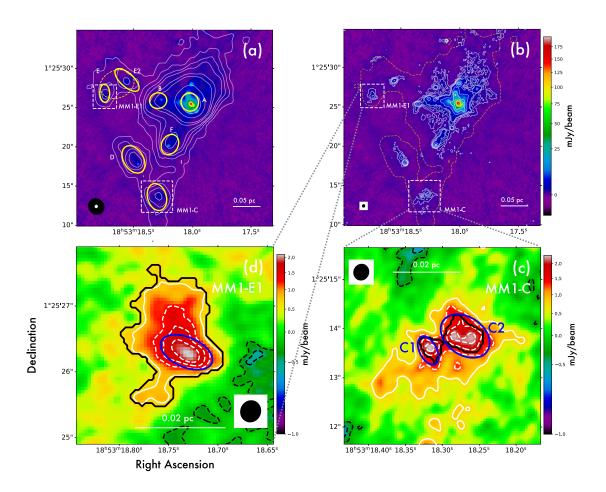

Figure 1. ALMA Band 3 and 6 continuum emission of G34.43+0.24 MM1 and the detected prestellar cores MM1-C and MM1-E1. Panel (a) shows Band 6 continuum emission overplotted with Band 3 continuum emission (Liu et al. 2022) using white contours of [3, 5, 7, 9, 15, 20, 50, 100, 200] × σ_{b3} , where $\sigma_{b3} = 0.3$ mJy beam⁻¹. The yellow solid ellipses labeled A-D and F and the dashed ellipse labeled E identify the cores extracted in Liu et al. (2022). The solid ellipses labeled E1 and E2 represent the re-estimated FWHM sizes of core E1 and E2. Panel (b) shows the contours of Band 6 continuum emission overplotted on the same colormap as Panel (a). The white contours are at levels of [3, 5, 7, 9, 20, 50, 100, 200] × σ_{b6} , where $\sigma_{b6} = 0.25$ mJy beam⁻¹. The orange dashed contour outlines the $3-\sigma_{b3}$ boundary of Band 3 continuum emission. Panel (c) zooms toward core MM1-C. The contours are at [3, 5, 7, 9] × σ_{b6} . The solid contour highlights the $3-\sigma_{b6}$ boundary. Panel (d) zooms toward core MM1-E1 with contours at [3, 5, 7]× σ_{b6} . The solid contour also emphasizes the $3-\sigma_{b6}$ boundary. The colorbars of both Panel (c) and (d) are set to start from 0 and end at their peak intensities to display the morphology of MM1-C and MM1-E1 more clearly. The blue ellipses in Panels (c) and (d) correspond to the FWHM sizes estimated from the 2-dimensional Gaussian fitting. The restoring beams are shown as black ellipses in each panel. The black solid contours outline the condensations identified by dendrogram. The black dashed contour is at [-2, -1]× σ_{b6} .

et al. (2020b). The angular resolution and maximum recoverable scales (MRS) for the ACA and 12-m array are 13".3 and 76".9, and 1".5 and 19".4, respectively. The ACA and 12-m combined data have resulted in a resolution of \sim 2" for continuum emission. The combined continuum image of G34-MM1 reaches an rms noise level of 0.3 mJy beam $^{-1}$. Eight spectral windows (SPWs) were set including six SPWs with high spectral resolution and two wide SPWs with 1875 MHz bandwidth. The spectral data reaches a noise level of 12 mJy beam $^{-1}$ per 0.062 MHz channel (\sim 0.2–0.4 km s $^{-1}$) for six SPWs, and 3.6 mJy beam $^{-1}$ per 0.488 MHz channel (\sim 1.6 km s $^{-1}$) for wide SPWs.

