ABSTRACT

We present the results of a ~60-hour mic confirmed and lensed sub-*L** galaxy at *z* emission from rest frame 90 to 370 μ m a by targeting the CO (7 – 6) and [C I](³ *P*₄ with deep optical and near-IR photometr of which is obscured by dust. This is a between the fraction of the obscured stan light-weighted dust temperature of *T*_{dust} and with possible negative gradients. We a gas mass of $M_{gas} ~ 2 \times 10^9 M_{\odot}$. Their The dust-to-stellar mass fraction of *f*_{dus} supernovae, as predicted by existing mod at *z* = 6 from a subset of these models is of gravitational lensing and deep multiw lower than what has been explored so far of the high-redshift and faint sub-*L** galaxies. Galaxies: high-redshift, IS **1. Introduction**Over the past few years, the num at redshift *z* > 6 and deeper in has soared. Interferometric (sub)m ground-based and, more recently, near-IR spectroscopy have been in to observe and connect all componer a complete view of these systems opportunity and observing time cost the brightest and rarest targets that corrates – but in doing so we have beet typical galaxy populations at *z* > 6. We present the results of a ~60-hour multiband observational campaign with the Atacama Large Millimeter Array targeting a spectroscopically confirmed and lensed sub- L^* galaxy at z = 6.07, first identified during the ALMA Lensing Cluster Survey (ALCS). We sampled the dust continuum emission from rest frame 90 to 370 μ m at six different frequencies and set constraining upper limits on the molecular gas line emission and content by targeting the CO (7 – 6) and [C1](${}^{3}P_{2} - {}^{3}P_{1}$) transitions in two lensed images with $\mu \gtrsim 20$. Complementing these submillimeter observations with deep optical and near-IR photometry and spectroscopy with JWST, we find this galaxy to form stars at a rate of SFR ~ 7 M_{\odot} yr⁻¹, ~ 50-70% of which is obscured by dust. This is consistent with what one would predict for a $M_{\star} \sim 7.5 \times 10^8 M_{\odot}$ object by extrapolating the relation between the fraction of the obscured star formation rate and stellar mass at z < 2.5 and with observations of IR-detected objects at 5 < z < 7. The light-weighted dust temperature of $T_{dust} \sim 50$ K is similar to that of more massive galaxies at similar redshifts, although with large uncertainties and with possible negative gradients. We measure a dust mass of $M_{dust} \sim 1.5 \times 10^6 M_{\odot}$ and, by combining [C I], [C II], and a dynamical estimate, a gas mass of $M_{\rm gas} \sim 2 \times 10^9 M_{\odot}$. Their ratio ($\delta_{\rm DGR}$) is in good agreement with predictions from models and empirical relations in the literature. The dust-to-stellar mass fraction of $f_{dust} \sim 0.002$ and the young stellar age (100 - 200 Myr) are consistent with efficient dust production via supernovae, as predicted by existing models and simulations of dust evolution. Also, the expected number density of galaxies with $M_{dust} \sim 10^6 M_{\odot}$ at z = 6 from a subset of these models is in agreement with the observational estimate that we set from the parent ALCS survey. The combination of gravitational lensing and deep multiwavelength observations allowed us to probe luminosity and mass regimes up to two orders of magnitude lower than what has been explored so far for field galaxies at similar redshifts. Our results serve as a benchmark for future observational endeavors of the high-redshift and faint sub- L^* galaxy population that might have driven the reionization of the Universe.

Key words. Galaxies: high-redshift, ISM, star formation, formation, evolution; Gravitational lensing: strong

Over the past few years, the number of galaxies confirmed at redshift z > 6 and deeper into the reionization epoch has soared. Interferometric (sub)millimeter observations and ground-based and, more recently, space-based optical and near-IR spectroscopy have been instrumental in allowing us to start exploring the physics regulating the growth of the first galaxies. Truly multiwavelength studies proved to be necessary to observe and connect all components in galaxies and provide a complete view of these systems. However, for reasons of opportunity and observing time cost, priority has been given to the brightest and rarest targets that could maximize the detection rates - but in doing so we have been missing more numerous,

In light of the possible preponderant role played by average, rather than exceptional, galaxy populations in the reionization of the Universe (Robertson 2022), there has been a renewed focus on spectroscopic studies of faint sources around or below the knee of the luminosity function (L^{\star}) and on the main sequence of star formation (Daddi et al. 2007) at these redshifts, particularly after the launch of the James Webb Space Telescope (JWST). Moreover, observational campaigns of faint objects are even more affordable when the Universe comes to our aid with the gravitational lensing effect. This phenomenon provides a unique window onto the formation of faint galaxies on small scales, which would otherwise be impossible to probe without the presence of massive objects along the line of sight.

Here we attempt to push the existing boundaries for deep multiwavelength extragalactic studies at high redshifts by leveraging state-of-the-art instruments and the lensing effect. Our primary objective is to start exploring a new portion of the cold gas and dust parameter space at intrinsic low stellar masses, star formation rates (SFRs), and metallicities. These regimes are critical to understanding the first phases of galaxy formation. The availability of cold gas reservoirs and the impact of intense, hard radiation feedback from young stars with low metallicities ultimately regulate the growth of the numerous population of low-mass galaxies and their ability to reionize the Universe. Furthermore, these processes are intricately linked to the rate at which metals and dust accumulate, and the relationship between these two components in the earliest phases of galaxy assembly remains itself a debated topic (see, e.g., Péroux & Howk 2020; Popping et al. 2023; Heintz et al. 2023a; Konstantopoulou et al. 2024; Schneider & Maiolino 2023, for a few recent examples). Fortunately, both dust and metals can now be traced in early galaxies. Thanks to JWST, we can directly measure the metallicity of large samples of very distant sources (e.g., Curti et al. 2023). In contrast, over the past few years, observations with the Atacama Large Millimeter Array (ALMA) have

Table 1. Summary of the ALMA observations presented here.

Band 3	13.3	100.5	370	41	1.55×1.27	4

Notes. Program IDs: (1): 2022.1.00195.S (PI: S. Fujimoto); (2): 2021.1.00247.S (PI: S. Fujimoto); (3): 2021.1.00055.S (PI: S. Fujimoto); (4): 2021.1.00181.S (PI: F. Valentino). The on-source integration times t_{int} are for each z6.3 and arc image. Band 6 were obtained in C5 ($t_{int} = 1.8$ hr on target per source, $0.35'' \times 0.29''$ beam) and C2 ($t_{int} = 0.8$ hr, $1.26'' \times 1.05''$ beam) and combined with CASA. The rms per beam in the continuum maps is estimated as described in Section 3.1.

revealed the existence of dust-rich, and in some cases seemingly over-abundant, galaxies within a few hundred million years of the Big Bang (see Witstok et al. 2023 for a recent compilation). This has sparked discussions on the creation and maintenance of dust grains in early galaxies. The short timescales involved seem to preclude a dominant role for asymptotic giant branch (AGB) stars, leaving supernovae (SNe) and grain growth in the interstellar medium (ISM) as the most viable alternatives for dust production, contending against destruction via reverse shocks (Gall et al. 2011; Popping et al. 2017; Schneider & Maiolino 2023). Different flavors of these mechanisms have been incorporated into models and simulations, yet the ever increasing body of observations persistently challenges their predictions.

In this work we delve into these subjects, concentrating our investigation on a faint sub-L^{*} galaxy at z = 6.072, positioned in projection behind the cluster RXJ0600-2007 (Fujimoto et al. 2021; Laporte et al. 2021, F21 and L21 hereafter; Sun et al. 2022). An extensive observational campaign to characterize the full spectrum of this source commenced soon after its discovery (Fujimoto et al. 2024) and is still ongoing. Here we present the initial findings from a series of programs conducted with ALMA. With the latter we accumulated approximately ~60 hours of observations, which were complemented by Hubble Space Telescope (HST) and JWST imaging as well as integral field near-IR spectroscopy from JWST. Armed with this rich dataset, we also aim to provide a reference for further studies involving larger samples of similar galaxies whose spectroscopic confirmation is now within reach (e.g., Khullar et al. 2021; Glazer et al. 2023; Fudamoto et al. 2024).

