(Dated: July 3, 2024)

The proton-proton (pp) fusion chain dominates the neutrino production from the Sun. The uncertainty of the predicted pp neutrino flux is at the sub-percent level, whereas that of the best measurement is $\mathcal{O}(10\%)$. In this paper, we present the first result to measure the solar pp neutrinos in the electron recoil energy range from 24 to 144 keV, using the PandaX-4T commissioning data with 0.63 tonne×year exposure. The pp neutrino flux is determined to be $(8.0 \pm 3.9 \, (\text{stat}) \pm 10.0 \, (\text{syst})) \times$ $10^{10} \,\mathrm{s}^{-1} \mathrm{cm}^{-2}$, consistent with Standard Solar Model and existing measurements, corresponding to a flux upper limit of $23.3 \times 10^{10} \text{ s}^{-1} \text{cm}^{-2}$ at 90% C.L..

According to the Standard Solar Model (SSM) [1–3], approximately 99% of solar power comes from a series of reactions fusing hydrogen into helium. Neutrinos emitted in the initial fusion of two protons to a deuteron constitute roughly 91% of the total solar neutrino flux. These neutrinos are commonly referred to as the pp neu-

FIG. 1. Neutrino-electron elastic scattering spectrum of solar neutrinos with liquid xenon. If the binding energy of atomic electrons (AE) is considered [18] (red curve), the scattering event rate in our region of interest is lower than the free electron (FE) scenario (green curve). The more complete treatment using the relativistic random phase approximation (RRPA) is shown in cyan, but only for a recoil energy less than 30 keV.

trinos, with a theoretical flux uncertainty at the subpercent level. The sub-dominant neutrinos from electron capture of ^7Be account for an additional 7% of the flux. The precise measurement of solar neutrino flux is essential for verifying the SSM and shedding light on the solar metallicity puzzle [4]. Solar neutrinos are also crucial for neutrino physics, especially for understanding the matter effect of neutrino oscillation [5]. The first observation of pp neutrino flux is achieved using radiochemical material of gallium by GALLEX/GNO [6] and SAGE [7]. The first real-time detection is made by Borexino with now a state-of-the-art precision of $\mathcal{O}(10\%)$ and an electron recoil energy threshold of 165 keV [8, 9]. In this paper, we present a new result to measure pp neutrino flux in real-time by PandaX-4T within a previously unaccessible recoil energy window between 24 to 144 keV. It also represents the first such measurement using a detector primarily designed for dark matter direct detection.

A number of multi-tonne-scale liquid xenon (LXe) experiments, including PandaX-4T [10], LZ [11], and XENONnT [12] are under operation to search for dark matter particles, coherent scattering of solar neutrinos on xenon nuclei [13, 14], and possible abnormal magnetic moments of neutrinos [15–17] in the few or few-tens of keV-scale electron or nuclear recoil energy. By design, these detectors also effectively cover an electron recoil energy up to several hundred keV, spanning over most of the energy region of the *pp* neutrino.

The solar pp neutrinos have a continuous energy spectrum with an endpoint at 420 keV. The ⁷Be neutrinos are mono-energetic at 384 keV (approximately 10%) and

FIG. 2. The energy resolution using characteristic peaks at 41.6 keV, 163.9 keV, 208.1 keV, and 236.1 keV. The red curve shows the fit function $\sigma/E = 0.40/\sqrt{E \,[\text{keV}]} + 0.0061$.

862 keV (90%). The neutrino and electron interact via the electroweak force through the exchange of a Z or W boson, the latter of which is only possible for an electron neutrino. The expected electron recoil event rate per unit recoil energy is

$$\frac{dR}{dE_r} = N \sum_j \int \phi(E_\nu) P_{ej} \frac{d\sigma_j(E_\nu, E_r)}{dE_r} dE_\nu , \qquad (1)$$

where N is the number of target electrons, $\phi(E_{\nu})$ is the neutrino flux as a function of neutrino energy, P_{ej} $(j = e, \mu, \tau)$ is the oscillation probabilities of ν_e into flavor j and $d\sigma_j$ is the differential cross-section. Fig. 1 shows the electron recoil energy spectrum of solar pp and ⁷Be neutrinos in a LXe detector, as given in Ref. [18]. When the xenon atomic effects are considered (adopted in this paper), the rate in the region of interest (ROI) is suppressed by a few percent compared to the free electron scenario.

The PandaX-4T detector is located in the B2 hall of the China Jinping Underground Laboratory [19, 20]. The sensitive target of PandaX-4T contains 3.69 tonne of liquid xenon in a cylindrical dual-phase xenon time projection chamber (TPC) with 118.5 cm in diameter and 116.8 cm in height [21]. The prompt scintillation photons (S1) and the delayed electroluminescence photons (S2)are produced when a given energy is deposited in the sensitive volume. Both S1 and S2 signals are recorded by the top and bottom photomultipliers (PMT) arrays, which have 169 and 199 Hamamatsu 3-inch PMTs installed. Detailed discussions of the PandaX-4T detector can be found in Ref. [10].

