#### Abstract

Economic structure comparisons between China and Japan have long captivated development economists. To delve deeper into their sectoral differences from 1995 to 2018, we used the annual input-output tables (IOTs) of both nations to construct weighted and directed inputoutput networks (IONs). This facilitated deeper network analyses. Strength distributions underscored variations in inter-sector economic interactions. Weighted, directed assortativity coefficients encapsulated the homophily among connecting sectors' features. By adjusting emphasis in PageRank centrality, key sectors were identified. Community detection revealed their clustering tendencies among the sectors. As anticipated, the analysis pinpointed manufacturing as China's central sector, while Japan favored services. Yet, at a finer level of the specific sectors, both nations exhibited varied structural evolutions. Contrastingly, sectoral communities in both China and Japan demonstrated commendable stability over the examined duration.

Keywords: community detection; dynamical analysis; input-output table; key sector identification; network analysis; strength distribution

# 1 Introduction

China and Japan are both major players in the global economy. While China has a larger economic scale and faster growth rate, Japan has a more advanced industrial structure and higher labor productivity (Chansarn, 2010). As of 2022, China's Gross Domestic Product (GDP) in current prices was 18.32 trillion US dollars (USD), with 12,970 USD per capita; Japan's GDP was 4.3 trillion USD, with 34,358 USD per capita (International Monetary Fund, 2023). The service sectors hold a larger share in Japan's economy at 69.5%, compared to China's 54.5%, indicating that Japan's sectoral structure is more advanced (Chenery et al., 1986). Although China and Japan follow distinct development paths and possess different natural resources, there are intriguing parallels between China's recent economic growth and Japan's historical development, suggesting that potential lessons from Japan's experience could benefit China (Minami and Ma, 2010; Fukumoto and Muto, 2012). For example, the move from a manufacturing-based economy to a knowledge- and service-based economy was vital for Japan to maintain its economic momentum (Alvstam et al., 2009); the structural problems due to the aging demographic in Japan led to sluggish economic growth and recession since the early 1990s (Yoshino and Taghizadeh-Hesary, 2016). Many insights and lessons from Japan could be learned by China to prolong its economic growth and prevent long-term recessions through comparing the economic structures of China and Japan over time (e.g., Fujita et al., 2004; Ogunmakinde, 2019).

While there is a plethora of research focused on the economies of China and Japan, comparative studies on their sectoral structures remain sparse. The existing literature extensively covers various facets of both economies, encompassing trade relationships (Howe, 1990; Marukawa, 2012; Katz, 2013), economic influences in other regions (Dreger and Zhang, 2014; Wang and Wang, 2022), investment strategies (Fung et al., 2002; Katada and Liao, 2020), and financial markets (Okimoto, 2009; Schnabl, 2017). However, direct juxtapositions of their sectoral structures are notably limited. Of the few studies that exist, the majority lean on traditional input-output table (IOT) methodologies (Leontief, 1963; Miernyk, 1965). For instance, Min et al. (2019) delved into the industrial spillover effects between the two nations, while Liu (2018) spotlighted their core industrial structures. Surprisingly, network analysis tools, which are inherently suited for IOT analyses, have been underutilized in this comparative context. A rare exception is Li et al. (2017), but their scope was confined to quantitatively probing evolutionary trends in industrial structures.

A modern and powerful tool to analyze IOTs is network analysis (e.g., Newman, 2003; Boccaletti et al., 2006) since an IOT naturally defines an input-output network (ION). By converting the IOT's sectors into nodes and transaction flows into edges, it facilitates the creation of an economic network graph, thereby illuminating the intricate relationships and dependencies intrinsic to the ION (Schweitzer et al., 2009; Contreras and Fagiolo, 2014; Xu and Liang, 2019; Wang et al., 2021; Li et al., 2022). The salient advantages of this approach include its ability to vividly present data, translating input-output information into intuitive and comprehensible graphical forms (Cruz et al., 2014). Moreover, it offers a deeper understanding of sectoral interdependencies, extending beyond the simple metrics of traditional input-output analysis. This depth encompasses global metrics, such as directed strength distributions and weighted, directed assortativities, and sector-specific centrality measures. Finally, network analysis introduces novel techniques for pinpointing key sectors and discerning sectoral clusters, techniques that eclipse traditional input-output methodologies (Muñiz et al., 2008; Xiao et al., 2022). The key sector identification further allows for a tailored approach where key sector identification can be adapted based on specific analytical objectives in centrality metrics (Zhang et al., 2022; Xiao et al., 2022). Embracing all these network analytic tools provides an unparalleled framework for comparing the sectoral architectures of nations based on their IONs.

This paper compares the sectoral structures between China and Japan, leveraging both traditional and newly developed network analysis methodologies. While existing research in this domain has primarily focused on degree distribution and key sectors, these studies often overlook the directionality and weight of IONs. Moreover, they tend to bypass auxiliary information when identifying key sectors and largely omit sectoral clustering within IONs. To address these gaps, we harness IOTs from China and Japan spanning 1995–2018, presenting three major contributions. First, we juxtapose the characteristics of inter-sectoral connections in both nations, focusing on node strength distribution and the cutting-edge concept of weighted, directed assortativity coefficients (Yuan et al., 2021), along with jackknife standard deviations (Lin et al., 2020). Second, we identify the top five key sectors and trace their evolution in both countries, drawing upon the recently introduced PageRank (PR) centrality measure (Zhang et al., 2022). Lastly, we group tightly-knit sectors into communities using an optimal modularity algorithm tailored for weighted, directed networks (Newman, 2006), and assess the similarities of the community structures over time in each nation. Together, our analyses furnish a comprehensive understanding of China and Japan's sectoral dynamics, elucidating their distinctions from a network vantage.

The paper is structured as follows. Section 2 introduces the IOT data source and the resulting IONs. In Section 3, we compare the strength distributions of sectors between China and Japan. Section 4 investigates the assortative characteristics of sector connections while taking uncertainties into account with a jackknife approach. Section 5 ranks important sectors in each country by a PR centrality measure that incorporates auxiliary information. Section 6 compares clusterings of sectors through community detection. Finally, Section 7 concludes with a discussion.