Details on the data reduction and analysis are presented in Sections 2 and 3. In Section 4 we report on the obscured SFR, its fraction of the total value, the dust mass and temperature (M_{dust} and T_{dust}), the cold gas mass and properties as traced by dust, neutral and ionized atomic carbon (C I and C II), carbon monoxide (CO), dynamics, and direct estimates of dust-to-stellar and dust-to-gas ratios (δ_{DGR}), and we put them in the context of the literature values for brighter UV galaxies and models at similar redshifts. Our conclusions are presented in Section 5. The reader can find detailed descriptions of the whole dataset (Fujimoto et al. 2024) and a focused analysis of the JWST photometry (Giménez-Arteaga et al. 2024) in companion papers. The study of the properties of the photon-dominated regions traced by multiple far-IR (FIR) lines is left to a dedicated work (Lee et al. in prep.).

Throughout this work we make use of the AB system to report magnitudes. Unless otherwise specified, we adopt a Chabrier (2003) initial mass function (IMF) and a Λ cold dark matter cosmology with $\Omega_{\rm m} = 0.3$, $\Omega_{\Lambda} = 0.7$, and $H_0 =$ 70 km s⁻¹ Mpc⁻¹.

2. Data

2.1. The target

The target presented in this study was discovered serendipitously during the mapping of dust emission at $\lambda_{obs} = 1.1 \text{ mm}$ within and around 33 clusters from legacy surveys using HST and the Spitzer Space Telescope - the ALMA Lensing Cluster Survey (ALCS; Kohno et al. 2023; Fujimoto et al. 2021, 2023; Kokorev et al. 2022). Five lensed images of this galaxy are now securely spectroscopically confirmed. In particular, a highly magnified arc composed of two images of a peripheral region of the source (dubbed "z6.1-6.2"; magnification factor $\mu \sim 100$) crosses a caustic line and stands out as one of the brightest observed [C II]158 μ m emitters at z > 6 (F21). The emission of a second lensed image ("z6.3"), approximately 15" distant from the arc, is also strongly boosted ($\mu \sim 20$) and offers an excellent view of global properties of this galaxy. This has already allowed for investigations of resolved properties in the UV wavelength regime down to < 300 pc with HST observations. Its total intrinsic absolute UV rest-frame magnitude is $\sim 3 \times$ fainter than the knee of the luminosity function of Lyman break galaxies at z = 6 (F21).

2.2. ALMA multiwavelength observations

The goal of our ALMA campaign is to characterize the properties of the cold ISM in this sub- L^* galaxy as completely as possible. We thus followed up its lensed images in Bands 3, 5, 6, 7, and 8¹, targeting known FIR and submillimeter lines and their underlying dust continuum emission. A summary of

Valentino, Fujimoto, et al.: Molecular gas and dust in a normal sub- L^{\star} galaxy at z = 6

Fig. 1. ALMA continuum bands of the arc (top rows, 7.5" side) and the z6.3 image (bottom rows, 5" side). The rest-frame wavelength of each map is labeled. The ALMA images are color-scaled within ± 5 times the rms per pixel in each band. Solid (positive) and dashed (negative) blue contours are at ± 3 , 5, 7, and 9σ . The solid red line and shaded area indicate the aperture adopted to extract the photometry. The beam size is shown in the bottom-right corner of each cutout. The bottom-right panel of each series shows the JWST/NIRCam image at 4.5 μ m. In the latter, the point spread function has a full width at half maximum of 0".16 and the blue contours mark the continuum at 158 μ m (C5+C2). The blue bar shows a 10 kpc scale.

observations, their integration time, observed and rest-frame frequency and wavelengths, depths, and beam sizes is provided in Table 1. The ALMA data were consistently reduced and calibrated using the Common Astronomy Software Applications (CASA) package version 6.2.1.7 (McMullin et al. 2007) with the standard pipeline script. TCLEAN was used to produce the continuum maps averaging all channels in the spectral windows not dominated by bright lines (whose expected position is accurately known from the robust redshift estimate). The

TCLEAN routines were executed down to the 2σ level. We chose a pixel scale approximately ten times smaller than the beam size and adopted a common spectral channel bin of 40 km s⁻¹. The final natural-weighted map has synthesized beams and continuum sensitivities listed in Table 1. More details about the individual ALMA programs and the data reduction can be found in Fujimoto et al. (2024).

2.3. Ancillary datasets

RXJ0600-2007 (z = 0.43) has been observed as part of the Reionization Lensing Cluster Survey (RELICS; Coe et al. 2019) and the Massive Cluster Survey (MACS; Ebeling et al. 2001). It thus benefits from ample UV to near-IR photometric coverage with the HST and Spitzer. A homogeneous data reduction of all programs targeting this cluster and a consistent reextraction of the photometry is presented in Kokorev et al. (2022) as part of the Complete Hubble Archive for Galaxy Evolution (CHArGE) initiative. It has been recently complemented by JWST observations with the Near-Infrared Camera (NIR-Cam; Rieke et al. 2005) and Spectrograph (NIRSpec; Jakobsen et al. 2022) integral field unit (#GO 1567, PI: S. Fujimoto). The imaging was taken with the F115W, F150W, F277W, F356W, and F444W filters. The data reduction is performed following the same steps described in Valentino et al. (2023). NIRCam images of the arc and the z6.3 images at 4.5 μ m are shown in Figure 1. The integral field spectroscopy came at high spectral resolution with the G395H/F290LP combination $(R \sim 2700, \lambda_{obs} \sim 2.9 - 5.1 \,\mu\text{m})$, thus covering the redshifted optical rest-frame emission of lines from the ionized gas (notably including H α , H β , [O III] $\lambda\lambda$ 4959, 5007, [N II] $\lambda\lambda$ 6549, 6584, [S II] $\lambda\lambda$ 6716, 6731, the auroral line [O III] λ 4364, and many others). For further details about the JWST and HST imaging and spectroscopy, we refer the reader to the companion papers (Giménez-Arteaga et al. 2024; Fujimoto et al. 2024).

3. Analysis

3.1. Dust continuum photometric extraction

We extracted the photometry within elliptical apertures in the continuum emission ALMA maps. We ran the pythonic version of Source Extractor (Bertin & Arnouts 1996), SEP (v1.2.1, Barbary 2016), to detect the centroid, orientation, and ellipticity of the apertures in each band independently. We measured total flux densities within adaptively scaled Kron (1980) apertures (FLUX AUTO in SOURCE EXTRACTOR'S nomenclature). To ensure that we measured flux densities across wavelengths within consistent portions of each lensed image, in every band we fixed our fiducial aperture to that retrieved for Band 7 in the 122 μ m rest frame, where the S/N of the detection is high (10 and 14 for z6.3 and the arc, respectively). We show the extent of such an aperture in every map in Figure 1. The resulting dust continuum emission flux densities for z6.3 and the arc are reported in Table 2, together with available upper limits on Herschel photometry (de-blended and extracted as described in Sun et al. 2022). The uncertainties are computed from the rms per beam in each continuum image scaled by the number of independent beams within the aperture (e.g., Béthermin et al. 2020).

When observing in Bands 6, 7, and 8, we separately pointed each lensed image. Given the larger field of view in Bands 3 and 5, the pointing was centered between z6.3 and the arc. In this case, the lensed images are well within the inner portions of the primary beam. Therefore, a correction for the primary beam was not needed. In the case of Band 6, we obtained observations in two configurations (C2 and C5), which allows us to test for possible flux lost on the full arc scale (the maximum recoverable scale for Band 6 in C5 is of \sim 3"). Independent measurements of the continuum emission in the two configurations are consistent (Table 2). We thus combined these datasets with CASA for our final measurements, improving the signal-to-noise of the detection.