G34-MM1 was also observed as part of a new ALMA project, "Querying Underlying mechanisms of massive star formation with ALMA-Resolved gas Kinematics and Structures" (QUARKS, PIs: Lei Zhu, Guido Garay and Tie Liu). The QUARKS project targets are the same objects as in the ATOMS survey but with a much higher resolution, of ~ 0.25", at Band 6 (ALMA Project IDs: 2021.1.00095.S and 2023.1.00425.S; PI: Lei Zhu). The observations were conducted with ACA and 12-m arrays (C43-2 and C43-5) at Band 6. The observation setup and data reduction of QUARKS are described in Liu et al. (2023). The ACA and 12-m combined data were resulting in an angular resolution

of 0.73, and the corresponding combined continuum image achieves a rms noise level of $0.25\,\mathrm{mJy}$ beam⁻¹. Four wide SPWs with 1875 MHz bandwidth were set, resulting in a noise level of $5\,\mathrm{mJy}$ beam⁻¹ per 0.488 MHz channel ($\sim 0.6\,\mathrm{km}\,\mathrm{s}^{-1}$).

3. RESULTS

3.1. Detection of massive starless core candidates

Fig. 1 presents the ALMA Band 3 (3 mm) and Band 6 (1.3 mm) continuum emission maps of the G34-MM1 clump. Reexamination of the Band 3 continuum emission revealed that the MM1-E core identified in Liu et al. (2022) is in fact two separate cores (namely E1, E2) instead of one single core, as clearly seen from higher-resolution 1.3 mm emission. We performed two-component two-dimensional Gaussian fitting toward E1 and E2 following the same procedure as in Liu et al. (2021a), which is a combination of *Dendrogram* (Rosolowsky et al. 2008) and *CASA-imfit* for consistency. The measured core properties of these two cores are summarized in Table 1. In this work, we only focus on the two massive starless core candidates MM1-C and MM1-E1.

Since the MRS of the Band 3 data is two times larger than that of the Band 6 data and the 3 mm continuum emission is relatively optically thin than the 1.3 mm continuum emission, we use the 3 mm continuum emission to calculate the total gas masses of dense cores MM1-C and MM1-E1. Assuming that the 3 mm continuum emission is optically thin under local thermodynamic equilibrium (LTE) conditions, the core masses can be calculated as (e.g., Liu et al. 2021b),

$$M_{\rm gas} = \frac{R_{\rm gd} S_{\nu} D^2}{\kappa_{\nu} B_{\nu} (T_{\rm dust})},\tag{1}$$

where S_{ν} is the integrated 3 mm continuum flux, D is the distance to the region (3.0 kpc), and $B_{\nu}(T_{\rm dust})$ is the Planck function at dust temperature $T_{\rm dust}$. The dust temperature $T_{\rm dust}$ =14.2 K and 22.6 K for MM1-C and E1 respectively are taken as the gas kinetic temperature of NH₃ from VLA observations at the resolution of $\sim 3''$ (Lu et al. 2014). We assume a typical gas-dust mass ratio $R_{\rm gd}$ of 100. A value for κ_{ν} of 0.18 cm² g⁻¹ is adopted from the 'OH5' model(Ossenkopf & Henning 1994; Pollack et al. 1994) and extended to the longer wavelength by Young & Evans (2005). Furthermore, by assuming a spherical geometry, the number density can be estimated as $n_{\rm H_2} = 3M/(4\pi\mu_{\rm H_2}m_{\rm H}R_{\rm core}^3)$, where the molecular weight per hydrogen molecule $\mu_{\rm H_2}$ is 2.8, and $m_{\rm H}$ is the mass of a proton. The effective radii of the cores R_{core} are estimated as $(FWHM_{major}^{Deconv} \times FWHM_{minor}^{Deconv})^{\frac{1}{2}}/2 \times D$ where $FWHM_{major}^{Deconv}$ and $FWHM_{minor}^{Deconv}$ are the deconvolved FWHM of the major and minor axis, respectively.

Several sources of uncertainty can influence the mass determination. Following Sanhueza et al. (2017, 2019), we conservatively assign the uncertainties of 25% for R_{dg} and κ_{ν} ,

5% for the absolute flux uncertainty at Band 3² and the distance $(3.03^{+0.17}_{-0.16} \, \text{kpc})$. The combined uncertainty of mass determination is $\sim 50\%$. The mass, deconvolved size, number density, and column density estimated from Band 3 continuum emission are summarized in Table 1. We find that the cores MM1-C and E1 are massive and dense, having masses of 71 M_{\odot} and 20 M_{\odot} , respectively, on a scale of approximately 4000-8000 au (0.02-0.04 pc). Their densities reach up to $\sim 3 \times 10^7$ cm⁻³. Considering a star formation efficiency (a conversion efficiency of core mass into star mass; $\epsilon_{\rm core}$) of 50%, which is reasonable and maybe even conservative for extreme density cores (Bontemps et al. 2010; Palau et al. 2013; Motte et al. 2018; Pouteau et al. 2022), the two massive and dense cores in G34-MM1 clump (MM1-C and E1) will have the potential to form a massive star or a small star cluster with a stellar mass $M_{\rm star} > 8 M_{\odot}$ eventually.

