

CMP: Cooperative Motion Prediction with Multi-Agent Communication

Zehao Wang^{1*}, Yuping Wang^{2*}, Zhuoyuan Wu^{3*}, Hengbo Ma⁴, Zhaowei Li⁵, Hang Qiu^{1‡}, and Jiachen Li^{1‡}

Abstract—The confluence of the advancement of Autonomous Vehicles (AVs) and the maturity of Vehicle-to-Everything (V2X) communication has enabled the capability of cooperative connected and automated vehicles (CAVs). Building on top of cooperative perception, this paper explores the feasibility and effectiveness of cooperative motion prediction. Our method, CMP, takes LiDAR signals as model input to enhance tracking and prediction capabilities. Unlike previous work that focuses separately on either cooperative perception or motion prediction, our framework, to the best of our knowledge, is the first to address the unified problem where CAVs share information in both perception and prediction modules. Incorporated into our design is the unique capability to tolerate realistic V2X bandwidth limitations and transmission delays, while dealing with bulky perception representations. We also propose a prediction aggregation module, which unifies the predictions obtained by different CAVs and generates the final prediction. Through extensive experiments and ablation studies on the OPV2V and V2V4Real datasets, we demonstrate the effectiveness of our method in cooperative perception, tracking, and motion prediction. In particular, CMP reduces the average prediction error by 16.4% with fewer missing detections compared with the no cooperation setting and by 12.3% compared with the strongest baseline. Our work marks a significant step forward in the cooperative capabilities of CAVs, showcasing enhanced performance in complex scenarios. The code can be found on the project website: <https://cmp-cooperative-prediction.github.io/>.

I. INTRODUCTION

The current autonomous driving system is critically dependent on its onboard perception. Similar to human drivers, however, such dependency is vulnerable to situations with occlusions or impaired visibility. Leveraging multiple vantage points, cooperative perception [1]–[5] uses Vehicle-to-Everything (V2X) communications to share sensory information among connected and automated vehicles (CAVs) and infrastructure. This shared information varies in format, including raw data, processed features, or detected objects, along with relevant metadata (e.g., timestamps and poses). Fusing this information from multiple viewpoints to the perspective of a vehicle recipient, the *augmented* onboard perception can now “see” beyond their direct line of sight and through occlusions.

Current V2V research has largely been confined to either cooperative perception or motion prediction, with no comprehensive studies on their joint application. Beyond

Fig. 1: A comparison between the traditional pipeline and the proposed multi-vehicle cooperative prediction pipeline. (a) The traditional pipeline conducts perception and prediction based on a single AV’s raw sensor data. (b) The proposed pipeline involves multiple cooperative CAVs, which share information to enhance both perception and prediction.

object detection, most works incorporate other tasks, such as prediction [3] and mapping [6] as auxiliary outputs. Wang *et al.* [3] proposes a V2V method for perception and prediction, which transmits intermediate representations of point cloud features. However, integrating perception and prediction, as illustrated in Fig. 1(b), to fully realize V2V cooperation remains unexplored. On motion prediction, initial efforts [7]–[9] use LSTM-based networks on simple datasets. Recent studies [10]–[12] adopt attention networks and graph convolutional networks to enhance motion prediction. However, these approaches rely on the ground-truth trajectory data, neglecting the uncertainties and inaccuracies propagated from upstream detection and tracking tasks. This reliance on ground truth data remains insufficient to address the real-world challenge of handling uncertain trajectories, underscoring the need for research that integrates perception and prediction in V2V cooperation.

To fill the gap between cooperative perception and motion prediction, we introduce a novel framework for cooperative motion prediction based on the raw sensor data. To the best of our knowledge, we are the first to develop a practical method that jointly solves the perception and prediction problem with CAV communications in both components.

Each CAV computes its own bird-eye-view (BEV) feature representation from its LiDAR point cloud. The data is processed, compressed, and broadcast to nearby CAVs. The ego CAV fuses the received features and performs detections on surrounding agents. A multi-object tracker then generates the historical trajectories of the surrounding objects. Each CAV then performs motion prediction. After that, the individually predicted trajectories from each connected vehicle are broadcast again. As our model collects the predictions from surrounding CAVs, the predictions and intermediate features from perception are used to refine the motion predictions. Our method allows for realistic transmission delays between

CAVs and bandwidth limitations.