Fig. 2. Observed Band 3 spectra of the arc (top) and the z6.3 image (bottom). The expected positions of the $[C I]({}^{3}P_{2} - {}^{3}P_{1})$ and CO (7-6) lines are marked.

Choosing Bands 5 or 6, where the detections are also robust, as references to determine the aperture instead of Band 7 does not appreciably impact the measurements. Also, we excluded possible strong biases due to widely different spatial distribution of the dust emission across bands by measuring total flux densities independently at each frequency, obtaining consistent results.

Finally, we counterchecked our aperture photometry against modeling of the emission with the task IMFIT in CASA and single Gaussians profiles. The results are overall in good agreement with those from aperture photometry especially when detections are robust (Table 2). Low signal-to-noise estimates and upper limits are also consistent (e.g., Band 8). We note that the assumption of a single, smooth profile captures reasonably well the global light emission from each lensed image, but clumping on smaller scales is likely present. This is evident from the optical rest-frame emission captured by JWST (Figure 1) and, to a lesser extent, by the highest resolution ALMA map in Band 6. Also, the assumption of a Gaussian light distribution is arguably not apt for the highly stretched arc, where two distinct peaks have been identified in the [CII] maps at low spatial resolution (F21). Yet, the total flux densities are consistent with those from aperture photometry, which are robust against clumping and spatial inhomogeneities. This suggests that the these spatial variations are not fully captured by ALMA at the current spatial resolution and depths in most bands, but this does not affect our conclusions.

3.2. Spectral extraction

We extracted the spectra of the lensed images over the same apertures used to measure the continuum emission in order to derive consistent ratios. Here we focus particularly on Band 3 observations targeting the [C I](${}^{3}P_{2} - {}^{3}P_{1}$) ($v_{rest} = 809.34$ GHz) and CO (7 - 6) ($v_{rest} = 806.65$ GHz) lines, proxies of the molecular gas of the galaxy, and we defer detailed analyses of photondominated regions to future work (Lee et al. in prep.). We show

Notes. All estimates are not corrected for lensing. All upper limits are at 3σ . *Herschel*/SPIRE from Sun et al. (2022). In Band 6, for z6.3: $\mu F_{\nu,\text{aper}} = (0.25 \pm 0.06)$ and (0.18 ± 0.12) mJy for C2 and C5, respectively. For the arc: $\mu F_{\nu,\text{aper}} = (0.37 \pm 0.08)$ (C2) and (0.52 ± 0.16) mJy (C5). Band 3 lines: [CI](${}^{3}P_{2} - {}^{3}P_{1}$) ($\lambda_{\text{rest}} = 370.41 \,\mu\text{m}$, $\nu_{\text{rest}} = 809.34 \,\text{GHz}$), CO (7 – 6) ($\lambda_{\text{rest}} = 371.65 \,\mu\text{m}$, $\nu_{\text{rest}} = 806.65 \,\text{GHz}$). Upper limits over $\Delta \nu = 180 \,\text{km s}^{-1}$ and estimated from spectra binned at $d\nu = 40 \,\text{km s}^{-1}$.

the extracted Band 3 spectra around the expected location of the [C I] and CO line emission in Figure 2. We do not detect any line emissions. We thus set upper limits on the fluxes integrated on the [C II] line width from low spatial resolution measurements ($\Delta v = FWHM = 180 \text{ km s}^{-1}$, F21). Based on spectra binned at $dv = 40 \text{ km s}^{-1}$, we obtain 3σ upper limits on the line fluxes as $I_{\text{line}} = 3 \times \text{rms} \sqrt{\Delta v \, dv}$, where rms is the aperture noise per channel in the spectral window where the lines fall. We applied a mild clipping at 3σ to remove outliers, which resulted in a 6% lower rms. The limits on line fluxes and luminosities are reported in Table 2. We note that the upper limits on z6.3 and the arc differ because of the areas that we considered to estimate the rms.

3.3. Long-wavelength spectral energy distribution modeling

We modeled the ALMA and Herschel photometry using the Bayesian code Mercurius (Witstok et al. 2022, 2023). We assumed optically thin dust emission and initially left the dust temperature (T_{dust}) and emissivity slope (β) free to vary. For consistency with the literature compilation presented in Witstok et al. (2023), a primary reference later in this work, we adopted their same priors. For the dust temperature, we used the default gamma distribution with shape parameter a = 1.5 and shifted it to start at the temperature of the cosmic microwave background (CMB, T_{CMB}); for β , we imposed a Gaussian prior centered at 1.8 and with a standard deviation of 0.25. These priors reflect the belief that T_{dust} is less likely to be extremely high and the known distribution of β across redshifts (Witstok et al. 2022, 2023). The effect of the CMB is taken into account in the modeling (da Cunha et al. 2013). We adopt the built-in dust emissivity coefficient $\kappa = \kappa_0 (\nu/\nu_0)^{\beta}$ with $\kappa_0 = 8.94 \,\mathrm{cm}^2 \,\mathrm{g}^{-1}$ at

 $v_0 = 1900 \text{ GHz}$ (~ 158 μ m, Hirashita et al. 2014), consistent with the choice in several recent works (Schouws et al. 2022; Witstok et al. 2022, 2023; Valentino et al. 2022). The choice of different emissivity coefficients has an obvious systematic impact on the final fit estimates with differences amounting up to an order of magnitude. The best-fit models for z6.3 and the arc are shown in Figure 3 and the parameters are reported in Table 3. We also attempted alternative models at fixed $\beta = 1.5, 2$ – typical choices when fewer data points are available - and implementing a self-consistent calculation of the wavelength λ_0 at which the dust emission becomes optically thin (i.e., optical depth $\tau = 1$), given the knowledge of the intrinsic source size from high-spatial resolution measurements (effective radius $R_{\text{eff}} = 1.2^{+1.4}_{-0.1}$ kpc measured in the source plane after de-lensing, F21). The results are overall consistent with the free parameter fit. On the one hand, the absence of strong observational constraints at short wavelengths does not allow for a robust determination of T_{dust} , as expected. On the other hand, the multiple ALMA detections in the Rayleigh-Jeans tail of the dust emission better constrain M_{dust} . The range spanned by the best-fit solutions, also subject to the choice of the priors, reflects the systematic uncertainties hindering the modeling of the long-wavelength spectral energy distributions (SEDs) - here and in the rest of the literature. For completeness and transparency, we report on a different selection of priors and treatment of the optical depth in Appendix A.

We estimate $T_{dust} \sim 37$ and ~ 50 K for the arc and z6.3, respectively. Both are consistent with typical T_{dust} values at $z \sim 6$ for more massive UV-, optical-, and IR-selected sources (Witstok et al. 2023). We note that, in principle, gradients in T_{dust} or dust composition (thus, β) could be present (Akins et al. 2022)

Notes. All estimates are not corrected for lensing (excluding the dy-

namical mass). The estimates of physical properties from optical and FIR/submillimeter SED modeling are expressed as the median value and the 16-84% of their posterior distributions. Upper limits at 3σ . To-tal μ SFR(FUV_{corr}), μ SFR(H α_{corr}) are derived from the luminosities at 1500Å and of the H α line corrected for the dust attenuation as in Hao et al. (2011) and Murphy et al. (2011) (Section 4.4). μ SFR(H α_{corr}) is decreased by a factor of $k_Z = 2.5$ with respect to the calibration in Murphy et al. (2011) to account for the low metallicity (12 + log(O/H) = (8.11 ± 0.20) or $Z \sim 0.25 Z_{\odot}$, Kennicutt & Evans 2012; Theios et al. 2019; Shapley et al. 2023).