This analysis selects different data samples compared to existing analyses of the commissioning data release [10, 13, 22]. The energy ROI is from 24 keV to 144 keV, with more than 60% of the solar pp neutrino events included.

The lower boundary is chosen to be above the dark matter particle search region and the upper boundary is to avoid the prominent 163.9 keV peak from 131m Xe produced in the neutron calibration runs. In the ROI, the detector noise has a negligible effect on both S1 and S2 signals. Therefore, we can recover approximately 9.5% of exposure previously excluded in the dark matter analysis due to elevated detector noise [10]. On the contrary, 8.4 days of data following a neutron calibration run is removed because of a high concentration of activated ¹³³Xe and ¹²⁵I. In the end, a total data set of 86.5 days is used for this analysis.

The PMT gains are calibrated with a newly implemented "rolling gain" approach, which fits single photoelectron (SPE) spectra in individual PMTs run by run, adopted already in recent Ref. [21]. Our previous analyses calculated PMT gains with weekly light-emittingdiode (LED) calibration. To avoid biases in our data selections, selection cuts are first determined with LEDgain calibration data, validated with about 13.5 days of rolling gain physics data, and finally applied to the entire data set.

The quality cut variables are inherited from the dark matter analysis [10], but cut parameters are modified to suit the differing energy window. The main difference is the relaxation of the top and bottom PMT charge ratio requirement in the S2 signal selection to accommodate the top S2 saturation. The total quality cut efficiency is $(99.1 \pm 0.1)\%$. The scattering of solar *pp* neutrinos on electrons is primarily single-site (SS). The identification of SS events follows the same procedure as in Ref. [10]. The SS efficiency is $(99.7 \pm 0.1)\%$, calculated using the ²²⁰Rn calibration and consistent with simulation.

The horizontal position reconstruction follows the same procedure in Ref. [21], where de-saturated waveforms and improved optical Monte Carlo simulation are used. The reconstruction uniformity is confirmed with the diffusive ^{83m}Kr calibration source injected into the TPC [23]. The mono-energetic peak of ^{83m}Kr is also used to generate an energy response map. The corresponding correction procedure follows Ref. [10].

The energy in LXe TPC is reconstructed as in Refs. [24, 25]. The energy spectrum is further corrected using a quadratic function between reconstructed energy and true energy of characteristic peaks at 41.6 keV (83m Kr), 163.9 keV (131m Xe), 208.1 keV (127 Xe), and 236.1 keV (129m Xe and 127 Xe). After the correction, the residual offset of energy peaks in the ROI is smaller than 1 keV, which is considered as the systematic uncertainty of the energy reconstruction. The relative 1 σ energy resolution at 24 keV (144 keV) is 8.8% (3.9%), as shown in Fig. 2.

The fiducial volume (FV) cuts and events in the ROI are shown in Fig. 3 as dashed lines and blue dots, respectively. The FV selection is the same as in the dark matter analysis geometrically, and a total of 2.66 ± 0.02 tonne of LXe in the center of the TPC is used. The slight differ-

FIG. 3. The spatial distributions of the selected physics events in Z vs. R^2 (top) and Y vs. X (bottom). The dashed lines show the boundary of the fiducial volume, and blue (gray) dots represent events inside (outside) the fiducial volume.

ence with respect to Ref. [10] is from the event position reconstruction.

The primary challenge in this analysis lies in the accurate rate estimation of various background components with smooth energy spectra that resemble the shape of the solar pp signals. The background sources in the ROI include radon and krypton impurities in liquid xenon, detector materials, and radioactive xenon isotopes. The expected background sources are listed in Table I and described below.

One major background in the ROI arises from the progeny of the internal 222 Rn – the β decay of 214 Pb to the ground state of 214 Bi [21]. The ratio of the events in the ROI to the full SS energy spectrum of 214 Pb β decay is determined by a dedicated 222 Rn injection cali-

bration run, with 3.5×10^5 ²¹⁴Pb SS events accumulated over approximately 11 days. The event ratio is measured to be 0.039 ± 0.001 , with the uncertainty estimated based on the difference between our data and a recent theoretical prediction to accommodate the non-unique first-forbidden nature of the ²¹⁴Pb decay [26]. The corresponding number of 214 Pb events in the ROI is 1865 ± 110 , in which the uncertainty combines both the fitted uncertainty of the overall ²¹⁴Pb decay rate in the physics data [21] and the uncertainty of the event ratio within our ROI. Also along the decay chain of 222 Rn, the β decay of ²¹⁴Bi can be identified effectively using the ²¹⁴Bi-²¹⁴Po coincidence, as the half-life of 214 Po is 164 μ s. In our analysis, when a ²¹⁴Bi-like event is found, we reject the event if an α event is found within the following 5 ms window. The residual $^{214}\mathrm{Bi}$ is no longer included in the spectrum fit. The loss of live time due to random coincidence is negligible.