In this paper, our main contributions are as follows:

- We propose a practical, latency-robust framework for cooperative motion prediction, which leverages the information shared by multiple CAVs to enhance perception and motion prediction performance.
- We develop an attention-based prediction aggregation module to take advantage of the predictions shared by other CAVs, which improves prediction accuracy.
- Our method achieves state-of-the-art performance in cooperative prediction under practical settings on the OPV2V and V2V4Real datasets.

II. RELATED WORK

A. Cooperative Perception

Cooperative perception allows CAVs to use advanced communication systems to share information to enlarge their fields of view. Previous works have developed early fusion techniques for cooperative object detection based on shared raw LiDAR or RGB camera data [2]. Using this strategy, however, requires high transmission bandwidth due to the preservation of complete sensor measurements. Another strategy, late fusion, allows vehicles to only share their final detections and rely on another model to fuse the detections generated by CAVs [13]. However, in real-life deployments, the performance of late fusion is capped by the loss of context information and individual detection accuracy.

To balance this trade-off, the middle-ground strategy of intermediate fusion [3], [5], [14], [15] has become more prevalent. In this strategy, CAVs employ encoder models to process the surrounding traffic information and map information to intermediate features, and then share these features with the surrounding vehicles. Upon receiving these features, CAVs fuse them with their own information and generate better perception results. For example, V2VNet [3] employed a Graph Neural Network to aggregate information from different viewpoints. AttFuse [4] deployed an attention mechanism to fuse the intermediate features. Qiao and Zulkernine [15] proposed a fusion model that adaptively chooses intermediate features for better integration. CoBEVT [5] and HM-ViT [16] have largely adopted vision transformer models

to enhance camera input processing and feature integration and achieve promising results on the OPV2V dataset [4].

B. Motion Prediction

Motion prediction is another key research topic in autonomous driving. Mainstream research mostly focuses on a non-cooperative environment where a single AV predicts without communication [10], [17]–[29]. Recent methods [18], [23], [30] encode dynamic agent historical trajectories and static map polylines into high-dimensional vectors and use graph neural networks to capture their spatial and temporal relationships, followed by decoding layers to produce multi-modal prediction hypotheses with Gaussian Mixture Models. These frameworks improve prediction accuracy by capturing the interactive behavior among agents and influence from road semantics. The most recent work introduced transformer structure into their models due to its efficient attention mechanism and ability to handle long-term prediction. MTR [10], MTR++ [11] use motion query pairs where each pair is in charge of one motion mode prediction, which is more efficient than goal-based strategies [31] and converges faster than direct regression strategies [21], [32].

III. PROBLEM FORMULATION

The goal of the cooperative prediction task is to infer the future trajectories of all the movable agents in the scene that can be detected by multiple collaborative CAVs with onboard sensors. In this work, we only use the LiDAR information for perception (i.e., object detection and tracking) to obtain the agents' trajectories. We denote the number of CAVs as N_{CAV} , the LiDAR point cloud of i -th CAV at time t as \mathbf{L}_t^i , $i = 1, \dots, N_{\text{CAV}}$, and the local map information as \mathbf{M}_t^i . Assume that there are N_t detected agents at time t , we denote their historical trajectories as $\mathbf{X}_{t-T_h+1:t}$ where T_h represents the history horizon. We aim to infer their multi-modal future trajectories $\hat{\mathbf{X}}_{t+1:t+T_f}$ based on the above information where T_f represents the prediction horizon.

IV. METHOD

A. Method Overview

Fig. 2 provides an overall diagram of our CMP framework, which consists of three major components: cooperative

perception, trajectory prediction, and prediction aggregation. The cooperative perception module takes in the raw sensor data obtained by CAVs and generates the observed agents' trajectories through object detection and multi-object tracking. Then, the trajectory prediction module takes in the historical observations and infers future trajectories from the perspective of each CAV. Finally, the prediction aggregation module leverages the predictions from all CAVs and generates the final prediction hypotheses.

B. Cooperative Perception

The cooperative perception module aims to detect and track objects based on the 3D LiDAR point clouds obtained by multiple CAVs. We modify CoBEVT [5] to serve as the backbone of the cooperative object detection model followed by the AB3DMOT tracker [33] to obtain historical trajectories of agents.