# 2 ION data

An IOT is a valuable tool for analyzing the interdependent relationships and structures between different sectors within an economy by tracking the monetary transactions between them. The basic structure of an IOT for an economy with  $n$  sectors is shown in Table 1. The IOT consists of three parts: (1) the intermediate use matrix  $W := (w_{ij})_{n \times n}$ , where  $w_{ij}$ denotes the cost of the products or services that sector i provides to sector j,  $i, j \in \{1, \ldots, n\}$ ,

			Intermediate use	Final use	Total output		
		Sector 1	$\cdots$	Sector $n$			
	Sector 1						
Intermediate input			W		$\boldsymbol{F}$	Y	
	Sector $n$						
Value added		$X^{\top}$					
Total input							

Table 1: Fundamental structure of a national IOT.

and each row i and column j contain the amount of value that sector i provides to and consumes from other sectors, respectively; (2) the final use  $F := (f_i)_{n \times 1}$ , which is the horizontal extension of  $W$ , with each  $f_i$  represents the product produced by sector  $i$  for consumption, investment, and net export; and (3) the value added  $X^{\perp} := (x_j)_{n \times 1}^{\perp}$ , which is the vertical extension of W, with each  $x_j$  represents the value-added by sector j. The total output, which equals the total input, is represented by  $Y := (y_i)_{n \times 1}$ . The table satisfies both row and column balance, with the former stating that total output equals the sum of intermediate use and final use for each sector, and the latter indicating that total output equals the sum of intermediate use and value added for each sector.

The intermediate use matrix W of an IOT defines a weighted, directed ION  $G(V, E, W)$ , where each node  $v_i \in V$  represents a sector and each edge  $e_{ij} \in E$  represents a transaction from the source sector i to the target sector j with a weight of  $w_{ij}$ . The edge structure of the ION is described by the adjacency matrix  $A := (a_{ij})_{n \times n}$ , where  $a_{ij} = 1$  if  $e_{ij} \in E$  and  $a_{ij} = 0$ otherwise. Analyses of the IONs determined by the IOTs provide a network perspective in studying the sectoral transaction structures of economies, and can provide insights into topics such as propagation of economic shocks and the role of sectors in the overall economy (e.g., Contreras and Fagiolo, 2014).

To examine the sectoral structures of China and Japan, we must construct IONs from consistent IOTs. However, direct comparisons using each country's IOTs are problematic: China updates its IOT every five years, the most recent one for 2017 (National Bureau of Statistics of China, 2023), whereas Japan's data is available for 2005, 2011, and 2015 (Ministry of Internal Affairs and Communications of Japan, 2019). Additionally, the unique economic landscapes and sectoral details in each country mean their IOTs feature different sector configurations. International IOT databases, like the World Input-Output Database (WIOD) (Timmer et al., 2015) and the Asian Development Bank's Multiregional Input-Output database (ADB-MRIO) (Asian Development Bank, 2023), offer alternative sources. The diagonal blocks of these international IOTs can be used to construct individual national IOTs. However, these too have limitations; for instance, the WIOD only spans 2000–2014; and the ADB-MRIO database covers 35 sectors, while China's data includes only 33 of these sectors.

The IOTs that we used are from the STructural ANalysis (STAN) database, a valuable resource for IOTs from many countries (Organisation for Economic Cooperation and Development, 2021). Based on the International Standard Industrial Classification of all economic activities, Revision 4 (ISIC Rev.4) (United Nations, 2008), the current version of the STAN database includes annual IOTs with 45 sectors in a unified form for member countries. The STAN database was constructed using annual national accounts by activity tables from member countries, and other data sources such as national industrial surveys and censuses were used to estimate missing quantities (Antràs et al., 2012). Transaction amounts are reported in USD of 2015, and data is available from 1995 to 2018. The data from China and Japan are publicly available in the R package **ionet** (Xiao et al., 2024). However, it should be noted that the 45th sector, "activities of households as employers; undifferentiated goodsand services-producing activities of households for own use", is missing for both China and Japan, resulting in 44 sectors for their respective IONs. A description of the 44 sectors used in the analyses for China and Japan from 1995 to 2018 is provided in Table 3 in the Appendix A. Based on the STAN database, we constructed IONs of both countries including 44 sectors form 1995 to 2018.

Figure 1: Half-violin plots with boxplots overlaid, for in-, out- and total-strength (in million USD of the 2015 price on the log scale) of the IONs of China and Japan in 1995, 2007 and 2018.

# 3 Node strength analysis

We begin by examining the differences in the node strength distribution. For a directed and weighted network, the strength of a node  $i$  can be partitioned into its in-strength and out-strength, which represent the total weight of incoming and outgoing edges, respectively. Specifically, we define  $s_i^{\text{in}}$  and  $s_i^{\text{out}}$  as the sums of weights of all edges that are incoming to and outgoing from node *i*, respectively. In the context of IONs,  $s_i^{\text{in}}$  and  $s_i^{\text{out}}$  correspond to the total monetary input and output, respectively, that sector  $i$  receives from and supplies to other sectors. We can also define the total strength of a node as  $s_i = s_i^{\text{in}} + s_i^{\text{out}}$ .

Figure 1 displays half-violin plots (Tiedemann, 2022) of the in-, out-, and total-strength for 44 sectors of China and Japan in 1995, 2007, and 2018, measured in millions of USD in 2015 price and using a log scale. In 1995, the distributions of all three strengths overlapped, but with Japan's distribution clearly shifted to the right, indicating larger monetary linkages between sectors in Japan compared to China. By 2007, the two countries' distributions largely overlapped, but with China's distributions now slightly to the right of Japan's. By 2018, the overlapping areas decreased significantly, and China's distributions were considerably shifted to the right of Japan's, suggesting that between-sector economic flows in China had surpassed those in Japan. Vertical comparisons across years reveal little change in the strength distribution for Japan, but notable increases for China. These increases reflect the rapid growth of China's economy, leading to expansion in the sizes of its sectors and between-sector connections.