[†] For the arc, this factor is defined as the observed luminosity of the image divided by the local luminosity of the strongly lensed sub region near the caustic line shown in Figure 4 of F21. The global μ factor for the whole galaxy (i.e., the observed luminosity of the multiple image divided by the overall intrinsic luminosity of the galaxy) is $\mu_{whole} = 29^{+4}_{-7}$ (F21).

‡ From [C II] observations in F21.

and potentially detectable, given the lensing configuration. As described in F21, the arc strongly magnifies ($\mu_{local} = 163^{+27}_{-13}$) a peripheral region of the source plane and it can be used to gauge possible gradients within the galaxy. On the contrary, z6.3 is the brightest lensed image that captures the global properties of the intrinsic source. Marginally higher T_{dust} are indeed preferred for z6.3, suggesting the presence of a negative dust temperature gradient. However, in practice the resolution and S/N of the integrated detections in crucial ALMA bands at the shortest and longest wavelengths do not allow for a full-fledged resolved analysis at this stage and current speculations on the presence of gradient will have to be tested against new observations. For reference, in the rest of this work we make use of the best-fit parameters with free β under the optically thin assumption and we focus on the global properties of the galaxy from the z6.3 im-

age. For completeness, the measurements for the arc are shown __in figures and reported in tables.

3.4. Modeling of optical and near-IR observations

We modeled the JWST photometry as described in detail in the companion paper by Giménez-Arteaga et al. (2024) and previous works (Giménez-Arteaga et al. 2023). Briefly, we first point-spread-function-matched the observations to the lowest available resolution in NIRCam F444W (FWHM = 0'.'16) and then we modeled the emission with BAGPIPES (Carnall et al. 2018). Since we cannot consistently resolve the molecular gas and dust emission within the galaxy with ALMA (especially that at the longest wavelengths to determine M_{dust}), we made use of the SED modeling of the integrated fluxes. However, we encourage the reader interested in the details of a pixel-by-pixel analysis of z6.3 to consult the dedicated companion paper.

We adopted Bruzual & Charlot (2003) single stellar population models², a grid of CLOUPY (Ferland et al. 2017) emission line grids extended to higher ionization parameters (up to $\log(U) = -1$), and a Calzetti et al. (2000) attenuation curve. We imposed uniform priors on the attenuation ($A_V = 0 - 3$), metallicity ($Z = 0 - Z_{\odot}$), formed stellar mass ($M = 10^5 - 10^{11} M_{\odot}$). We finally adopted the stellar mass estimate obtained with a double power-law star formation history (SFH) that is a robust choice against the "outshining" effect of young stellar populations (Section 4.2). The M_{\star} estimate is consistent with those from other parameterizations of the SFHs on resolved scales, while that of SFR is notoriously dependent on the shape of the formation history and the time window to average for the calculation. We thus refrained from using the SFR from optical/near-IR SED modeling in this work.

Finally, we derived the gas-phase metallicity and unobscured SFR on global scales by integrating the measurements of the ionized line emissions in the NIRSpec spectrum (Fujimoto et al. 2024) and the stellar continuum in the far-UV (FUV) range of the z6.3 image. The former, expressed as the oxygen gas-phase abundance [12+log(O/H)], was derived via the "direct method" based on the electron temperature T_e and the detection of the [O III] λ 4364 auroral line. The global resulting metallicity is 12 + log(O/H) = 8.11 ± 0.20 ($Z \sim 0.25 Z_{\odot}$ for a solar abundance of 12 + log(O/H) = 8.69; Asplund et al. 2009). In Section 4.3, we return to a discussion of the SFR from the H α Balmer line, sensitive to the formation of stars on timescales of ≤ 10 Myr.

4. A view of the cold gas and dust properties of a sub- L^{\star} galaxy at z = 6

4.1. Gas and dust emission tracers

We show ALMA-derived observables (or closely related quantities) in context of what is available in the literature in Figure 4. The data compilation is briefly described in Appendix B. In the space of observables, the upper limits on CO (7 – 6) and $[CI]({}^{3}P_{2} - {}^{3}P_{1})$ are consistent with the loci of L'/L_{IR} ratios (and their scatter) of variously selected IR-emitting galaxies spread across the last 13 Gyr of cosmic time. This is true also for

[§] The calibration in Heintz et al. (2021) returns the HI gas mass.

² As detailed in Giménez-Arteaga et al. (2024), a Kroupa (2001) IMF was used to model the JWST/NIRCam photometry. The stellar mass estimates are similar to those derived using a Chabrier (2003) prescription.

Fig. 3. FIR SED modeling for z6.3 (*left*) and z6.1-6.2 (arc, *right*). Black circles and arrows indicate detections and 3σ upper limits on the observed photometry. The dashed line and shaded areas mark the best-fit model with MERCURIUS under the assumption of an optically thin emission.

the $L'_{[CI]^3P_2 - {}^3P_1}/M_{dust}$ ratio, both tracers of the cold gas mass in galaxies. The combination of lensing and deep observations allows for the exploration of L_{IR} and line ratios typical of local IR-detected objects – but at the end of reionization. This is a jump of ~ 2 orders of magnitude in intrinsic L_{IR} at $z \sim 6$. The exact location of the intrinsic values in Figure 4 is of course dependent on the lensing models and it is affected by their uncertainties (Table 3), but these are confidently smaller than the jump in L_{IR} . The ratios of line and continuum emissions are also affected by uncertainties on differential lensing, but this effect seems limited especially for z6.3 (Fujimoto et al. 2024), our anchor to derive the global properties of this galaxy.

The ratios shown in Figure 4 start telling us the story of our target. In broad terms, CO(7 - 6) traces the dense and warm star-forming molecular gas and linearly correlates with L_{IR}, a classical tracer of the obscured SFR. The [C I] $({}^{3}P_{2} - {}^{3}P_{1})$ luminosity correlates with the total molecular gas content (Yang et al. 2017; Valentino et al. 2020b), despite its exact calibration being sensitive to (here unknown) excitation corrections (Dunne et al. 2022). The $L'_{[C1]^{3}P_{2}-{}^{3}P_{1}}/L_{IR}$ ratio is thus a proxy for the depletion timescale in the galaxy ($\tau_{depl} = M_{gas}/SFR$). Since the dust mass is also a tracer of the cold gas mass in galaxies (Magdis et al. 2012), the $L'_{[C_1]^3P_2 - {}^3P_1}/M_{dust}$ ratio can serve as a proxy of the (inverse of the) dust-to-gas ratio (δ_{DGR}). Figure 4 thus suggests that the z = 6 sub- L^* galaxy is generally consistent with the observed or extrapolated properties and trends of IR-detected galaxies in terms of depletion timescales and dust-to-gas ratios as a function of the obscured SFR.