Cooperative Object Detection. PointPillar [34] is employed to extract point cloud features for each CAV with a voxel resolution of (0.4, 0.4, 4) along x , y , and z axes. Before the cross-agent collaboration, each CAV i calculates a bird-eye-view (BEV) feature $\mathbf{F}^i \in \mathbb{R}^{H \times W \times C}$, where H , W , and C denote height, width, and channels, respectively.

Due to the real-world hardware constraints on the volume of the transmitted data for V2V applications, it is necessary to compress the BEV features before transmission to avoid large bandwidth-induced delays. As in [5], a convolutional auto-encoder is used for feature compression and decompression. Upon receipt of the broadcast messages containing intermediate BEV representations and the sender's pose, a differentiable spatial transformation operator Γ_ξ is used to align the features to the ego vehicle's coordinate, which is written as $\mathbf{H}^i = \Gamma_\xi(\mathbf{F}^i) \in \mathbb{R}^{H \times W \times C}$. Our method allows for up to a 100 ms latency during feature transmission by taking in the messages sent by other CAVs at the last frame. Since sensors refresh faster than 10 fps, frames taking longer than 100 ms to transmit (e.g. partially re-transmitted or lost) will be dropped, and the latest frame will be used instead.

Then, FuseBEVT [5] is used to merge the BEV features received from various agents. More specifically, the ego vehicle first aggregates all the available features into a tensor $\mathbf{h} \in \mathbb{R}^{N_{\text{CAV}} \times H \times W \times C}$, which is then processed by the FuseBEVT module to obtain the fused feature $\mathbf{h}' \in \mathbb{R}^{H \times W \times C}$. Finally, two 3×3 convolutional layers are applied for classification and regression to obtain the 3D bounding boxes of objects.

CoBEVT outputs a collection of detections at time t denoted by $\mathbf{D}_t = \{\mathbf{D}_t^1, \dots, \mathbf{D}_t^{N_t}\}$, where N_t represents the total number of detections. Each detection D_t^j is characterized by a tuple $(x, y, z, \theta, l, w, h, s)$, which encapsulates the 3D coordinates of the object's center (x, y, z) , the 3D dimensions of the object bounding box (l, w, h) , the orientation angle θ , and the confidence score s .

Multi-Object Tracking. The tracking module is employed to associate the detected 3D bounding boxes of objects into trajectory segments. We adopt AB3DMOT [33], an online multi-object tracking algorithm, which takes in the detections in the current frame and the associated trajectories

in previous frames. Excluding the pre-trained cooperative object detection module, AB3DMOT requires no additional training and is simply applicable for inference.

More specifically, after obtaining the 3D bounding boxes from the cooperative object detection module, we apply a 3D Kalman filter to predict the state of the associated trajectories from previous frames to the current frame. Then, a data association module is adopted to match the predicted trajectories from the Kalman filter and the detected bounding boxes in the current frame. The 3D Kalman filter updates the state of matched trajectories based on the matched detections. Throughout the tracking process, a birth and death memory creates trajectories for new objects and deletes trajectories for disappeared objects. More details of these operations can be found in [33]. The tracker outputs the historical trajectories of all the agents detected at time t , denoted as $\mathbf{X}_{t-T_h+1:t}$, which serves as the input of the trajectory prediction module.

C. Motion Prediction

Our trajectory prediction module is built upon MTR [10], a state-of-the-art model consisting of a scene context encoder and a motion decoder. We only provide a general introduction, and more details about the model can be found in [10].

For the i -th CAV, the scene context encoder extracts features from the agents' trajectories $\mathbf{X}_{t-T_h+1:t}$ and the local map information \mathbf{M}_t^i . The agents' trajectories are represented as polyline vectors [18], which are processed by a PointNet-like polyline encoder [35] to extract agent features. The map information is encoded by a Vision Transformer [36] to extract map features. Then, a Transformer encoder is used to capture the local scene context. Each layer uses multi-head attention with queries, keys, and values defined relative to previous layer outputs and position encodings, integrating the trajectory embeddings and map embeddings. Future agent movements are predicted via regression based on the extracted past agent features. These predictions are re-encoded by the same polyline encoder and merged with historical context features.