Chord plots (Gu et al., 2014), as seen in Figure 2, effectively visualize the nuanced intersectoral connections in the IONs of both China and Japan for 1995 and 2018. Each uniquely colored outer arc corresponds to a sector, with its width indicating the sector's total strength. Connecting chords symbolize inter-sectoral flow, their bandwidths being proportionate to the strengths, and their colors matching the source sectors. A few observations stand out. In both years, manufacturing holds a larger chunk of China's total strength than Japan's. Conversely, Japan's service industry dominates in total strength over China's. Sectorally, China's "agriculture, hunting, forestry" (01) claims a more significant share than in Japan, a share which grew by 2018. Meanwhile, Japan's "wholesale and retail trade; repair of motor vehicles" (26) takes the lead. Examining supply, or sectoral out-strength, China's primary contributors include "basic metals" (15), "agriculture, hunting, forestry" (01), "wholesale and retail trade; repair of motor vehicles" (26), and "chemical and chemical products" (11). For Japan, leading sectors are "wholesale and retail trade; repair of motor vehicles" (26) and "basic metals" (15). From a demand perspective (in-strength), "construction" (25), "food products, beverages and tobacco" (06), and "basic metals" (15) are predominant in China, whereas in Japan, "wholesale and retail trade; repair of motor vehicles" (26), "motor vehicles, trailers and semi-trailers" (20), and "construction" (25) lead. In general, sectoral linkages in two countries have distinct characteristics, necessitating detailed network analyses for a

Figure 2: ION visualization of China and Japan in 1995 and 2018. The width of the chord connecting the arcs is directly proportional to the magnitude of economic flow. Longer arcs represent greater outputs. The unit of economic flow is 100 billion USD of the 2015 price.

comprehensive quantitative assessment.

## 4 Assortative mixing properties

The assortativity of a network measures the homophily of a network, that is, the tendency of nodes to connect with similar partners in a network. A commonly used assortativity measure is the degree-degree correlation (Newman, 2002), which is easily adapted to total strength assortativity by replacing the degrees with strengths. Since IONs are directed and weighted, we further use a class of weighted, directed assortativity measures calculated with node strengths (Yuan et al., 2021):

$$
r_{\alpha,\beta} = \frac{\sum_{i,j \in V} w_{ij} \left(s_i^{(\alpha)} - \bar{s}_{\text{sou}}^{(\alpha)}\right) \left(s_j^{(\beta)} - \bar{s}_{\text{tar}}^{(\beta)}\right)}{\sqrt{\sum_{i,k \in V} w_{ik} \left(s_i^{(\alpha)} - \bar{s}_{\text{sou}}^{(\alpha)}\right)^2} \sqrt{\sum_{k,j \in V} w_{kj} \left(s_j^{(\beta)} - \bar{s}_{\text{tar}}^{(\beta)}\right)^2}},
$$

where  $s_i$  and  $s_j$  is the pair strengths of nodes i and j corresponding to edge  $e_{ij}$ ,  $(\alpha, \beta) \in$ {in, out} index strength type, and

$$
\bar{s}_{\text{sou}}^{(\alpha)} = \frac{\sum_{i,j \in V} w_{ij} s_i^{(\alpha)}}{W_n} \quad \text{and} \quad \bar{s}_{\text{tar}}^{(\beta)} = \frac{\sum_{i,j \in V} w_{ij} s_j^{(\beta)}}{W_n}
$$

are the weighted mean of the  $\alpha$ -type strength of the source nodes and the  $\beta$ -type strength of the target nodes, respectively, with  $W_n := \sum_{i,j \in V} w_{ij}$ . The value of  $r_{\alpha,\beta}$  is between -1 and 1. An implementation of the weighted, directed assortativity is available in the open-source R package wdnet (Yuan et al., 2023).

The directed assortativity coefficients provide a nuanced perspective on node connection attributes, going beyond the general assortativity coefficients based solely on total strength. In the context of IONs, assortativity assesses the preference of one sector with certain sector-level feature channels products to another sector with another sector-level feature. The features of the supplying sector and the receiving sector do not have to be the same feature. We consider here only two features in-strength and out-strength. Positive assortativity coefficients signify assortative-mixing, suggesting that nodes with higher strength tend to connect with similarly strong nodes. In contrast, negative values indicate disassortative-mixing, where high-strength nodes connect with weaker ones. For instance, a positive out-in assortativity coefficient means sectors with significant out-strength tend to channel their products to sectors with high in-strength. Conversely, a negative out-out assortativity coefficient suggests sectors with large out-strength are more inclined to direct their products to sectors with low out-strength. Other assortativity types can be understood in a similar vein.

In empirical studies, assessing the uncertainty of sample assortativity coefficients is as crucial as it is in simple correlation analysis. Unfortunately, past analyses often neglected to incorporate uncertainty measures (e.g., Cerina et al., 2015), limiting the depth of discussions about assortativity coefficients' temporal evolution. Some changes over time that seem dramatic might actually be minor when considering confidence intervals. To address this oversight, we calculated the standard errors of the sample assortativity coefficients using a recently developed jackknife approach tailored for networks (Lin et al., 2020). This method involves repeatedly calculating the assortativity of networks obtained by omitting one sector at a time, along with its associated edges, from the observed network.

Figure 3 showcases the assortativity coefficients for five types, accompanied by their one-standard deviation error bars, for both China and Japan from 1995 to 2018. A salient disparity in the assortativity coefficient values between the two countries is evident. For China's IONs, all five assortativity coefficients lie between 0.10 and 0.25. Given the minuscule standard deviations resulting from the jackknife procedure, these coefficients are distinctly positive. This positive assortative mixing indicates that sectors in China with a higher out/in/total strength tend to direct their products more towards sectors with a correspondingly high out/in/total strength, as opposed to those with a lower strength.

In contrast, Japan presents a more varied landscape. While the in-in assortativity coeffi-

Figure 3: Weighted and directed assortativity coefficients of the IONs from China and Japan from 1995 to 2018. Error bars depict the range of one standard deviation above and below the sample assortativity coefficients, derived from a jackknife procedure.

cients are significantly positive post-2002, their magnitudes are subdued compared to those of China, peaking in 2008 before observing a marked decline-potentially an aftermath of the global financial crisis. The in-out, out-in, and out-out coefficients, although positive, achieve statistical significance only in 2008, followed by a substantial reduction. This suggests a more nuanced, potentially non-obvious, assortative pattern in Japan. The total assortativity coefficients for Japan even venture into the negative spectrum, especially prominent up to 2002. Their modest absolute values, around 0.05, hint at a slight inclination for high total-strength nodes to associate with nodes of a lower total-strength. Further distinguishing the two nations is the higher standard deviation of Japan's coefficients. Such a variance indicates a more pronounced homogeneity in China's sectoral connections: removing a single sector in China's network results in comparatively minor shifts in its assortativity coefficients than in Japan.

The temporal progression of assortativity coefficients over the years brings forth insightful revelations. Japan's IONs witnessed an uptrend in all directed assortativity metrics until 2008, with in-in assortativity being particularly pronounced. However, total assortativity remained relatively stable with a mild negative inclination. Post-2008, a marked decline in directed assortativity metrics is evident, a testament to the profound impact of the 2008 global financial crisis on Japan. The crisis ostensibly disrupted the congruence of sectoral supply chains and sectoral clusters within the nation (Grimes, 2009). Given Japan's deep integration into global economic operations, its susceptibility to international shocks became manifestly evident.