4.2. Gas and dust masses

We computed the total gas mass of our galaxy by leveraging the measurements available for z6.3. We converted the $[CI]({}^{3}P_{2} - {}^{3}P_{1})$ upper limit to M_{gas} as (Papadopoulos & Greve 2004)

$$M_{\rm gas}([\rm CI]) = 1375.8 \times 10^{-12} \frac{D_{\rm L}^2 Q_{21} S_{\nu} \Delta \nu}{(1+z) A_{21} X_{\rm [CI]}},$$
(1)

where D_L is the luminosity distance in Mpc, Q_{21} is the excitation factor, $S_v \Delta v$ the upper limit on the velocity-integrated

line flux, $A_{21} = 2.68 \times 10^{-7} \text{ s}^{-1}$ the Einstein coefficient, and $X_{\rm [CI]}$ the neutral atomic carbon abundance. The excitation correction is a major factor of uncertainty and it is unknown for this object. In order to obtain an upper limit on M_{gas} , we considered $Q_{21} = [0.05 - 0.4]$, the range expected for $T_{dust} \sim 50$ K (Papadopoulos et al. 2022). Similarly, we do not know the abundance $X_{[CI]}$. We thus adopted the value for lower redshift main-sequence objects with solar-like metallicity (~ 1.5×10^{-5} , Valentino et al. 2018, similar to the average obtained by Dunne et al. 2022 for their literature sample) and assumed that it scales linearly with metallicity to our ~ 25% Z_{\odot} estimate from NIRSpec (Glover & Clark 2016; Heintz & Watson 2020). For reference, the metallicity scaling in Heintz & Watson (2020) has an intrinsic scatter of ~ 0.2 dex. With these variety of assumptions, the upper limit on $L'_{[C1]^3P_2 - {}^3P_1}$ is converted into $\mu M_{\rm gas} < (0.1 - 1.0) \times 10^{10} \ M_{\odot}.$

We calculated an alternative estimate of the gas mass from the [C II] emission. This bright line is well detected in our source (F21, Lee et al. in prep.), so the uncertainty must be due to the calibration itself. By assuming the conversion factor in Zanella et al. (2018), we find $\mu M_{gas}([CII]) = 30 \times L_{CII} = (6.9 \pm 0.6) \times 10^{10}$ M_{\odot} (F21). More recently, lower conversion factors for specific galaxy populations have also been suggested ($\alpha_{[CII]} \leq 10$ M_{\odot}/L_{\odot} Rizzo et al. 2021; Sommovigo et al. 2021). Heintz et al. (2021) proposed a metallicity-dependent calibration to the neutral atomic gas mass M(HI) based on a sample of local dwarf galaxies and distant gamma-ray bursts with [C II] in absorption in the rest-frame UV. By applying this conversion, we obtain $\mu M_{\text{HI}}([\text{CII}]) = 2.2^{+1.5}_{-0.9} \times 10^{11} M_{\odot}$, where the uncertainties include those on the metallicity and the calibration.

The gas dynamics derived in F21 offer an upper limit on $M_{\rm gas}$ independent of the assumptions on these calibrations. The subtraction of the intrinsic M_{\star} from the dynamical mass estimate $M_{\rm dyn} = (3 \pm 1) \times 10^9 M_{\odot}$ leaves $(2 \pm 1) \times 10^9 M_{\odot}$ for all the remaining components. Neglecting dark matter and dust as major contributors to the total mass of the central disk, this value can be ascribed to cold gas. The upper

Fig. 4. Observed L'/L_{IR} for CO (7 – 6) (*top*), $[CI]({}^{3}P_{2} - {}^{3}P_{1})$ (*center*), and $L'_{[CI]^{3}P_{2} - {}^{3}P_{1}}/M_{dust}$ ratios (*bottom*) as a function of L_{IR} for our targets, as labeled (downward triangles; 3σ upper limits) and a literature compilation described in Appendix **B** (red circles; colors and sizes scale with redshift). The red arrows connect the observed and de-lensed estimates of L_{IR} for our targets. The open triangles show the upper limits on our targets when fixing $\beta = 1.5 - 2$ in the SED modeling. The dashed line in the top panel indicates the empirical L_{IR} - $L'_{CO(7-6)}$ relation from Valentino et al. (2020a). The black arrows in the central and bottom panels indicate the direction of increasing depletion timescales ($L'_{[CI]^{3}P_{2} - {}^{3}P_{1}}/L_{IR} \propto M_{gas}/SFR$) and the dust-to-gas mass ratio ($L'_{[CI]^{3}P_{2} - {}^{3}P_{1}}/M_{dust} \propto \delta_{DR}^{-1}$, respectively.

limits from $[CI]({}^{3}P_{2} - {}^{3}P_{1})$ are consistent with the dynamical estimate $(M_{gas}([CI]) < (0.6 - 4.8) \times 10^{8} M_{\odot})$ and so is $M_{gas}([CII]) = (3 \pm 1) \times 10^{9} M_{\odot}$ following Zanella et al. (2018) (F21). The metallicity-dependent calibration from Heintz et al. (2021) exceeds the current limit set by dynamical arguments $(M_{HI}([CII]) = 1.0^{+0.7}_{-0.4} \times 10^{10} M_{\odot})$. However, it is useful to remind that the distribution and extension of [CII] H I, and H₂ gas might differ. An extended H I disk might not be accounted for by the dynamical modeling as traced by the [CII] emission. Also, the calibration of H I([CII]) partially relies on absorption measurements in gamma ray bursts. These measurements are sensitive to the integrated column density and might be representative of the dense central cores of galaxies. These factors should be borne in mind when comparing these calibrations

(see Heintz et al. 2023b for a discussion in the case of a similar low-metallicity galaxy at high redshift).

Figure 5 shows the global dust-to-gas mass ratio, δ_{DGR} , as a function of metallicity based on the $M_{\rm gas}$ estimates described above. The upper limits on $M_{gas}([CI])$ (under two sets of excitation conditions) reflect the location of z6.3 in the $L_{\text{IR}}-L'_{[C_1]^3P_2-{}^3P_1}/M_{\text{dust}}$ ratio shown in Figure 4. For the fiducial galaxy-integrated metallicity $12 + \log(O/H) = (8.11 \pm 0.20)$ measured via the direct method, the δ_{DGR} is generally consistent with models and empirical relations in the literature (Rémy-Ruyer et al. 2014; De Vis et al. 2019; Magdis et al. 2012; Vijayan et al. 2019; Mauerhofer & Dayal 2023; Popping et al. 2017; Popping & Péroux 2022; Popping et al. 2023; furthermore, the results from De Vis et al. 2019 are consistent with the predictions from Li et al. 2019). We note that no strong evolution in the δ_{GDR} -metallicity relation is seen as a function of redshift and estimates from distant absorption systems are in agreement with local measurements (Péroux & Howk 2020; Popping & Péroux 2022; Heintz et al. 2023a). Reversing the argument, $\delta_{\text{DGR}} \sim 0.001$ (~ 10× lower than typical values of massive dusty star-forming galaxies, Magdis et al. 2012) is consistent with the detection of [C II] and upper limits on $[C I]({}^{3}P_{2} - {}^{3}P_{1})$, under the assumptions on the calibrations mentioned above.

However, we note that the uncertainties on the measurements, the intrinsic scatter of the relations involved in Figure 5, and the fact that we are reporting measurements for a single object certainly do not allow us to exclude any models or trends. Also, given the original blind detection in [CII] and dust, we might be selecting an intrinsically dust-rich object - yet, consistent with the scaling relations shown so far. In addition, as for every global measure in this and common in the literature, we are averaging measurements on large spatial regions. The derived quantities are thus luminosity-weighted and this might introduce biases (an "outshining" effect, Sawicki & Yee 1998; Papovich et al. 2001; Giménez-Arteaga et al. 2023). In this case, the most metal-poor and least dust-obscured regions dominate the emission of the [O III] auroral line used to estimate the metallicity. These might not be the same regions emitting in the FIR. There are indeed hints of different FIR and optical emission distributions when we compare the highest ALMA resolution maps and those from JWST (Figure 1) and across the JWST photometry itself (Giménez-Arteaga et al. 2024). The geometric distributions of gas (H₂, HI, and HII) and dust and their spatial overlap (or lack-of) are factors in the calculation of δ_{DGR} . However, we are not in the position to fully explore the presence of gradients in the ALMA maps, given their resolution. Future work on higher spatial resolution data will trace the dust distribution within the galaxy and allow for the quantification of the "outshining" effect at long wavelengths.