After obtaining the scene context features, a Transformer-based motion decoder is employed to generate multi-modal prediction hypotheses through joint optimization of global intention localization and local movement refinement. More specifically, K representative intention points $\mathbf{I} \in \mathbb{R}^{K \times 2}$ are generated by adopting the k -means clustering algorithm on the endpoints of ground truth trajectories ($K = 64$ in our setting), where each intention point represents an implicit motion mode that represents the motion direction. The local movement refinement enhances global intention localization by iteratively refining trajectories with fine-grained trajectory features. The dynamic searching query is initially set at the intention point, and updates dynamically based on the trajectory predicted at each decoder layer, serving as a spatial point's position embedding.

In the decoder, static intention queries transmit information across motion intentions while dynamic searching queries gather trajectory-specific information from the scene context. The updated motion query is expressed as $\mathbf{C}^j \in \mathbb{R}^{K \times D}$

in the j -th layer where D is the feature dimension. Each decoder layer adds a prediction head to \mathbf{C}^j for creating future trajectories. Due to the multi-modal nature of agents' behaviors, a Gaussian Mixture Model (GMM) is adopted for trajectory distributions. For each future time step $t' \in \{t+1, \dots, t+T_f\}$, we infer the likelihood p and parameters $(\mu_x, \mu_y, \sigma_x, \sigma_y, \rho)$ of Gaussian components by

$$\mathbf{Z}_{t+1:t+T_f}^j = \text{MLP}(\mathbf{C}^j), \quad (1)$$

where $\mathbf{Z}_{t'}^j \in \mathbb{R}^{K \times 6}$ contains the parameters of K Gaussian components $\mathcal{N}_{1:K}(\mu_x, \sigma_x; \mu_y, \sigma_y; \rho)$ and the corresponding likelihoods $p_{1:K}$. The distribution of the agent's position at time t' is written as

$$P_{t'}^j(o) = \sum_{k=1}^K p_k \cdot \mathcal{N}_k(o_x - \mu_x, \sigma_x; o_y - \mu_y, \sigma_y; \rho), \quad (2)$$

where $P_{t'}^j(o)$ denotes the probability of the agent located at $o \in \mathbb{R}^2$ at time t' . The trajectory predictions of all the agents $\hat{\mathbf{X}}_{t+1:t+T_f}$ can be derived from the center points of corresponding Gaussian components.

D. Prediction Aggregation

Besides sharing the BEV features between CAVs, we also propose to transmit the prediction hypotheses generated by each CAV to others. Each CAV adopts an aggregation mechanism to fuse the predictions received from others with its own predictions. The underlying intuition is that the predictions for a certain agent obtained from different CAVs may have different levels of reliability. For example, a CAV closest to the predicted agent may generate better predictions than others. Thus, the predictions from different CAVs may complement each other, leading to the best final prediction. This mechanism is scalable and can effectively handle varying numbers of CAVs. More specifically, in a scenario with N_{CAV} CAVs and N_o predicted agents, the GMM prediction components for agent j by CAV i at time t are denoted as $\mathbf{Z}_{j,t+1:t+T_f}^i$. The local map and BEV features of CAV i are denoted as \mathbf{M}_t^i and \mathbf{H}_t^i , respectively. Before applying the attention mechanism, the predictions from each CAV are concatenated with relevant contextual features, including local map information and BEV features. This concatenation enriches the input by providing spatial context, which is crucial for accurately aligning and integrating predictions from multiple CAVs. We aggregate the GMM components of the predicted trajectories, BEV features, and map information for all CAVs. For CAV i , it begins the aggregation process by concatenating its GMM, map, and BEV features:

$$\mathbf{E}_{j,t}^i = [\text{MLP}(f(\mathbf{Z}_{j,t+1:t+T_f}^i)), \text{MLP}(f(\mathbf{M}_t^i)), \text{MLP}(f(\mathbf{H}_t^i))], \quad (3)$$