Conversely, China's trajectory over the years offers a more intricate tale. While the trends in the four directed assortativity metrics are not obvious, there are exceptions that punctuate the narrative. Notably, 2003 saw a spike in both in-in and out-in assortativities, likely a reverberation from China's induction into the World Trade Organization two years prior. This inclusion could have catalyzed an uptick in foreign demand, subsequently fueling the expansion of domestic production scales and fortifying the supply chain (Andersen et al., 2014). Another conspicuous deviation is observed in 1998 with a surge in in-out and outout assortativities. This can be traced back to China's nimble response to the 1997 Asian financial crisis. Decisive interventions by the Chinese government, encompassing proactive fiscal policies complemented by circumspect monetary strategies, invigorated domestic demand. This likely culminated in more robust supply-centric sectoral chain (Wang, 1999). However, given that the preponderant demand was steered by policy-induced infrastructural investments during this epoch (Li, 2000), this ascent proved ephemeral.

#### 5 Key sectors identification

Key sectors often underpin the growth and evolution of economies (Sonis et al., 1995). Recognizing their pivotal role, governments may shape policies to bolster these sectors. However, this necessitates an astute method for their identification, with many turning to the centrality measures of IONs as a practical solution (e.g., Hewings, 1982; DePaolis et al., 2022). While a myriad of centrality definitions exists (e.g., Bonacich, 1987; Brin and Page, 1998; Newman, 2001; Barrat et al., 2004), it is vital to note that IONs are weighted and directed networks. Moreover, they offer supplementary data beyond the intermediate flow matrix, such as sector-level value added and final use showcased in Table 1. Therefore, a centrality measure that accommodates both node weight and edge direction, supplemented by auxiliary IOT variables, is desired.

We utilized an extended PR measure tailored for weighted, directed networks, integrating auxiliary ranking information as detailed by Zhang et al. (2022). Specifically, the PR measure of node i is

$$
P_i = \gamma \sum_{j \in V} \frac{w_{ji}}{s_j^{(\text{out})}} P_j + \frac{(1 - \gamma)\lambda_i}{\sum_{i \in V} \lambda_i}, \qquad i = 1, \dots, n,
$$

where  $\lambda_i$  is an auxiliary measure (which could be internal or external to the network structure) of the relative importance of node i, and  $\gamma \in [0,1]$  tunes the relative importance of the auxiliary measure. When all  $\lambda_i$ 's are equal, this measure reduces to a weighted PR (Ding, 2011). When, additionally,  $w_{ji}$  is replaced with  $a_{ji}$  and out-strength  $s_j^{(out)}$  with out-degree, the measure further reduces to the standard PR (Page et al., 1998). The influence of the auxiliary variable  $\lambda_i$  operates in a scale-free manner; the contribution  $\lambda_i$  to the PR lies in its proportional contribution to the entire economy rather than its absolute value.

In the standard PR,  $\gamma$  serves as a damping factor that prevents the iteration for eigenvector in the algorithm from getting stuck in sinking nodes (those without outgoing edges). Typically, a value of  $\gamma = 0.85$  is adopted, as recommended by Page et al. (1998). In the context of the extended PR (Zhang et al., 2022), a sector attains a high PR score if it possesses a prominent auxiliary ranking, if it has substantial incoming edge weights, or if its immediate upstream sectors exhibit high PR scores. Our investigations indicated that setting  $\gamma = 0.85$ strikes a desired balance between the ION and the auxiliary metric. A lower  $\gamma$ , like 0.5, would overly emphasize the auxiliary variable; see Section 1 in the Supplementary Material for a comparison. The results reported next were obtained with  $\gamma = 0.85$  as implemented in the R package wdnet (Yuan et al., 2023).

The selection of the auxiliary variable, represented by  $\lambda_i$ 's depends on the research objectives. For instance, in labor economics, one might opt for sectoral employment scale as

Figure 4: Bar plots of the share of valued added of each sector in the GDP in China and Japan in 1995 and 2018.

the auxiliary data, whereas in innovation economics, the sectoral research and development expenditure might be more apt, as highlighted by Xiao et al. (2022). In our investigation, we used the sectoral value added as the auxiliary metric (Zhang et al., 2022). This choice was logical because the sectoral value added is readily accessible within the IOT, yet remains external to the ION's formation. Additionally, this metric adeptly reflects the economic prominence of each sector. To offer perspective, Figure 4 displays the sectoral shares to the national GDP for 1995 and 2018 in China and in Japan. As expected, while Japan's service sectors have higher value-added contributions, China's manufacturing sectors lead in this regard. Nonetheless, the heterogeneity in sector-level value added is similar for both nations. In 1995 and 2018, China's standard deviations were 0.0261 and 0.0214, and Japan's were 0.0275 and 0.0278. With a focus on economic growth, integrating value added as an auxiliary insight when discerning key sector rankings via PR scores offers a compelling analytical lens.

Country	Rank	1995	1998	2001	2004	2007	2010	2013	2016	2018
China		$25\,$	07	25	07	25	25	25	25	25
	$\overline{2}$	06	06	07	25	07	17	20	06	17

	4	20	20	20	25	37	37	37	37	37
	5	37	37	37	37	25	25	25	25	25

Table 2: The sectors with top 5 extended PR scores of China and Japan from 1995 to 2018 every three years with value added as auxiliary information.

Table 2 presents the top 5 sectors in China and Japan ranked by their PR scores from 1995 to 2018, with value added as auxiliary information. The economic landscapes of these countries, as represented by these sectors, exhibit stark contrasts, reflecting their individual development narratives and strategic priorities. For China, a fluidity in the top sectors can be observed over the years. Between 1995 and 2002, primary sectors such as "agriculture, hunting, forestry" (01), "food products, beverages and tobacco" (06), and "textiles, textile products, leather and footwear" (07) dominated the list, interspersed with "construction" (25) and "wholesale and retail trade; repair of motor vehicles" (26). The prominence of sectors 07 and 25, which interchanged leadership roles, underscores China's focus on both its agrarian roots and its burgeoning infrastructure development. However, post-2007 marks a clear shift towards industrialization, with the rise of manufacturing sectors like "computer, electronic and optical equipment" (17) and "motor vehicles, trailers and semi-trailers" (20), while "construction" (25) retained its top position. This transition can be attributed to China's strategic push towards rapid industrialization, technological adoption, and urbanization processes (Zhang et al., 2014).