Fig. 2 shows the core-averaged spectra of MM1-C and E1 in four wide-band spectral windows at Band 6, and two wideband spectral windows at Band 3. For comparison, we also plot the spectra of the hot molecular core MM1-A, which has already formed high-mass protostars (Qin et al. 2022). It can be easily noticed that very few lines are detected toward MM1-C and E1, which is in strong contrast with the 'line forest' of MM1-A. Some absorption features in the spectra of molecules including H₂CO, ¹³CO, C¹⁸O, and CH₃OH are likely caused by the missing flux issue as a result of interferometer observations due to sidelobe or a lack of shorter baselines and total power (TP) data. As shown in the moment 0 maps in Fig. A1, no clear emission or absorption features of CH₃OH with signal-to-noise ratios (SNRs) larger than 3σ were detected toward both MM1-C and E1. In addition, as shown in Figure B1, the beam-averaged spectra at band 6 toward the continuum emission peak of MM1-C1 show no absorption features in either H₂CO or CH₃OH lines, which could be caused by warm or hot continuum background sources (or protostars) within MM1-C1.

Additionally, Liu et al. (2022) identified six outflow lobes in the MM1 clump, but none of them seem to come from MM1-C or E1. We also carefully checked the 12 CO J=2-1 and SiO J=5-4 lines toward the two cores and found no evidence of high-velocity emission. We present the CO outflows in Fig. C1. Both MM1-C and E1 are far away from CO outflow lobes. Also, no radio jets are detected by the GLOSTAR survey (Dzib et al. 2023) associated with these two cores (Yang et al. 2023). Taking into account both the paucity of spectral lines and the absence of outflows, we postulate that there is no ongoing star-formation activity within cores MM1-C and E1. Thus, we classify these two cores as

² ALMA proposal guide:https://almascience.eso.org/proposing/ proposers-guide#autotoc-item-autotoc-79

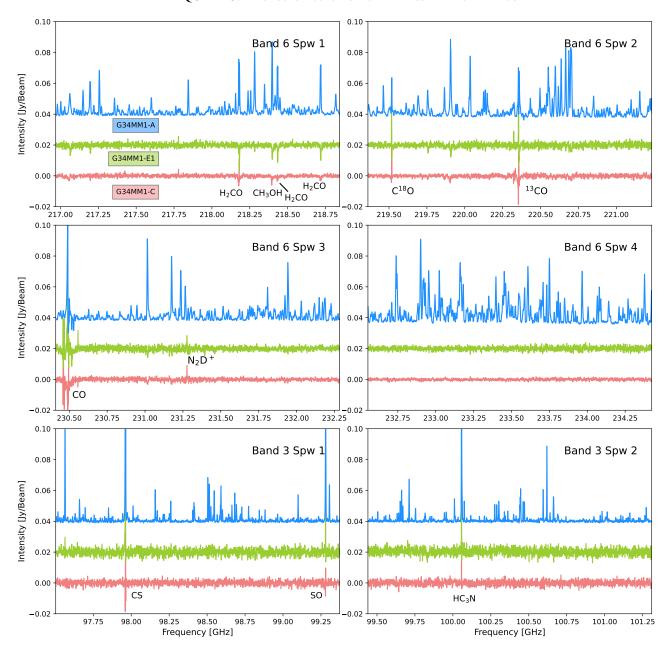

Figure 2. Core-averaged spectra of all four windows at Band 6 and two windows at Band 3 at the positions of two candidate prestellar cores MM1-C (red) and MM1-E1 (green), and the hot core MM1-A(blue) for comparison (Qin et al. 2022). The spectra are averaged over a circular area of 2".5 in diameter (shown as green circles in Figure A1). The offset of intensity for MM1-E1 and MM1-A is for visual clarity. The intensity of the spectra from MM1-A was divided by 5 for Spw 1, 2, 3 at Band 6, and by 4 for Spw 1, 2 at Band 3, and Spw 4 at Band 6. The spectra show the line-poor characteristics of MM1-C and MM1-E1 indicating their possible prestellar nature, and the clear detection of N_2D^+ indicating the cold environment. Appendix B also shows the beam-averaged spectra.

starless cores, among which MM1-C is a more promising massive starless core (> $30 M_{\odot}$, e.g., Sanhueza et al. 2017).