Upon receiving the GMM components from other CAVs k ($1 \leq k \leq N_{\text{CAV}}, k \neq i$), the same map, BEV features from the ego are concatenated again:

$$\mathbf{E}_{j,t-1}^k = [\text{MLP}(f(\mathbf{Z}_{j,t:t+T_f-1}^k)), \text{MLP}(f(\mathbf{M}_t^i)), \text{MLP}(f(\mathbf{H}_t^i))], \quad (4)$$

followed by a multi-head self-attention to fuse the features across all CAVs,

$$\mathbf{G}_{j,t}^i = \text{MHA}([\mathbf{E}_{j,t}^i, \dots, \mathbf{E}_{j,t-1}^k]), 1 \leq k \leq N_{\text{CAV}}, k \neq i \quad (5)$$

where MHA is multi-head self-attention, f is the flatten operation, and $\mathbf{G}_{j,t}^i$ is the aggregated feature for agent j from the perspective of CAV i . The GMM components from other CAVs are delayed by one frame. Finally, two separate MLPs derive the aggregated Gaussian parameters by

$$\mathcal{N}_{j,1:K,t+1:t+T_f}^i(\mu_x, \sigma_x; \mu_y, \sigma_y; \rho) = \text{MLP}(\mathbf{G}_{j,t}^i), \quad (6)$$

$$p_{j,1:K,t+1:t+T_f}^i = \text{MLP}(\mathbf{G}_{j,t}^i), \quad (7)$$

which will be used to sample the final prediction hypotheses.

E. Loss Functions

Cooperative Object Detection. We adopt the same loss function as CoBEVT [5]. In particular, our framework incorporates the two convolutional layers for the detection head and employs the smooth $L1$ loss for bounding box localization $\mathcal{L}_{\text{det.loc}}$ and the focal loss for classification $\mathcal{L}_{\text{det.cls}}$, as outlined in [37]. The complete loss function is

$$\mathcal{L}_{\text{det}} = (\beta_{\text{loc}} \mathcal{L}_{\text{det.loc}} + \beta_{\text{cls}} \mathcal{L}_{\text{det.cls}}) / N_p, \quad (8)$$

where N_p denotes the count of positive instances, $\beta_{\text{loc}} = 2/3$, and $\beta_{\text{cls}} = 1/3$.

Motion Prediction. Our prediction model is trained with two loss terms. An $L1$ regression loss is used to refine the outputs in Eq. (1). We also employ a negative log-likelihood loss based on Eq. (2) to enhance the prediction accuracy of the actual trajectories. We take the weighted average of these two terms as the total loss, which is written as

$$\mathcal{L}_{\text{pred}} = \omega_{\text{loc}} \mathcal{L}_{\text{pred.loc}} + \omega_{\text{cls}} \mathcal{L}_{\text{pred.cls}}. \quad (9)$$

Following [21], we apply a hard-assignment technique for optimization by choosing the motion query pair that is closest to the ground truth (GT) trajectory's endpoint as the positive Gaussian component, determined by the distance between each intention point and the GT endpoint. The Gaussian regression loss is applied at every decoder layer, and the overall loss combines the auxiliary regression loss with the Gaussian regression losses with equal weights.

Prediction Aggregation. Our prediction aggregation module produces outputs in the same format as the motion prediction module, and we thus apply the same loss function as Eq. (9) to supervise the final prediction.

V. EXPERIMENTS

A. Dataset

We use the OPV2V [4] and V2V4Real [38] datasets to validate our approach. The OPV2V dataset contains 73 traffic scenarios with a duration of about 25 seconds with multiple CAVs. A range of two to seven CAVs may appear concurrently, which are equipped with a LiDAR sensor and four cameras from different views. Following [5], we use a surrounding area of $100\text{m} \times 100\text{m}$ with a map resolution of

39 cm for evaluation. The V2V4Real dataset is a recent real-world multi-modal dataset for cooperative perception, which is collected by two vehicles equipped with LiDAR sensors and two mono cameras driving together through 67 scenarios in the USA. Each scenario lasts 10-20 seconds long.

B. Baselines and Evaluation Metrics

To demonstrate the effectiveness of our method, we conduct ablation studies on various model components and compare our method with V2VNet [3], a state-of-the-art baseline that leverages V2V communication for joint perception and prediction. V2VNet does not have a tracking module, thus we do not include it in the comparison of tracking performance. We employ the following evaluation metrics to compare our method with baselines:

Motion Prediction. We predict the agents’ trajectories for the future 5.0 seconds based on 1.0 seconds of historical observations. We use the standard evaluation metrics as in [10], including minADE₆ and minFDE₆.