In stark contrast, Japan exudes stability in its top sectors. The unwavering dominance of "wholesale and retail trade; repair of motor vehicles" (26) as the foremost sector signifies Japan's entrenched consumer and trade dynamics. Furthermore, the consistent presence of "construction" (25), "motor vehicles, trailers and semi-trailers" (20), "human health and social work activities"  $(42)$ , and "real estate activities"  $(37)$  in the top ranks underlines Japan's position as a mature, service-oriented, and industrialized economy, aligning with its rich history as a global trade and technological powerhouse (Flath, 2022). We conjecture that such top-sector stability might emerge at a particular phase of economic development when the extended PR method leverages value-added as auxiliary information. China might need decades to reach this evolutionary stage (Nadvi and Schmitz, 1994).

Our analysis of key sectors, when juxtaposed with the findings of Li et al. (2017), presents both alignments and discrepancies. Both studies recognize the dominance of manufacturing sectors in China, indicative of its ongoing industrialization, and the crucial role of Japan's service sectors, especially commerce and commercial service. This is reflected in the elevated PR scores in Japan's sectoral network. Using degree centrality, Li et al. (2017) suggested diminishing prominence of the construction sector in China during 2000–2011, possibly due to the bursting of an economic bubble. Our study from the extended PR scoring points to its consistent dominance over the years. Using betweenness centrality, Li et al. (2017) reported high ranks of the chemical sector and the nonmetallic mineral products sector, followed by the metal smelting sector in Japan; and higher ranks of the printing sector and the electronic manufacturing in 2002 and 2007 in China. These different rankings are expected given the that the betweenness centrality measures the ability of sectors in connecting distant sectors (Xiao et al., 2022).

To enhance the depth of our analysis, we also used alternative centrality metrics. Still with the extended PR score, we used export value as the node-level auxiliary variable, recognizing its accessibility within IOTs and its externality to the IONs. Emphasizing export value highlights sectors critical for export-driven economic strategies, aligning with policy directives for countries emphasizing export-led growth. This examination is detailed in Appendix B. In addition, we applied a weighted version of the hubs and authorities centrality, as per Agosti and Pretto (2005) and the foundational work of Kleinberg (1999a) and Kleinberg (1999b). This metric, while more objective, omits auxiliary data considerations but did spotlight additional vital sectors, further discussed in Appendix C.

# 6 Community detection

Sectoral clusters are important for promoting national competitiveness, structural change, and economic development (e.g., Learmonth et al., 2003; Titze et al., 2011). These clusters consist of sectors that are more closely connected to one another than with other sectors, and community detection in a network can group nodes into clusters or communities based on their bond strength. Many algorithms for community detection are available (e.g., Ng et al., 2001; Girvan and Newman, 2002; Boykov and Kolmogorov, 2004). In this study, we used the modularity maximization algorithm developed by Newman (2006) to detect communities in a weighted network The modularity Q of a weighted network is

$$
Q = \frac{1}{W_n} \sum_{ij} \left( w_{ij} - \frac{s_i s_j}{W_n} \right) \mathbb{I}(h_i = h_j),
$$

where  $h_i$  denotes the community to which node i is assigned, and  $\mathbb{I}(\cdot)$  is the indicator function taking value 1 if nodes  $i$  and  $j$  are in the same community and 0 otherwise. For node  $i$ and j, the term  $(w_{ij} - s_i s_j/W_n)$  represents the difference between the actual edge weight and what would be expected if all the edges are randomly placed among the nodes. From the definition, higher Q values reflects more pronounced community structure of the network under the corresponding clustering strategy  $h := (h_i)_{i=1}^n$ . Therefore, community detection aims to maximize Q with respect to all possible clustering strategies. We used the greedy algorithm proposed by Clauset et al. (2004) to solve the optimization problem, which is provided in the R package **igraph** (Csardi and Nepusz,  $2006$ ).

Figure 5 displays the community structures of China and Japan in 1995 and 2018; results from other years are available in Section 2 of the Supplementary Material. Some community

Communities of China in 1995

Communities of Japan in 1995

Figure 5: Community detection of China and Japan in 1995 and 2018.

structures clearly reflect different parts of sectoral chains including upstream, midstream, and downstream sectors. For instance, one community of China in 1995 includes "agriculture, hunting, forestry" (01), "fishing and aquaculture" (02), "food products, beverages and tobacco" (06), and "accommodation and food service activities" (32). This community covers the complete life cycle of agricultural products, from planting to processing to consumption. To be specific, as the upstream sectors, "agriculture, hunting, forestry" (01) and "fishing and aquaculture" (02) provide raw materials for agricultural products. By acquiring raw materials for reprocessing, the midstream sector "food products, beverages and tobacco" (06) carries out the production and then acts as the bridge between upstream and downstream, moving the products to the downstream sector "accommodation and food service activities" (32), which is the consumer of food products. Another example is the community of Japan in 1995, which presents a clear picture of the production and consumption process of the medical industry, including "chemical and chemical products" (11), "pharmaceuticals, medicinal chemical and botanical products" (12), "rubber and plastics products" (13), and "human health and social work activities" (42). Additionally, both countries possess construction-centered communities, which also include upstream sectors for the "construction" (25), such as "other non-metallic mineral products" (14), "basic metals" (15), and "fabricated metal products" (16).

The community structures of China and Japan show differences in the formation of the communities. In Japan, the top sector "wholesale and retail trade; repair of motor vehicles" (26) usually appears with "agriculture, hunting, forestry" (01), "food products, beverages and tobacco" (06), and "accommodation and food service activities" (32) in the same community. In China, however, "wholesale and retail trade; repair of motor vehicles" (26) is not in the same community as food production and services, but in the service-centered community. In Japan, sectors "electrical equipment" (18) and "machinery and equipment, not elsewhere classified" (19) are in the same community with sectors "computer, electronic and optical equipment" (17) or "other transport equipment" (21), which demonstrates the clustering characteristic of the Japan's transport equipment manufacturing industry. In China, however, the two sectors mostly belong to the construction-centered community. Another interesting example is about the biopharmaceutical industry. China's "pharmaceuticals, medicinal chemical and botanical products" (12) and "human health and social work activities" (42) are closely linked to belong to the same community, but do not form a stable community structure with "chemical and chemical products" (11) and "rubber and plastics products" (13) as they do in Japan, implying there was a quite gap between the two countries in biopharmaceutical industry. In the Japanese service sector community, "financial and insurance activities" (36) and "real estate activities" (37) are closely linked, illustrating the connection between Japan's real estate and financial industries. While there is no apparent clustering between the two sectors in China's service sector community.