3.2. Detection of extremely dense Substructures within Core MM1-C

Panels (c) and (d) in Fig. 1 show high-resolution Band 6 (1.3 mm) continuum emission at a resolution of $\sim 0''.3$ toward

the two massive cores MM1-C and MM1-E. MM1-E1 shows no evidence of fragmentation, remaining a single condensation at this resolution, whereas two prominent condensations (namely, C1 and C2) are clearly seen in MM1-C. The fragmentation could be interferometric artifacts, as discussed in Caselli et al. (2019). However, the detection was at the 3σ level in their synthetic observations, while in our observations, the detection of the fragments is more reliable, at

Table 1. Core properties.

	6.5	1704	5.76	0.54	1013	1.21	0.23	

Note—The effective diameters of MM1-C1 and C2 are 1400 and 2760 au, respectively.

 $\sim 10\sigma$ level. In particular, the fragments are well separated by 2400 au (about 3 beam sizes, or 0'.'8 at 3 kpc), and can be reliably identified by the *Dendrogram* algorithm. Therefore, we argue that core MM1-C shows obvious fragmentation.

As shown by the black contour in Panel (c) in Fig. 1, two condensations were identified by $Dendrogram^3$. Due to the proximity, we performed a simultaneous 2D Gaussian fitting of the cores. The estimated sizes of C1 and C2 are 701 and 1381 au, respectively. We also assign the uncertainties of the parameters in Eq. (1) as in Sec. 3.1, with the exception of the absolute flux, which has an uncertainty of 10% at Band 6 (See also ALMA proposal guide). For κ_{ν} at Band 6, we adopt a value of $0.9 \text{ cm}^2 \text{ g}^{-1}$ (Ossenkopf & Henning 1994).

Assuming they have the same temperature as the natal core, the masses of C1 and C2 are $\sim 2.1 M_{\odot}$ and $\sim 7.3 M_{\odot}$, respectively. The derived densities are remarkably high, of the or $der \sim 10^8 cm^{-3}$. Negative temperature gradients of prestellar cores have been reported (Crapsi et al. 2007; Spear et al. 2021). The core-average temperature is possibly an upper limit, and therefore the estimated masses are lower limits. We further calculate their masses assuming lower temperatures of 10 K and 6.5 K. The corresponding parameters of C1 and C2 are also listed in Table 1. The mass of MM1-C2 can be as high as $10-30 M_{\odot}$ if $T_{\rm dust} \leq 10 \, \rm K$. In addition, MM1-C2 could further accumulate its mass through accreting gas from its collapsing natal core as well as a cold filament (see section 4.2). Within such a small-scale region (~ 1000 au) containing extremely high density ($\sim 10^8 \text{ cm}^{-3}$) gas, a higher $\epsilon_{\rm core} \sim 50\% - 100\%$ could be possible (Bontemps et al. 2010; Palau et al. 2013; Benedettini et al. 2018; Motte et al. 2018; Pouteau et al. 2022). Thus, it is possible that MM1-C2 can form a massive star $(M_{\rm star} > 8 M_{\odot})$ in the future.