Object Detection. We use the standard evaluation metrics as [4], [39], including Average Precision (AP), Average Recall (AR), and F1-score at the Intersection over Union (IoU) thresholds of 0.3, 0.5 and 0.7, respectively.

Tracking. We employ a set of standard evaluation metrics same as [33], including Multi-Object Tracking Accuracy (MOTA), Average Multi-Object Tracking Accuracy (AMOTA), Average Multi-Object Tracking Precision (AMOTP), scaled Average Multi-Object Tracking Accuracy (sAMOTA), Mostly Tracked Trajectories (MT), and Mostly Lost Trajectories (ML).

C. Implementation Details

Object Detection. CoBEVT [5] assumes no delay in the communication between CAVs, which may not be realistic due to hardware or wireless communication constraints. To address this limitation, our model allows for up to a 100 ms (i.e., 1 frame) delay in receiving the messages (i.e., BEV features) from other CAVs. In addition, our BEV features are compressed by 256 times compared with that in CoBEVT. Instead of selecting a single CAV as the ego vehicle in the original OPV2V and V2V4Real traffic scenarios as in [5] [38], we augment the training data samples by treating each of the CAVs in the scene as the ego vehicle. This leads

to a more diverse and robust dataset, resulting in improved generalization and cooperative performance across various traffic scenarios. This also allows us to incorporate multiple CAVs fused BEV features in later prediction modules. We train our model using the AdamW [40] optimizer with a learning rate scheduler starting at 1×10^{-3} and reduced every 10 epochs. We keep the consistent experiment setting for all baselines, including LiDAR range and a 100ms communication delay.

Tracking. In our setting, we set $F_{\min} = 3$ and $\text{Age}_{\min} = 2$ in the birth/death memory module. The data association module uses a threshold of $\text{IoU}_{\min} = 0.01$ for vehicles, and Dist_{\max} is set to 10. More details can be found in [33].

Motion Prediction. We use 6 encoder layers for context encoding with a hidden feature dimension of 256. The decoder employs 6 layers and 64 motion query pairs, determined by k -means clustering on the training set. We pre-train the prediction model with an AdamW optimizer [40] with a learning rate of 1×10^{-4} and a batch size of 80 over 30 epochs. More details can be found in [10].

Prediction Aggregation. We use three MLPs to encode the GMM parameters, map features, and BEV features, respectively. Then, an 8-head, 5-layer transformer encoder is used to aggregate the features, followed by two MLPs to decode the outputs into the final GMM trajectory and scores, which follow the same format as the outputs of the prediction module. We train the aggregation module with a learning rate of 1×10^{-4} and fine-tune the prediction module with a reduced learning rate of 1×10^{-6} . The learning rates decay in the same manner as the prediction model. We train the model for 30 epochs with a batch size of 8.

D. Quantitative and Qualitative Results with Ablation

Since the end goal of our work is cooperative motion prediction, we first present and analyze the quantitative results of prediction followed by the object detection and tracking performance as intermediate steps. Additionally, we provide qualitative comparisons of the predicted trajectories between our framework and the no-cooperation setting.

Cooperative Motion Prediction. We present a series of quantitative and ablation studies on cooperative motion prediction. The detailed results are shown in Table I and Fig. 4. CMP (Ours) with the *Cooperative Perception* setting does

Fig. 3: The visualizations of predicted trajectories under different model settings in two traffic scenarios. In (a) and (c), some surrounding vehicles are not detected and the predicted trajectories (colored waypoints) without cooperation deviate significantly from the ground truth (black lines). In contrast, in (b) and (d) where cooperative prediction is enabled, the predicted trajectories become closer to the ground truth due to additional useful information from others.

Fig. 4: A comparison of motion prediction performance at 5s prediction horizon under different areas covered by CAVs in OPV2V. The area is calculated based on the smallest convex hull that covers all the CAVs. As the number of CAVs increases in different scenarios, more areas are likely covered, which boosts the performance gap between no cooperation and cooperative prediction.

not include our prediction aggregation module, and CAVs only share the compressed BEV features in the perception stage. Table I shows that CMP (Ours) with the *Cooperative P&P* setting enhances the prediction performance by a large margin and the improvement becomes more significant as the prediction horizon increases. Also, it outperforms the cooperative perception and prediction network proposed by the strongest baseline V2VNet [3].