4.3. Dust-obscured SFR

The SED modeling described in Section 3.3 returns L_{IR} , a direct tracer of the dust-obscured SFR(IR). The latter is computed as log(SFR(IR)/ M_{\odot} yr⁻¹) = log($L_{IR}/\text{erg s}^{-1}$)-43.41 (Murphy et al. 2011; Kennicutt & Evans 2012). We did not apply any further correction to homogenize the Kroupa (2001) and Chabrier (2003) IMFs, given their similarity. The significant uncertainties on T_{dust} propagate on L_{IR} and on SFR(IR) (Table 3). Given the well-established linear correlation between L_{IR}

Fig. 5. Dust-to-gas mass ratio as a function of metallicity. Purple triangles indicate the 3σ lower limits from [C I](${}^{3}P_{2} - {}^{3}P_{1}$) under high- and low-excitation conditions. The gold and blue stars indicate M_{gas} from [C II] using the conversions in Zanella et al. (2018) and Heintz et al. (2021), respectively. The red star shows the maximum amount of gas allowed by [C II] dynamics (F21). The points are slightly offset along the X axis for clarity. The uncertainty on the metallicity is represented by the horizontal red bar. The blue lines mark the (extrapolated) relations from Magdis et al. (2012), Rémy-Ruyer et al. (2014), De Vis et al. (2019), Popping & Péroux (2022), and Popping et al. (2017), Li et al. (2019), and Vijayan et al. (2019).

and $L'_{CO(7-6)}$ (Greve et al. 2014; Liu et al. 2015; Lu et al. 2017; Kamenetzky et al. 2016), we derived an alternative constraint on SFR(IR) from the upper limit on CO (7 – 6) (Figure 4). For this calculation, we adopted the parameterization:

$$\log(L'_{\rm CO(7-6)} / [\text{K km}^{-1} \text{ s}^{-1} \text{ pc}^{2}]) = (0.94 \pm 0.01) \times \log(L_{\rm IR} / L_{\odot}) + (-2.34 \pm 0.09)$$
(2)

with an intrinsic scatter of 0.16 dex (Valentino et al. 2020a). The 3σ upper limit on μ SFR(IR, CO(7-6))< 53 M_{\odot} yr⁻¹ is ~ 3× more stringent than the loosely constrained central value from the SED modeling for z6.3 (μ SFR_{IR} = $164^{+334}_{-95} M_{\odot}$ yr⁻¹), but consistent with it. The higher upper limit derived for the arc, which is a direct consequence of the larger projected area for the flux integration (Section 3.2), is also consistent with the estimate from the FIR photometry. We note that the lower estimates of L_{IR} and SFR(IR) derived by rescaling Band 6 observations in F21, L21, and Sun et al. (2022) are in full agreement with those in Table 3 – unsurprisingly, at least for the arc image whose best-fit T_{dust} ~ 37 K and β ~ 1.6 are similar to the shape assumed in these works.

4.4. Unobscured and total SFR

We computed the unobscured SFR from the FUV stellar continuum of z6.3 captured by JWST. We estimated the 1500Å rest-frame emission by convolving our blueshifted best-fit modeling of NIRCam imaging with the GALEX FUV filter and converting it into μ SFR(FUV) = $49^{+7}_{-6} M_{\odot} \text{ yr}^{-1}$ as $\log(\text{SFR(FUV)}/M_{\odot} \text{ yr}^{-1}) = \log(L_{\text{FUV}}/\text{erg s}^{-1}) - 43.35$ (Murphy et al. 2011). We obtain a similar μ SFR(UV) = 51^{+8}_{-6} $M_{\odot} \text{ yr}^{-1}$ from the total UV luminosity ($L_{\text{UV}} = 1.5\nu L_{\nu}$ with $\nu = \nu(\lambda_{\text{rest}} = 2800\text{ Å})$) following Bell et al. (2005). We note that no dust correction was applied to these estimates. We further computed a total SFR estimate (i.e., corrected for

the dust attenuation) of μ SFR(FUV_{corr}) = 135^{+171}_{-48} M_{\odot} yr⁻¹ from FUV luminosities following Hao et al. (2011), in which the correction to SFR(FUV)obs is less than that applied in Murphy et al. (2011). This value is in close agreement with μ SFR(H α_{corr}) = $141^{+42}_{-14} M_{\odot} \text{ yr}^{-1}$ using the same set of calibrations $(\log(SFR(H\alpha)/M_{\odot} \text{ yr}^{-1}) = \log(L(H\alpha)/\text{erg s}^{-1}) - 41.27,$ Murphy et al. 2011), but including a 2.5× correction for the $Z \sim 25\% Z_{\odot}$ metallicity measured for z6.3 (Fujimoto et al. 2024). In fact, these calibrations are valid under the assumptions of a constant SFH over 100 Myr timescales and solar metallicity. On the one hand, a correction for the metallicity will decrease the H α -based SFR by ~ 0.3 – 0.4 dex (a factor of ~ 2 – 2.5) because of higher production efficiency of ionizing photons by lower-metallicity, massive, and binary stellar systems (the exact conversion depends on the assumed models, e.g., Kennicutt & Evans 2012; Theios et al. 2019; Shapley et al. 2023). The metallicity effect only mildly affects the FUV output (Kennicutt & Evans 2012). The IR emission should follow that in the FUV, but the dust opacity decreases at low metallicity, reducing the IR emission at fixed SFR. The total SFR(H α_{corr}) value is broadly consistent with the sum of the IR and (uncorrected) FUV-based SFR estimate (Table 2). These total values are in slight excess, but consistent with the that in F21. This also confirms that this galaxy is consistent with the locus of the main-sequence in the M_{\star} -SFR plane at $z \sim 6$, as argued in F21.

4.5. Fraction of obscured SFR

Combining these estimates, we derive the obscured SFR fraction for z6.3 of $f_{IR} = SFR(IR)/(SFR(IR) + SFR(FUV)) = 0.76^{+0.14}_{-0.18}$ Based on the upper limit on $L_{IR}(CO(7-6))$, this fraction decreases to $f_{\rm IR}$ < 0.52. These values are in agreement with the individual IR-detections for $z \sim 7$ UV-selected sources in Algera et al. (2023) at $M_{\star} \gtrsim 10^9 M_{\odot}$ (see also Inami et al. 2022; Mitsuhashi et al. 2023a). Our more constraining upper limit on $L_{\rm IR}({\rm CO}(7-6))$ better agrees with their $f_{\rm IR}$ from stacking of the whole sample at similar M_{\star} , including non-IR detections. Similar values are reported also for more massive galaxies on the main-sequence at $z \sim 5$ (Fudamoto et al. 2020; Mitsuhashi et al. 2023b) and are in overall agreement with the f_{IR} estimates for mass-complete samples at z < 2.5 (Whitaker et al. 2017). This is also consistent with the absence of strong Ly α emission from the lensed images (rest-frame equivalent width (Ly α) \leq 4 Å for both z6.3 and the arc at 3σ , F21). Nonetheless, as mentioned above, it is useful to remember that our target was serendipitously discovered as a strong [CII] and dust continuum emitter in the first place and not preselected based on its UV emission or some rest-frame UV or optical line emission (which might miss dusty objects) as for the samples in Algera et al. (2023) and Fudamoto et al. (2020). Therefore, it does not suffer from the same selection biases of these literature works and might be a suitable representative of the more dust-rich population of sub- L^{\star} galaxies at these redshifts.

4.6. Dust production

The direct dust detection with ALMA and the fraction of obscured star formation point at efficient dust formation in this sub- L^{\star} galaxy at z = 6. The $f_{dust} = M_{dust}/M_{\star}$ fraction can offer an indication of the necessary dust yields. Considering the young average age of the galaxy (100 – 200 Myr, Giménez-Arteaga et al. 2024), the dust production via SNe is a more plausible channel than via longer-timescale AGB stars. Following the

Fig. 6. Dust mass as a function of stellar mass at 5 < z < 7. The red stars indicate the arc and z6.3 images of our galaxy, as labeled. Red arrows show the direction of the correction for the lensing magnification. The open blue symbols mark observed galaxies from the works in the legend. The empirical estimates are from Graziani et al. (2020), Pozzi et al. (2021), Sommovigo et al. (2021, 2022), and Witstok et al. (2022, 2023); the models are from Popping et al. (2017), Imara et al. (2018), Vijayan et al. (2019), Triani et al. (2022), and Mauerhofer & Dayal (2023). Arrows indicate upper limits. Blue lines show the predictions for the models listed in the legend.

recipe for a Chabrier (2003) IMF presented in Michałowski (2015), the galaxy-integrated $f_{dust} = 0.002^{+0.003}_{-0.001}$ from z6.3 is converted into a yield of $y_{SNe} = f_{dust} \times 84 = 0.19^{+0.24}_{-0.10} M_{\odot}$. This yield is in agreement with that reported in L21 ($y_{SNe} = 0.3^{+0.5}_{-0.2} M_{\odot}$). The magnified M_{dust} and M_{\star} are consistent with observed values in the local Universe and with the locus of efficient SNe dust production computed by Di Cesare et al. (2023) and Witstok et al. (2023) under similar assumptions as those adopted here.