Over the 24-year period, the community structure within each country has undergone changes, but certain sectors have remained consistent within the same community. In China, the sectors of "agriculture, hunting, forestry" (01), "fishing and aquaculture" (02), "food products, beverages and tobacco" (06), and "accommodation and food service activities" (32) have remained in the same community between 1995 and 2018. Similarly, the sectors of "mining and quarrying, energy producing products" (03), "coke and refined petroleum products" (10), and "electricity, gas, steam and air conditioning supply" (23) have also been relatively stable in their community affiliations. Likewise, there are certain sectors in Japan that have exhibited consistent community structures. For example, the community composed of "agriculture, hunting, forestry" (01), "food products, beverages and tobacco" (06), "wholesale and retail trade; repair of motor vehicles" (26), and "accommodation and food service activities" (32) has remained relatively stable over time. The 24-year period of the study may not have been long enough to observe drastic changes in community structures. However, the consistent presence of certain sectors within the same community across the study period suggests that these sectors have remained interconnected and interdependent over time.

Figure 6: The AMI in the community results of China and Japan from 1995 to 2018. The upper triangle entries indicate the pairwise similarities of community structures within China over time. The lower triangle entries reflect the pairwise similarities of community structures within Japan over time. The diagonal entries are the similarities between China and Japan over time.

The evolvement of the community structures over time can be quantitatively demonstrated by similarity measures between any pair of community structures. In particular, we used adjusted mutual information (AMI) (Vinh et al., 2009, 2010) as our similarity measure. The AMI takes value 1 when two identical community structures and 0 when the mutual information between two community structures equals the value expected due to chance alone. A higher AMI value indicates a higher agreement between the two community structures. Figure 6 visualizes the year-by-year AMI matrix whose elements are pairwise AMI values. The diagonal entries capture annual comparisons between the community structures of the two countries over the years. The fluctuating AMI values around 0.5 suggests a moderate level of similarity between the community structures in China and in Japan. The upper and lower triangle entries are year-year similarities in China's and Japan's community structures, respectively. In both countries, community structures exhibit similarities over 0.5. Japan's structures follow a consistent pattern, with high similarities before 2005 that gradually decreases over time. This decline might be attributed to minor shifts likely caused by advanced industrial development. China's community structures over time, which are less similar than Japan's. In addition, there appears to be no clear pattern. Even between adjacent years, the AMI values are rarely above 0.8. This possibly stemmed from its rapid economic growth and significant changes in sectoral structure. A full exploration into the forces steering these dynamics would be a compelling topic for subsequent research endeavors.

# 7 Concluding remarks

In this comparative study of China and Japan's sectoral structures, we applied several network analysis techniques, including some that were recently developed. We began with an examination of node strength distributions and illustrated sectoral connections. For a more nuanced understanding of the homophily of the supplying sectors and receiving sectors, we employed weighted, directed assortativity coefficients (Yuan et al., 2021), considering uncertainties through the jackknife method (Lin et al., 2020). Without uncertainty quantifications, some conclusions in existing works could be misleading (Cerina et al., 2015). To identify key sectors, we used the extended PR method that integrates research-specific auxiliary metrics, like total value added or export values (Zhang et al., 2022). We also detected sectoral community structures within each economy and assessed their similarities, both between countries and over time, using the AMI metric (Vinh et al., 2009, 2010). With this combination of methods, we provided detailed insights into the evolving sectoral dynamics of two pivotal Asian economies.

Utilizing network centrality measures to pinpoint key sectors in IONs is a logical approach, and there are hundreds of available centrality measures (e.g., Perra and Fortunato, 2008; Landherr et al., 2010; Das et al., 2018). The choice of a particular measure need to align with the unique objectives set by the researchers. While we leveraged the extended PR method (Zhang et al., 2022) and hubs and authorities (Deguchi et al., 2014), there exist other commonly used centrality metrics such as degree, betweenness, closeness, and randomwalk based measures that have been applied to ION analyses (Blöchl et al., 2011; Li et al., 2017; Tsekeris, 2017; DePaolis et al., 2022). The key is not to deem one method superior to another but to select based on the specific research context. Our preference for the extended PR method was due to its adaptability in accounting for external factors, allowing for a tailored approach depending on the research objective. For instance, researchers examining the interplay between industrial growth and employment might opt to integrate employment data as auxiliary input (Xiao et al., 2022). The diversity of centrality measures offer rich opportunities and perspectives to identify key sectors in IONs.

As an important tool for economic system research, IOTs are available from several sources. While national IOTs composed by individual countries contain detailed view of sectoral structures tailored to their specifications, inconsistencies in sector classifications hinder country comparisons. To facilitate comparison, some international organizations composed IOTs. Some of these contains individual national IOTs such as STAN, while others cover amalgamate data from multiple countries into expansive multi-region IOTs, such as WIOD and ADB-MRIO. With each country as a block, the diagonal blocks of a multi-region IOT give individual national IOTs. Our study did not use the WIOD due to its timeline ending in 2014, nor the ADB-MRIO data base because incorporates two non-applicable sectors for China. Nevertheless, future studies might benefit from analyzing the WIOD and data from other sources, such as the Eora Global Supply Chain Database (Lenzen et al., 2013) and the Global Trade Analysis Project (Aguiar et al., 2022), and juxtaposing the findings with ours for overlapping years. Although the 45-sector granularity of the STAN database serves our purposes, a finer sectoral resolution aligning the sectors of both China's and Japan's IOTs, which respectively have 142 and 187 sectors, would deliver deeper and more intricate perspectives.

Multi-region IOTs encompass not only the interconnections among sectors within individual countries but also the economic transactions between the sectors across nations (Dietzenbacher et al., 2013; Lenzen et al., 2013; Aguiar et al., 2022). Such databases are essential for conducting research in the field of international economics. By harnessing international IOTs in conjunction with network analysis methods, we can delve into various facets of economic relationships among different countries. This includes examining international trade (Zhu et al., 2014; Cerina et al., 2015), intermediate and final goods trade (Kleinert, 2003), global supply chains and value chains (Angelidis et al., 2020), energy flows (Chen et al., 2018), and carbon emission (Minx et al., 2009), among others. These insights hold significant implications for the formulation of trade, energy, and environmental policies. They provide a robust framework for assessing the stability of supply chains, gauging economic vulnerabilities, and evaluating the resilience of nations. Particularly concerning China-Japan economic relations, there remains a myriad of research questions related to their economic interplay that can be adeptly tackled using multi-region IOTs in tandem with advanced network analysis methodologies.