Our cooperative motion prediction (CMP) framework with cooperation in both perception and prediction stages leads to even greater improvement. In OPV2V at 5s prediction horizon, CMP achieves a 12.3%/16.4% reduction in minADE_6 and a 15.1%/19.7% reduction in minFDE_6 compared with the

V2VNet and *No Cooperation* settings, respectively. Similarly, in V2V4Real at the same prediction horizon, CMP achieves a 12.0%/22.2% reduction in minADE_6 and a 7.3%/19.0% reduction in minFDE_6 . The reason is that cooperative perception improves the detection accuracy and thus the quality of historical trajectories employed by the prediction module. Moreover, the prediction aggregation module allows CAVs to leverage the predictions from others to collectively compensate for their prediction in challenging situations. In Fig. 4, our cooperation modules bring more benefits as the CAVs in the scene cover larger fields of view. Specifically, we approximate the perception coverage area from the CAVs as the area of the convex hull formed by the CAVs. As this area grows to over 200 m², the performance improvement of our model climbs to 17.5%/28.4% compared to the other settings. The reason is that the communication between CAVs enhances the situational awareness of the ego car with more comprehensive, precise detections of surrounding objects and richer insights for future prediction.

Qualitative Results. We provide the visualizations of the predicted vehicle trajectories in two distinct scenarios in Fig. 3 to illustrate the effectiveness of cooperative prediction. Fig. 3(a) and 3(b) depict the same scenario involving two CAVs. It is evident that cooperative prediction significantly reduces the number of non-CAV vehicles that are overlooked, which highlights the enhanced sensing capability brought by cooperation, allowing each CAV to extend its perception range and detect vehicles that might otherwise be missed. Fig. 3(c) and 3(d) show another scenario, demonstrating the improved accuracy of cooperative prediction. In this case, the predicted trajectories by cooperative prediction align more closely with the ground truth thanks to information sharing between CAVs.

Cooperative Object Detection. In Table II, we demonstrate the effects of multi-vehicle cooperation, communication delay, and compression ratio of BEV features on the object detection performance. The comparisons between *No Cooperation* and other settings show the improvement brought by the CAV communications. In addition, a compression ratio of 256 only slightly degrades system performance but significantly reduces the bandwidth requirements from 82.5 MB/s to 0.32 MB/s in OPV2V. The compression only takes 0.5 ms, making its impact negligible compared with the 100 ms transmission delay, thus demonstrating efficiency in data transmission when sharing BEV features from one CAV to another. The results show that CoBEVT outperforms V2VNet on OPV2V and achieves comparable detection performance on V2V4Real. Based on these findings, we adopt a 256 \times compression ratio for BEV features and accommodate a 100 ms communication latency between CAVs, which balances between the model performance and real-world hardware constraints (i.e., bandwidth, latency).

Tracking. We show the enhancement of tracking performance enabled by multi-vehicle cooperations in Table III. V2V communication enables the fusion of perception information across different CAVs, which significantly increases the number of true positives (i.e., accurately detected objects) and reduces the instances of false positives and false negatives (i.e., missing objects). We observe a higher MOTA and MOTP in OPV2V compared to V2V4Real. The

improvement in object detection is a major cause for the enhanced performance of the tracking system. Furthermore, despite the substantial BEV feature compression, we observe no detrimental effect on the tracking performance in both OPV2V and V2V4Real, which implies that tracking remains robust even under significant feature compression.

VI. CONCLUSION

In this paper, we introduce the first-of-its-kind cooperative motion prediction framework that advances the cooperative capabilities of CAVs, addressing the crucial need for safe and robust decision making in dynamic environments. By integrating cooperative perception with trajectory prediction, our work marks a pioneering effort in the realm of connected and automated vehicles, which enables CAVs to share and fuse data from LiDAR point clouds to improve object detection, tracking, and motion prediction. Specifically, our contributions include a latency-robust cooperative prediction pipeline, communication bandwidth analysis, and a cooperative aggregation mechanism for motion prediction, which advance CAV performance and set a benchmark for future research. In this work, our framework does not yield a fully end-to-end approach due to the non-differentiable tracker. Future work will focus on developing a fully differentiable pipeline with more advanced architectures to enable a seamless cooperative system. We will also investigate multi-modal sensor fusion with heterogeneous CAVs to improve flexibility.