In Figure 6, we draw a comparison with more complex dust formation models and observations of objects at z = 5 - 7available in the literature (Di Cesare et al. 2023, and references therein), complemented with a few more recent works. We corrected the stellar mass estimates of the observations and models derived under the assumption of a Salpeter (1955) IMF to the prescriptions in Chabrier (2003) or Kroupa (2001), which are similar. We did not attempt to correct M_{dust} for the different IMFs (e.g., influencing the rate of SNe) in the models, given the complex relations among parameters. The choice of different IMFs, along with SFHs, stellar population synthesis models, and several other assumptions in the SED modeling, does remain a major source of systematic uncertainties that inflates the scatter of the distribution in Figure 6. We highlight the reanalysis of high-redshift sources in Witstok et al. (2022, 2023) as we used a consistent approach, code, and priors to model the FIR emission, and thus a direct comparison can be drawn in terms of M_{dust} . Both the global and localized measurements

in the periphery of the galaxy from the z6.3 and arc images, respectively, are broadly consistent with the existing models and can be explained by SNe without invoking the contribution of AGB or efficient grain growth. Nevertheless, a contribution from growth in the ISM to the dust mass budget is not excluded if we reasonably consider destruction processes such as SN shocks, astration, or ejection (see Figure 9 in Di Cesare et al. 2023 for a depiction of the dust mass budget for combination of processes at work at high redshift).

Finally, we cannot avoid noting that we are at a stage where systematic errors totally dominate the uncertainties on $M_{\rm dust}$ and M_{\star} from observations. Even with a common set of observations, the derived physical quantities may vary by up to 1 dex. This currently hinders a critical test of theoretical models and simulations – the latter predicting $M_{\star}/M_{\rm dust}$ ratios that vary by up to one order of magnitude at $M_{\star} \lesssim 10^9 M_{\odot}$.

4.7. The cosmological context

Given the promising increase in new ALMA detections of intrinsically low-mass and faint UV galaxies at $z \sim 6$ (Glazer et al. 2023; Fudamoto et al. 2024), we attempted to place our results in a broader cosmological framework. F21 and Fujimoto et al. (2023) already discussed how our target compares with brighter IR emitters in context of 1.1 mm number counts and the derived $L_{\rm IR}$ luminosity function. Here we took advantage of the better constraints on M_{dust} enabled by the multiple ALMA detections in the Rayleigh-Jeans tail of the SED. Figure 7 shows the constraint on the dust mass function at $6 \le z \le 7.5$ that we derived from our measurement at intrinsic low masses (i.e., after applying the magnification correction to z6.3). The number statistics are identical to those in Fujimoto et al. (2023) to facilitate the comparison, where the volume has been corrected for the lensing effect and the Poissonian error bars are computed following Gehrels (1986). For reference, we show the results for the serendipitous detections in the REBELS survey at $z \sim 7$ (Fudamoto et al. 2021; Bouwens et al. 2022), where we considered the published estimates of M_{dust} , comoving volume, and correction for clustering. We opted to show this as a lower limit, considering the uncertainties on its derivation (Algera et al. 2023 for a comparison among different estimates on the SFR density from a similar set of observations from REBELS). Still following Section 6.1 in Fujimoto et al. (2023), we added constraints from sources in cosmological fields and with the Rayleigh-Jeans tail of the SED sampled by two or more bands. These include a source at z = 7.13 (Watson et al. 2015; we adopt M_{dust} from Bakx et al. 2021 and increased it by $\sim 40\%$ to account for the extended emission as in Akins et al. 2022) and a dust-enshrouded quasar at z = 7.19 (Fujimoto et al. 2022). Finally, we show the dust mass functions from a handful of theoretical models (Popping et al. 2017; Vijayan et al. 2019; Di Cesare et al. 2023; DELPHI, Dayal et al. 2022; Mauerhofer & Dayal 2023). For thoroughness, within the supplementary material, we present an alternative perspective of this figure through cumulative number counts³.

Considering all the caveats and uncertainties discussed throughout this work and the low number statistics (dominant over the exact choice of the log-bin size in the case of single sources), we find that the models shown in Figure 7 are in the right ballpark of the constraints set by our blind survey at z = 6 and targeted surveys at slightly higher redshifts. A significant drop of the number density of low- M_{dust} galaxy is expected be-

³ Available on Zenodo doi: 10.5281/zenodo.10703293

Fig. 7. Dust mass function. The blue lines show the predictions of the models at z = 6, as labeled (Popping et al. 2017; Vijayan et al. 2019; Di Cesare et al. 2023; DELPHI, Dayal et al. 2022; Mauerhofer & Dayal 2023). For reference, the dashed gray line marks the dust mass function from the fiducial model in Popping et al. (2017) at z = 0. The filled red star and open circles indicate the observational constraints based on our target and other surveys at high redshifts, as labeled (Watson et al. 2015; Bakx et al. 2021; Akins et al. 2022; Fudamoto et al. 2021; Fujimoto et al. 2022; ϕ values estimated in Fujimoto et al. 2023).

yond the peak of the cosmic SFR density. For reference, in Figure 7 we show the evolution of the dust mass function from z = 0to 6 (~ 12.5 Gyr) predicted by the fiducial model by Popping et al. (2017), able to broadly reproduce the observational estimates at z = 0 up to $M_{\text{dust}} \sim 10^{8.3} M_{\odot}$ (e.g., Vlahakis et al. 2005; Dunne et al. 2011; Clemens et al. 2013; Pozzi et al. 2020). A decrease by a factor of ~ 10 in the number density of M_{dust} $\sim 10^6 M_{\odot}$ galaxies is expected, consistent with the predictions from alternative models and with our fiducial estimate at face value. Our constraint, being formally consistent with scattered observational estimates at z = 0 (Figure 7 in Popping et al. 2017, Pozzi et al. 2021), is currently not sufficient to pinpoint any redshift evolution (or shape of the mass function). However, it is a first step in the right direction: forthcoming blind surveys and detailed multiband follow-up to determine M_{dust} will populate Figure 7 and inform us on the global dust formation in a cosmological context.

5. Conclusions

We have presented a detailed physical characterization of the global properties of a sub- L^* lensed galaxy at z = 6 with particular emphasis on the cold dust and gas components. Dust and gas were traced in a 60-hour ALMA campaign that covered the emission from ~ 90 to ~ $370 \,\mu$ m rest-frame wavelengths and several gas-tracing emission lines. Based on these and ample ancillary data, including JWST imaging and integral field spectroscopy:

1. We derive a total SFR (unobscured from FUV and H α lines, obscured from the FIR SED modeling and with an upper

limit on CO (7 - 6)) of μ SFR ~ 140 M_{\odot} yr⁻¹ (lensingcorrected to ~ 7 M_{\odot} yr⁻¹). Coupled with an updated estimate of $\mu M_{\star} \sim 1.5 \times 10^{10} M_{\odot} (M_{\star} \sim 7.5 \times 10^8 M_{\odot}$ de-lensed), this source falls on the locus of main-sequence galaxies, while being intrinsically ~ 3 times fainter than the knee of the luminosity function at z = 6.