Impacts of global shocks to sectoral structures present a rich vein of research. Notably,

the 2008 global financial crisis has been analyzed for its ripple effects on global economies and network structures (Haldane, 2013; Battiston et al., 2012). While our study touched upon the repercussions of the 2008 crisis in China and Japan, a deeper exploration through a network lens is warranted. The Covid-19 pandemic, an unparalleled recent shock, has also been a focal point of many economic studies (Baldwin and Di Mauro, 2020; Brodeur et al., 2021; Aktar et al., 2021; Costa et al., 2022; Tanaka, 2022; Salisu et al., 2022; Ozili and Arun, 2023). The updated Eora Global Supply Chain Database (Lenzen et al., 2013) provides an excellent opportunity to delve into the pandemic's impact on economies like China and Japan (Han, 2022; Kitamura et al., 2020). Such explorations could illuminate the resilience and adaptability of these nations when faced with monumental challenges.

### A Sector codes

Table 3 summarizes the codes and the definitions of the 44 sectors in the 2021 edition of STAN database (Organisation for Economic Cooperation and Development, 2021). The 45th sector, "activities of households as employers; undifferentiated goods- and services-producing activities of households for own use", is missing for both China and Japan.

Code	Sector	Code	Sector
01	Agriculture, hunting, forestry	23	Electricity, gas, steam and air condi- tioning supply
02	Fishing and aquaculture	24	Water supply; sewerage, waste man-
03	Mining and quarrying, energy pro- ducing products	25	agement and remediation activities Construction
04	Mining and quarrying, non-energy producing products	26	Wholesale and retail trade; repair of motor vehicles
05	Mining support service activities	27	Land transport and transport via pipelines
06	Food products, beverages and to- bacco	28	Water transport
07	Textiles, textile products, leather and footwear	29	Air transport
08	Wood and products of wood and cork	30	Warehousing and support activities for transportation
09	Paper products and printing	31	Postal and courier activities
10	Coke and refined petroleum products	32	Accommodation and food service ac- tivities
11	Chemical and chemical products	33	Publishing, audiovisual and broad- casting activities
12	Pharmaceuticals, medicinal chemical and botanical products	34	Telecommunications
13	Rubber and plastics products	35	IT and other information services
14	Other non-metallic mineral products	36	Financial and insurance activities
15	Basic metals	37	Real estate activities
16	Fabricated metal products	38	Professional, scientific and technical activities
17	Computer, electronic and optical equipment	39	Administrative and support services
18	Electrical equipment	40	Public administration and defence; compulsory social security
19	Machinery and equipment, not else- where classified	41	Education
20	Motor vehicles, trailers and semi- trailers	42	Human health and social work activ- ities
21	Other transport equipment	43	Arts, entertainment and recreation
22	Manufacturing nec; repair and instal- lation of machinery and equipment	44	Other service activities

Table 3: Description of the sectors in the STAN.

Figure 7: Bar plots of the share of export value of each sector in the total value of exports in China and Japan for 1995 and 2018.

# B Extended PR incorporating exports

The extended PR allows flexible incorporation of auxiliary information in centrality ranking depending on the research objectives (Zhang et al., 2022). Here we use export value as the sector-specific auxiliary information in the extended PR. This variable is a component of the final use of an IOT, as presented in Table 1. Similar to value added, it is also external to the construction of the corresponding ION. Export value highlights sectors critical for export-driven economic strategies, aligning with policy directives for countries emphasizing export-led growth. Figure 7 presents the bar plots of the sectoral shares in the national exports for 1995 and 2018 in China and in Japan.

Table 4 summarizes top five sectors in China and Japan in their extended PR scores, with export value as auxiliary information, from 1995 to 2018. In China, a clear prominence of the

Country	Rank	1995	1998	2001	2004	2007	2010	2013	2016	2018
China		07	07	07	17	17	17	25	25	25
	$\overline{2}$	25	17	17	07	07	07	$17\,$	17	17
	3	26	25	25	25	25	25	07	07	07
	4	19	06	06	19	19	19	19	19	19
	$\overline{5}$	17	26	26	15	15	20	20	20	20
Japan		20	20	20	20	<b>20</b>	20	20	20	20
	$\overline{2}$	26	26	26	26	26	26	26	26	26
	3	17	17	17	17	17	17	19	19	19
	4	25	25	19	19	19	42	42	42	42
	5	19	19	25	25	15	19	25	25	25

Table 4: The sectors with top 5 extended PR scores of China and Japan from 1995 to 2018 every three years with export value as auxiliary information.

"textiles, textile products, leather and footwear" (07) sector is observed at the onset, which later gives way to sectors such as "computer, electronic and optical equipment" (17) and "construction" (25) in subsequent years. The "wholesale and retail trade; repair of motor vehicles" (26) and "machinery and equipment, not elsewhere classified" (19) sectors persistently remain in the top five over the years. For Japan, the tableau is marked by a steadfast dominance of the "motor vehicles, trailers and semi-trailers" (20) sector, with "wholesale and retail trade; repair of motor vehicles" (26) consistently following suit. Other sectors like "computer, electronic and optical equipment" (17) and "construction" (25) maintain their relevance in the top five throughout the years.

Contrasting these findings with the results from the value added auxiliary information, we note divergent trends. In the value added scenario, China's "construction" (25) sector dominated, reflecting the nation's infrastructural growth. However, when export value takes precedence, traditional manufacturing sectors gain traction, underscoring the nation's export-oriented economic growth. Japan, on the other hand, showcased more stability across both scenarios, resulting from its mature, service-oriented economy. The "human health and social work activities" (42) sector, which consistently appeared in Table 2, shows up only post-2007. The discernable shifts in sector prominence when transitioning from value-added to export value highlight capability of the extended PR score in reflecting the multifaceted nature of economic development.