4. DISCUSSION

4.1. Stability and Dynamical State

Dense cores or condensations will form stars only when they are presently collapsing or will be collapsing in the future. To assess the dynamical state of the dense core MM1-C and its two extremely dense substructures (C1 and C2), we estimated their virial parameters. We use molecular line data of N₂D⁺ J=3-2 from Band 6 observations and H¹³CO⁺ J=1-0 from Band 3 observations (Liu et al. 2022) to estimate the thermal velocity dispersion σ_{th} and non-thermal (turbulence) velocity dispersion σ_{nt} . The total velocity dispersion is $\sigma_{v}^{2} = \sigma_{th}^{2} + \sigma_{nt}^{2}$, where $\sigma_{th} = \sqrt{k_{B}T/\mu m_{H}}$. On the core scale, we obtain $\sigma_{v} = 0.73 \, \mathrm{km \, s^{-1}}$ for N₂D⁺ and

³ An intensity threshold of $2.5\sigma_{b6}$, step of $1\sigma_{b6}$, and a minimum pixel number contained in a restoring beam, 44 in this case, were fed into the *Dendrogram* algorithm.

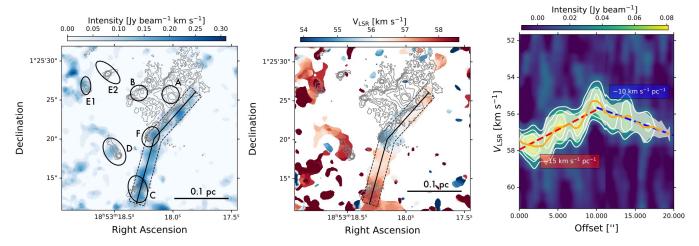

Figure 3. The left and middle panels show moment-0 and moment-1 maps of N_2D^+ , respectively. The overlaid gray contours show Band 6 continuum emission as in Fig. 1. The letter-labeled black ellipses show the same cores extracted by Liu et al. (2022) as in Figure 1. The right panel displays the position-velocity diagram extracted from the region represented by the black solid line and polygon in the left and middle panels. The white contours are at the levels of $[3,5,7] \times 8$ mJy beam⁻¹. The orange solid line is the peak velocity at each offset, and the gray shaded area corresponds to the $1-\sigma$ velocity dispersion. The red and blue dashed lines represent the fitted velocity gradients of the southern and northern filaments, respectively.

0.46 km s⁻¹ for H¹³CO⁺. We note that the velocity dispersion measured from gaussian fit of N₂D⁺ should be treated as an upper limit because of its hyperfine structure. We use the same σ_v for the two condensations in virial analysis. If we assume the gas temperature is 14.2 K, the thermal sound speed is $c_s = 0.22 \, \mathrm{km \, s^{-1}}$. The non-thermal velocity dispersion $\sigma_{\mathrm{nt}} = 0.72 \, \mathrm{km \, s^{-1}}$ for N₂D⁺ and 0.45 km s⁻¹ for H¹³CO⁺. The effective sound speed considering thermal and turbulent motion $c_s^{\mathrm{eff}} = \sqrt{c_s^2 + \sigma_{\mathrm{nt}}^2}$ is 0.76 and 0.50 km s⁻¹ for N₂D⁺ and H¹³CO⁺, respectively. The virial parameter $\alpha_{\mathrm{vir}} = M_{\mathrm{vir}}/M_{\mathrm{gas}} = 5\sigma_{\mathrm{3D}}^2 R_{\mathrm{eff}}/G M_{\mathrm{gas}}$, where the 3D velocity dispersion is $\sigma_{\mathrm{3D}} = \sqrt{3} c_s^{\mathrm{eff}}$. The derived virial parameters are listed in Table 2. We also derive virial parameters assuming a gas temperature of 10 K or 6.5 K.

The virial parameter of the core MM1-C is $\alpha_{vir} = 0.3-0.8$, lower than the critical limit, which suggests that the whole core is likely collapsing if additional support from the magnetic field is ignored. Therefore, MM1-C is a good candidate to be a massive prestellar core. We note that the condensation C1 is trans- or sub-virial except for the temperature of 14.2 K, while C2 is always sub-virial. Note also, that the parent core MM1-C appears more bound than the substructures. This is consistent with Gómez et al. (2021), which shows that for any collapsing object with a density profile shallower than r^{-2} , the central region will appear unbound. However, half of the super-viral objects in the simulation of Camacho et al. (2016) are contracting instead of being unbound, indicating that the external turbulent compressions provide the assembly of the gas. As their masses grow, gravitational contractions will take over. Since the natal core is in overall collapse, the $M_{\rm gas}$ of C1 and C2 should further grow continuously via

gas accretion. Therefore, both C1 and C2 are already contracting or will likely be gravitationally bound in the future.