The expected contribution from the β decay of ²¹²Pb in the ²²⁰Rn decay chain follows the approach in Ref. [21]. The ratio between ²¹²Pb and the subsequent ²¹²Po α events is determined using a ²²⁰Rn injection calibration run. Then using the ²¹²Po α events identified in the physics data, ²¹²Pb events in the ROI is estimated to be 276 ± 71, where the uncertainty is dominated by the variation of ²¹²Pb/²¹²Po ratio during the ²²⁰Rn injection run.

The concentration of 85 Kr is estimated to be 0.52 ± 0.27 parts per trillion [21], leading to 489 ± 254 events in the ROI. The levels of radioactivity from PMTs and detector vessels have been determined from the wide energy spectrum fit in Ref. [22], resulting in 683 ± 27 events. The expected background from 136 Xe $2\nu\beta\beta$ is 1009 ± 46 in the ROI, given by the half-life measured by the PandaX-4T experiment with an exposure of 15.5 kg×year of 136 Xe isotope [22].

The contributions of 133 Xe, 127 Xe, 125 I, and 124 Xe are free and fitted in the final spectral analysis, as they cannot be constrained by our data outside the ROI. The energy spectrum of ¹³³Xe, activated during a neutron calibration run, has a distinctive rising slope starting at 81 keV. Cosmogenic ¹²⁷Xe, introduced when some xenon exposed at the Earth's surface was filled into the detector, contributes to the background with K-shell electron capture around 33.2 keV. Neutron-activated 125 Xe decays quickly to the relatively long-lived ¹²⁵I with a half-life of 59.4 days. ¹²⁵I electron capture can release a total energy of 67.3 keV (K-shell), 40.4 keV (L-shell), and 36.5 keV (M-shell) [27]. The reduction rate of 125 I observed in the TPC is significantly more rapid than the natural lifetime of ¹²⁵I, likely due to the removal by the xenon circulation and purification system. Two-neutrino double-electron capture of ¹²⁴Xe (abundance $\eta = 0.095\%$, Q = 2857 keV) deposits energy within our ROI at 64.3 keV (KK-shell) and 32.3 - 37.3 keV (KL, KM, and KN-shells) [27, 28]. Therefore, ${}^{125}I$ (${}^{124}Xe$) events in the data are modeled as

TABLE I. Expected and fitted background and signal events in the ROI. Note that the fitted uncertainties contains both the statistical and some systematic components. See text for details.

Components	Expected events	Fitted events
²¹⁴ Pb	1865 ± 110	1849 ± 113
²¹² Pb	276 ± 71	271 ± 80

133 Xe	free	4767 ± 135
124 Xe	free	317 ± 63
^{125}I	free	31 ± 57
127 Xe	free	59 ± 23
$pp+^7$ Be neutrino	-	231 ± 257

three (four) Gaussian peaks with relative areas fixed by the capture fractions and widths fixed by the resolution function (Fig. 2), but the overall normalization as a free fit parameter.

The spectrum fit is based on a binned likelihood procedure using the RooFit package [29]. Each background component is simulated using BambooMC [30], a Monte Carlo simulation package based on the Geant4 framework [31]. The contributions from ²¹⁴Pb, ²¹²Pb, ⁸⁵Kr, detector materials, and ¹³⁶Xe are constrained using the uncertainties described earlier and listed in Table I. The normalizations of ¹³³Xe, ¹²⁷Xe, ¹²⁵I, and ¹²⁴Xe are kept free in the fit. The sum of solar *pp* and ⁷Be neutrino signals are combined into a single fit component.

The result of the spectrum fit is shown in Fig. 4. The number of solar pp + ⁷Be neutrino signals is 231 ± 257 events. Consistent results are obtained with a binned likelihood fit similar to that implemented in Ref. [22]. The fitted results of each background are listed in Table I. The best-fit background contributions from detector materials, ⁸⁵Kr, ²¹⁴Pb, and ²¹²Pb are very close to the input nominal values, indicating that the spectrum fit does not try to drive these background levels up and down, since their shape characters are similar.

The total uncertainty of the $pp + {}^{7}\text{Be}$ neutrino signals is broken down into three terms (Table II), the statistical uncertainty (σ_{stat}), the systematic uncertainty incorporated in the likelihood fit with nuisance parameters (σ_{sys1}), and additional systematic uncertainty evaluated by hand (σ_{sys2}). We shall discuss them in turn below.