- 2. We detect the rest-frame FIR continuum emission at six different wavelengths with ALMA, robustly confirming the presence of dust and obscured star formation at low stellar masses and metallicities ($Z \sim 25\% Z_{\odot}$ from JWST/NIRSpec).
- 3. We estimate dust temperatures in the range $T_{dust} \sim 37 50$ K, the lower end being observed in a highly magnified peripheral region of the galaxy. This might suggest the presence of a negative T_{dust} gradient, but the resolution, S/N, and lack of detections close to the peak of the dust emission currently hamper our ability to constrain T_{dust} and its possible spatial variations.
- 4. We constrain the amount of obscured star formation to $f_{IR} \leq 50 70\%$, which is consistent with trends at lower redshifts and a handful of detections and stacking at 5 < z < 7. The main uncertainties in this calculation are on T_{dust} and, by extension, on the SFR(IR).
- 5. We estimate a dust mass of $\mu M_{dust} \sim 0.3 \times 10^8 M_{\odot}$ ($M_{dust} \sim 1.5 \times 10^6 M_{\odot}$ de-lensed) and a dust-to-stellar mass fraction of $f_{dust} \sim 0.002$. This amount of dust is consistent with a rapid production from SNe without invoking AGB stars, which are unlikely to contribute due to the young age of the galaxy. Our measurements are broadly consistent with the wide range of predictions from more complex models of dust evolution.
- 6. We estimate a total gas mass, or upper limits, based on $[CI]({}^{3}P_{2} {}^{3}P_{1})$, [CII], and dynamical modeling. The dynamical modeling sets an intrinsic maximum amount of $M_{gas} \sim 2 \times 10^{9} M_{\odot}$, consistent with the upper limit on $[CI]({}^{3}P_{2} {}^{3}P_{1})$ and some of the calibrations of the [CII]- M_{gas} relation. This implies a dust-to-gas mass ratio, δ_{DGR} , on the order of $\sim 10^{-3}$, in good agreement with models and empirical $Z \delta_{DGR}$ relations in the literature.
- 7. Armed with an estimate of M_{dust} more robust and lower than typical values in the literature at these redshifts, we placed a constraint on the dust mass function at the low- M_{dust} end. Encouragingly, we find the predictions of a few recent dust formation models to be in the ballpark of our observational constraint despite all the caveats and uncertainties.

This is an example of how the synergy among cutting-edge instruments collecting deep observations across the electromagnetic spectrum opens a window onto the physics of numerous low-luminosity, low-mass, low-SFR, and low-metallicity galaxies at reionization. Future works in preparation and planned targeted observations (e.g., a ALMA high-frequency follow-up to pin down T_{dust} or at higher angular resolutions) will allow us to explore the cold gas and dust properties on sub-galactic scales. Larger samples will eventually be assembled and will be the key to constraining correlations and models, including the global production of dust in a cosmological framework, a task currently impossible given their scatter and the low number of galaxies with data of the necessary quality and coverage.

Acknowledgements. We thank the referee for their insightful comments that improved this article. We are grateful to Aswin Vijayan, Pratika Dayal, and Valentin Mauerhofer for sharing their models and predictions. FV warmly thanks Joris Witstok for help and support in using the fitting code MER-CURIUS; Kasper Heintz, Gergö Popping, and the rest of the GESO team at the European Southern Observatory for useful discussions while preparing this manuscript. Appendix A: Tests on the photometric extraction and SED modeling

In Figure A.1, we show the results of the best-fit elliptical Gaussian modeling with CASA/IMFIT (Section 3.1). For detections of both the arc and the z6.3 image, the total flux density from this modeling is consistent with that from aperture photometry (Figure A.2). This suggests that the clumping evident in Bands observed at higher resolution (Band 6 at $158 \mu m$ and shorter rest-frame wavelengths mapped by JWST) does not introduce major bias in our global estimates. Also, the detection in at $370 \mu m$ rest frame is less significant than in every other band except at $88 \mu m$. The elongated western tail in the arc image is consistent with noise.

Furthermore, as part of the supplementary material available online, we include variations on modeling of the FIR/millimeter SEDs with an alternative choice for the prior on β (flat within [1, 5]) and adopting the self-consistent treatment to estimate the wavelength at which the optical depth reaches unity ($\lambda_0(\tau = 1)$), Witstok et al. 2023). We applied this treatment to z6.3 after delensing and adopting the intrinsic effective radius in the source plane (Section 3.3). This approach confirms that, on average, the optical thin assumption holds for our target and that the ensuing best-fit parameters are consistent with those listed in Table 3 for a fixed sets of priors. Concerning the choice of the priors on the dust emissivity slope, β , the best-fit estimates (i.e., the median of the posterior distribution) determined using a uniform distribution are 15% higher and 20% lower for z6.3 and the arc, respectively, than using the physically informed Gaussian distribution. The error bars (i.e., the 16 - 84% inter-percentile range) also generally increase and the final estimates are overall consistent with the values presented in Table 3. The uncertainties connected with the exact choice on the priors (or fixed values) are known (Juvela et al. 2013; Bakx et al. 2021; Algera et al. 2023) and add up to the error budget and systematics when comparing different works in the literature. All corner plots for the SED models discussed in this work are available online as supplementary figures.

Article number, page 15 of 17

Fig. A.2. Photometric extractions. Filled circles indicate the ratio between the observed photometry extracted in Kron apertures and that from modeling with CASA/IMFIT. Large arrows show the 2σ upper limits on aperture photometry. Small gray arrows are 3σ upper limits on *Herschel*/SPIRE from Sun et al. (2022). For reference, we show both the measured Band 6 flux densities in configuration C2 and the combined C2+C5 (offset to improve the readability). *Left*: Arc (z6.1-6.2). *Center*: z6.3. *Right*: Aperture photometry of both lensed images. The flux densities are normalized to that in Band 7 (122 μ m rest frame) for clarity and to avoid introducing the uncertainties on the magnification factor. The measurements in Band 6 (158 μ m rest frame) from Fujimoto et al. (2021) are shown as orange squares.

Appendix B: Literature sample

In Figure 4, we show the measurements for our z=6 sub- L^{\star} galaxy in comparison with literature samples with available CO(7-6), $[CI]({}^{3}P_{2} - {}^{3}P_{1})$ luminosities, and reliable dust continuum detections to derive $L_{\rm IR}$ and $M_{\rm dust}$. $L_{\rm IR}$ refers to the total IR luminosity integrated between 8 and 1000 μ m. Estimates of FIR luminosities integrated over narrower ranges (e.g., 40-122 μ m) have been corrected to total with an average correction factor of ~ 1.3 . We note that similar corrections might apply depending on the exact models used in the FIR SED modeling (e.g., a modified black body predicts lower L_{IR} luminosities than physically motivated Draine & Li (2007) models, Berta et al. 2016; Valentino et al. 2018). Corrections for lensing were generally not applied. The samples include those already described in Valentino et al. 2020a, expanded to more recent results: local galaxies from the Herschel-FTS archive (Liu et al. 2015, 2021) and the HerCULES (Rosenberg et al. 2015) survey; main-sequence galaxies at $z \sim 1.5$ (Valentino et al. 2020b,a); blindly detected sources from ASPECS (Boogaard et al. 2020); variously selected submillimeter and IR-bright galaxies at z =2-6, including quasars (Walter et al. 2011; Strandet et al. 2017; Cañameras et al. 2018; Nesvadba et al. 2019; Yang et al. 2017; Andreani et al. 2018; Cortzen et al. 2020; Riechers et al. 2020; Harrington et al. 2021; Gururajan et al. 2022; Decarli et al. 2022; Lei et al. 2023; Gururajan et al. 2023; Hagimoto et al. 2023).