A core or condensation will fragment if the physical size is larger than Jeans length, when the internal pressure (thermal+turbulence) can not prevail over gravity. The Jeans length is given as (e.g., Wang et al. 2014)

$$L_{\rm J} = c_s^{\rm eff} \left(\frac{\pi}{G\rho}\right)^{1/2}$$

$$= 0.06 \,\mathrm{pc} \left(\frac{\sigma_{\nu}}{0.188 \,\mathrm{km \, s^{-1}}}\right) \left(\frac{n}{10^5 \,\mathrm{cm^{-3}}}\right)^{-1/2},$$
(2)

and the corresponding Jeans Mass is given by

$$M_{\rm J} = \frac{\pi^{5/2} c_{\rm s}^{\rm eff^3}}{6 \sqrt{G^3 \rho}}$$

$$= 0.8 \, M_{\odot} \left(\frac{\sigma_{\nu}}{0.188 \, \text{km s}^{-1}} \right) \left(\frac{n}{10^5 \, \text{cm}^{-3}} \right)^{-1/2}.$$
(3)

We use N_2D^+ and $H^{13}CO^+$ to determine the stability of C1 and C2. The Jeans lengths and the estimated Jeans masses are summarized in Table 2. As the temperature is varied from 6.5 to 14 K, C1 has a size larger than the Jeans length when $T_{\rm gas}$ is slightly higher than 6.5 K, suggesting C1 is Jeans unstable only when $T_{\rm gas} \lesssim 6.5$ K. C2 has a size larger than the Jeans length corresponding to $T_{\rm gas}$ of 10–14 K, suggesting that C2 is likely Jeans unstable and would undergo further fragmentation.

Interestingly, alongside the two notable condensations C1 and C2, two looming substructures are seen inside C2 with a separation of 0.3" (~900 au). As this separation is comparable to the synthesis beam size, *Dendrogram* can not resolve

these two peaks. These two substructures indicate that C2 itself is already undergoing further fragmentation, which can be tested by future higher-resolution observations.

Compact substructures have been detected in low-mass prestellar cores such as G205-M3 (Sahu et al. 2021), while fragmentation in massive prestellar cores is rarely reported. We have detected extremely dense substructures within MM1-C, representing the primordial fragmentation within a massive prestellar core. Statistic surveys of massive multiple systems reveal that the distribution of the mass ratio $q = M_{\text{comp}}/M_{\text{prim}}$ exhibits a peak at 0.3–0.5 for wide multiple systems, where M_{comp} is the mass of the companion and M_{prim} is the mass of the primary, accompanied by the negative power-law index(Duchêne & Kraus 2013; Offner et al. 2023, and references therein). That is to say, the massive wide multiple systems favor low-mass companions. Therefore we speculate that the massive prestellar core MM1-C will eventually form a multiple stellar system with one massive primary and 1–2 lower-mass companions. However, we cannot fully rule out the possibility that the massive prestellar core MM1-C could undergo further fragmentation and give birth to a cluster of low-mass stars eventually.

4.2. Cold Filaments Traced by N₂D⁺

As shown in Fig. 2, N_2D^+ is detected firmly toward core MM1-C. To increase the signal-to-noise ratio, the N_2D^+ data was smoothed to 1" resolution. Shown in Fig. 3, MM1-C appears to be situated at one end of a 0.3 pc-long thin structure traced by N_2D^+ with a clear velocity gradient. This thin structure seems to trace two filaments connecting dense cores: the southern filament is a gas bridge connecting MM1-C and MM1-F, and the northern filament extends to the filament hub region close to MM1-A.

We extracted a position-velocity (PV) diagram along the filaments. By fitting the PV diagram, we determined the velocity gradients of ~ 15 and $10~\rm km~s^{-1}~pc^{-1}$ for the southern and northern filaments, respectively. The velocity gradients are quite comparable with the velocity gradients along small-scale filaments in other observations of massive star forming regions (Sanhueza et al. 2021; Zhou et al. 2022; Hacar et al. 2023; Xu et al. 2023b) and also in simulations (e.g. Smith et al. 2020). Through the filaments, cold unbounded gas from the envelope of the clump could be channeled to dense cores (Kirk et al. 2013), further increasing their gas masses.