# C Weighted hubs and authorities

Hubs and authorities are two centrality measures involved in hyperlink-induced topic search (HITS) algorithm to rank webpages (Kleinberg, 1999a,b). The key idea is that web pages serve two primary roles: they provide content (making them an authority) and they link to other pages (making them a hub). A good authority is a page that is linked to by many good hubs. A good hub is a page that links out to many good authorities. The two concepts are interdependent. A hub's value is determined by the quality of the authorities it links to. An authority's value is determined by the quality of the hubs that link to it. The HITS algorithm involves a recursive process: it begins with an arbitrary assignment of values to nodes as hubs and authorities. Then, it updates the hub and authority scores of each node based on the initial (or previous) scores of its neighboring nodes. This iterative process continues until the scores converge. In theory, the hub score and the authority score eventually converge to the principal eigenvectors of  $AA^{\dagger}$  and  $A^{\dagger}A$ , respectively, where A is the adjacency matrix of the network. To stabilize the numerical range and facilitate the comparison of the relative importance, the results are normalized to make the two score vector sums equal to one.

The HITS algorithm has been extended to allow edge weight by replacing the adjacency matrix  $\vec{A}$  with the weighted adjacency matrix  $W$  in the calculation (Agosti and Pretto, 2005). The weighted HITS algorithm finds applications in a variety of fields, such as trade network (Deguchi et al., 2014) and road network (Sun et al., 2018). We used the implementation in R package **igraph** (Csardi and Nepusz,  $2006$ ) in our analysis.

In IONs, sectors that act as major hubs distribute products or services to various authority sectors, while high-authority sectors receive from many notable hubs. The HITS method, unlike the extended PR approach (Zhang et al., 2022), does not incorporate auxil-

Centrality	Country	Rank	1995	1998	2001	2004	2007	2010	2013	2016	2018

		$\overline{4}$	26	06	06	15	25	25	25	25	25
		$\overline{5}$	06	19	19	19	26	19	19	19	19

Table 5: The sectors with top 5 weighted hub and authority centrality scores of China and Japan from 1995 to 2018 every three years.

iary information, making it straightforward but potentially omitting valuable data. Hub and authority scores showcase distinct facets of sectoral significance within the IONs. Table 5 lists the top five sectors by weighted hub and authority scores from 1995 to 2018 for China and Japan. As expected, the results are different from those obtained using the PR method with value added as auxiliary information.

The distinct trajectories of China and Japan are evident in their leading hub sectors. China's consistent top hub sectors like "basic metals" (15), "other non-metallic mineral products" (14), and "agriculture, hunting, forestry" (01) across the years reveal its industrial foundation, rooted in heavy industries and primary sectors. This mirrors China's expansive manufacturing base and the momentum of its rapid urbanization. Conversely, Japan's hub sectors gravitate towards "wholesale and retail trade; repair of motor vehicles" (26), "basis metals" (15), and "motor vehicles, trailers and semi-trailers" (20), underscoring its pivot towards export-driven industries, notably in technology and automobiles. This orientation aligns with Japan's established trade relationships and its globally esteemed automotive and tech brands.

The leading authorities also demonstrate varying sectoral strengths and priorities. China's top authority sectors, including "textiles, textile products, leather and footware" (07), "basic metals" (15), and "construction" (25) in subsequent years, highlight its robust infrastructure expansion, fueled by industrial policies that champion infrastructure as an economic growth catalyst. In contrast, Japan's authority sectors such as "construction" (25), "motor vehicles, trailers and semi-trailers" (20), and "basic metals" (15) reflect its stature as a developed, industrialized nation, renowned as a global automobile leader, and underscore its consumercentric market dynamics. These sectors' enduring relevance attests to Japan's sophisticated, service-led economy.

## 1 Extended PR with different tuning parameters

The choice of the parameter  $\gamma$  in the context of extended PR rankings (Zhang et al., 2022) holds substantial importance, as it determines the balance between the weight placed on the ION structure and the auxiliary information, in this case, value-added, depending on the researchers' objectives and preferences. Although  $\gamma = 0.5$  suggests an even weighting between the network structure and the value-added, it over-dilutes the influence of the network's connectivity when deriving significance rankings for sectors based on the IONs. Table 1 presents a side-by-side comparison of the top 5 sector for China and Japan from the extended PR algorithm using value added as auxiliary information, with tuning parameters  $\gamma = 0.5$  and  $\gamma = 0.85$  from 1995 to 2018, assessed every three years.

In China, at  $\gamma = 0.5$ , the sectors like "agriculture, hunting, forestry" (01) and "textiles, textile products, leather and footwear" (07) are predominant across several earlier years. But as  $\gamma$  shifts to 0.85, which puts more emphasis on the network structure, there is a marked transition in the rankings. Specifically, the prominence of the "construction" (25) sector becomes apparent and early, while the significance of the "agriculture, hunting, forestry" (01) sector diminishes. The rankings from  $\gamma = 0.85$  appear to better reflect China's rapid infrastructural development

Table 1: The sectors with top 5 extended PR scores, based on the sensitivity analysis of the tuning parameter at the levels  $\gamma = \{0.5, 0.85\}$  for China and Japan from 1995 to 2018 every three years with value added as auxiliary information.

Country	Rank	$\gamma=0.5$							$\gamma = 0.85$										
		1995	1998	2001	2004	2007	2010	2013	2016	2018	1995	1998	2001	2004	2007	2010	2013	2016	2018

and urbanization over the past decades, as the country moves from a largely agrarian society to an industrial powerhouse.

In stark contrast, Japan exhibits remarkable consistency in the top-ranked sectors, regardless of  $\gamma$ . The "wholesale and retail trade; repair of motor vehicles" (26) sector consistently holds the top position, while sectors such as "construction" (25) and "motor vehicles, trailers and semi-trailers" (20) remain firmly rooted in the top ranks for both  $\gamma$  values. This steadfastness showcases the well-established and mature industrial and trade sectors of Japan, a hallmark of its developed economy.

The use of  $\gamma = 0.85$ , akin to the standard PR, aligns with prior economic network research emphasizing the importance of network connections in economic dynamics (Page et al., 1998). It appears to offer a balanced interplay between value-added and network structures, ensuring that the economic interactions among sectors are adequately represented. Given the notable shifts observed in China's rankings between the two  $\gamma$  values, it is evident that while valueadded considerations are crucial, the inter-sectoral connections and interactions are still our focus. On the other hand, the stability of rankings in Japan across both  $\gamma$  values provides a testament to the resilience and established nature of its economic sectors. We conjecture that the stability in the top 5 sectors may be achieved after certain economic development stage when using the extended PR method with value-added as auxiliary information. The conjecture merits further investigation.

#### 2 Community structures

Figures 1, 2, 3, 4 and 5 provide the detailed information about the community structures of China and Japan for the years 1997, 1999, 2001, 2003, 2005, 2007, 2009, 2011, 2013, 2015 and 2017.