The statistical uncertainty σ_{stat} is determined to be 113 events, by re-fitting the data with all constrained parameters fixed to their best-fit values without the penalty terms. The overall size of σ_{sys1} is then evaluated as $\sqrt{\sigma^2 - \sigma_{\text{stat}}^2}$ to be 231 events, representing the residual component of the fit uncertainty. To quantify the contribution to σ_{sys1} due to a given component (assuming that it is uncorrelated with the rest), we use a similar approach by refitting the data by only "tuning on" the nuisance parameter of this component, and all other nuisance parameters fixed to their best-fit values. The resulting fit uncertainty is then subtracted by σ_{stat} in quadrature. Individual contributions thus evaluated are also summarized in Table II. Among all constrained backgrounds, ⁸⁵Kr, ²¹⁴Pb and ²¹²Pb dominate the contribution to σ_{sys1} with an uncertainty of 202, 87, and 69 events, respectively. The uncertainties of data selection, including the FV, quality cuts, and the SS fraction, affect the signal number proportionally with an estimated uncertainty of 29 events.

Additional systematic uncertainties $\sigma_{\rm sys2}$ are evaluated manually. The uncertainty from the reconstructed energy scale is determined by comparing the baseline fit result with new fit results, obtained by shifting the data energy spectrum by ± 1 keV. The larger difference led by the shifts is 142, which is used as the uncertainty. To evaluate the contribution due to the energy resolution uncertainty, we perform the fit by imposing different background spectra with different energy resolution. A $\pm 1\sigma$ difference in the energy resolution function propagates into an uncertainty of 19 events. The fit range uncertainty is evaluated to be 29 events by varying the ROI to 25 - 143 keV and 23 - 145 keV. The uncertainty introduced by the ²¹⁴Pb spectrum shape estimated to be 84 events, by comparing the theoretical spectrum in the baseline fit to the shape directly measured in the calibration data. Similarly, the spectral shape differences between the Geant4 [30] prediction and a recent theoretical calculation of ²¹²Pb and ⁸⁵Kr [26] are also considered, and the systematic uncertainties are found to be 18 and 5, respectively. We also fit the data by taking the half-life of 136 Xe $2\nu\beta\beta$ from EXO-200 [32], the most precise result so far, as the input value. This results in a difference of 16 events in comparison to our baseline fit, which is also taken as a component of systematic uncertainty. In total, σ_{sys2} is 170 events.

Therefore, the final detected number of $pp + {}^{7}\text{Be}$ neutrinos is $231 \pm 113 \text{ (stat)} \pm 287 \text{ (syst)}$ events from our analysis. The corresponding solar pp neutrino flux is $(8.0 \pm 3.9 \text{ (stat)} \pm 10.0 \text{ (syst)}) \times 10^{10} \text{ s}^{-1} \text{cm}^{-2}$, using the expected ratio of the pp to ${}^{7}\text{Be}$ fluxes from SSM and their contributions to the ROI. The result is consistent with the SSM expectation [4] and the Borexino measurement [9], as shown in Fig. 5. Based on this, we obtain a pp neutrino flux upper limit of $23.3 \times 10^{10} \text{ s}^{-1} \text{cm}^{-2}$ at 90% C.L..

This analysis represents the first result to directly measure the solar pp neutrinos at an electron recoil energy below 150 keV. It demonstrates the potential of multitonne-scale LXe detectors for solar neutrino studies in a completely new energy window. With an optimized online cryogenic distillation system, we expect to reduce the radon and krypton concentration by a factor of 1.8 or more [33]. Additional efforts, such as replacing TPC materials and circulation pumps, are being implemented for

TABLE II. Summary of contributions to the pp + ⁷Be neutrino signal uncertainties. The contribution of each constrained parameter is extracted by turning on/off the corresponding penalty term in the fitter, assuming no correlation with other constraints. As a result, the quadrature combination of those rows is slightly different from the subtotal σ_{sys1} obtained directly by the fitter with all correlations properly built in.

background reduction. Additional ²²²Rn calibration data and improved detector response with upgraded PMT readout circuit boards are expected to significantly reduce systematic uncertainties. Assuming a ²²²Rn level of $3.5 \ \mu$ Bq/kg, a krypton-to-xenon mole concentration of 0.25 ppt, and no short-lived xenon isotopes being activated, and imposing a 5% constraint on all backgrounds, PandaX-4T can measure the solar *pp* neutrinos with an

FIG. 5. The solar pp neutrino flux measured by PandaX-4T (red), in comparison to those from gallium experiments [34] and Borexino [9]. The vertical dashed line is the average pp neutrino flux from the high-metallicity and low-metallicity SSM [4]. The PandaX-4T projection with 6 tonne×year exposure is indicated at the bottom (centered at the SSM).

uncertainty of 30% with 6 tonne×year exposure.