4.3. Indications to high-mass star formation Models

Our observations reveal a very promising massive prestellar core (MM1-C) that seems to align with the *Turbulent Core* model. However, the presence of internal fragmentation and the identification of a cold gas filament connecting to the core (MM1-C) challenges the model's expectation of forming a high-mass star through monolithic collapse of an isolated and

centrally concentrated core. On the contrary, the presence of a cold filament seem to follow the competitive accretion scenario or other "clump-fed" models that suggest dynamical mass inflow beyond cores in high-mass star formation. However, the initial conditions in those "clump-feed" models do not favor the existence of a massive prestellar core with such a large gas mass. The complexities in our observations pose questions about the dynamics of massive star formation. The coexistence of massiveness with internal fragmentation and ongoing accretion in core MM1-C underscores the need for more comprehensive comparisons between theories and observations in future studies.

5. CONCLUSIONS

We present the new ALMA Band 6 continuum and line observations toward the G34-MM1 clump. Accompanied by ATOMS Band 3 data, we report the discovery of two massive prestellar core candidates MM1-C and E1. The line-poor spectra and the absence of outflows suggest their prestellar nature. Their total gas masses are 70 and 20 M_{\odot} for MM1-C and E1, respectively. Band 6 observations of ~ 0.43 resolution show that MM1-E1 remains a singular condensation at this resolution. On the other hand, MM1-C is found to be fragmented into two condensations C1 and C2, with mass estimates ranging 1.9–7.0 and 6.5–24.3 M_{\odot} , respectively, assuming the temperature is in the range of 6.5–14.2 K. The effective radii are 700 and 1380 au for C1 and C2, resulting in an extremely high density $n_{H_2} \sim 10^{8-9} cm^{-3}.$ Condensation C1 is found to be Jeans stable if $T_{\rm gas} \gtrsim 6.5$ K, while C2 is Jeans unstable when $T_{\rm gas} \lesssim 14.2$ K. In addition, C2 seems to have begun to further fragment into two substructures, hinting at its thermal instability. We also detected two gas filaments in N₂D⁺ line emission, one connecting core MM1-C to MM1-F, and another extending from MM1-F to the central hub region. Both filaments show a clear velocity gradient of 10–15 km s⁻¹ pc⁻¹. The core MM1-C may further accumulate gas mass along the filament.

To conclude, we detected a fragmenting massive prestellar core candidate, which may give birth to a multiple stellar system containing high-mass star(s).

APPENDIX

A. INTEGRATED INTENSITY MAPS OF CH₃OH LINES

Fig. A1 shows the integrated intensity maps of CH₃OH 4_2 - 3_1 (rest frequency: 218.440063 GHz; E_u =45.46 K) at Band 6 and another low excitation transition CH₃OH 2(1,1)-1(1,0)A (rest frequency: 97.582798 GHz; E_u =21.56 K) at Band 3. Panel (a) in Fig. A1 with negative and positive contours demonstrates that the absorption features like CH₃OH seen in the spectra in Fig. 2 could be due to the missing flux issue in interferometric observations. As shown in Panel (b), the low excitation transition line CH₃OH 2(1,1)-1(1,0)A as extended as the high excitation one shown in Panel (a), while no emission or absorption is detected toward MM1-C. That means CH₃OH is still frozen onto dust grain in such a relatively cold environment. The other molecules such as H₂CO and C¹⁸O are similar to CH₃OH toward MM1-C.

B. SPECTRA AT THE CONTINUUM EMISSION PEAK OF MM1-C1

Figure B1 presents the beam-averaged spectra at Band 6 toward the continuum emission peak of MM1-C1. No absorption features are seen in H₂CO and CH₃OH lines, indicating that there are no warm or hot continuum background sources within MM1-C1.

C. CO OUTFLOWS

To better illustrate the starless characteristics of core MM1-C, we integrated the blue and red wings of the CO high-velocity emission. As Fig. B1 shows, G34-MM1 clump shows complicated outflow activities, which will be fully explored in a forthcoming paper. However, no CO outflow emission originates from either core MM1-C or MM1-E1.
