Abstract

Participatory budgeting, as a paradigm for democratic innovations, engages citizens in the distribution of a public budget to projects, which they propose and vote for implementation. So far, voting algorithms have been devised and studied in social choice literature to elect projects that are popular, while others prioritize on a proportional representation of voters' preferences, for instance, equal shares. However, the anticipated impact and novelty in the broader society by the winning projects, as selected by different algorithms, remains totally under-explored, lacking both a universal theory of impact for voting and a rigorous framework for impact and novelty assessments. This paper tackles this grand challenge towards new axiomatic foundations for designing effective and fair voting methods. This is via new and striking insights derived from a large-scale analysis of biases over 345 real-world voting outcomes, characterized for the first time by a novel portfolio of impact and novelty metrics. We find strong causal evidence that equal shares comes with impact loss in several infrastructural projects of different cost levels that have been so far over-represented. However, it also comes with a novel, yet over-represented, impact gain in welfare, education and culture. We discuss broader implications of these results and how impact loss can be mitigated at the stage of campaign design and project ideation.

1 Introduction

Participatory budgeting is nowadays one of the most promising paradigms of direct and digital democracy [1, 2, 3], with over 11,000 cases worldwide [4] and annual investments in the scale of €137M by countries such as Poland [5]. In a participatory budgeting process [6, 7, 8, 9, 10], citizens initially propose their project ideas with estimated costs for implementation, given a total budget is made available by the city. These proposals are evaluated by city officials (and often by citizens' representatives) to put a number of them for voting [11]. Subsequently, citizens express their preferences using an input voting method (e.g. approval, cumulative, Knapsack [12]) and the final winning projects are calculated using a voting aggregation method (e.g. utilitarian greedy [13], Phragmen's sequential voting [13], equal shares [14]).

Fair voting outcomes with equal shares. Recently, the method of equal shares has been tested in real world, for instance, the City Idea project in Aarau, Switzerland or the projects in Wieliczka (Green Million) and Swiecie in Poland. This creates a significant momentum for key democratic innovation [11] and a breakthrough for fairer voting outcomes [14]. In contrast to the standard voting aggregation method of utilitarian greedy

¹Corresponding author: Sajan Maharjan, School of Computing, University of Leeds, Leeds, UK, E-mail: scsmah@leeds.ac.uk

that simply selects the next *most popular* project (most received votes) as long as the available budget is not exhausted, the method of equal shares selects projects that make *the most people happy*. This means that equal shares provides a proportional representation by enabling every voter to decide about an equal part of the budget. The full explanation of the method is out of the scope of this paper and it can be found in related work [14, 15]. Nevertheless, in practice the method results in voting outcomes that may sacrifice a large costly project that can be highly popular (among the ones with the top received votes), to ‘replace’ it with several smaller low-cost projects so that more voters are satisfied (yet, not to the same extent of satisfaction). For instance, in the participatory budgeting campaign of Aarau, the method of equal shares selected 10 more projects than utilitarian greedy (17 vs. 7 out of 35), while strikingly, the third most popular project is sacrificed [16].

Do fair voting outcomes come with a price? A large-scale systematic investigation of these particular effects is the motivation and focus of this paper. In particular, we hypothesize that the fairness of equal shares results in potential compromises of impact and novelty in the voting outcomes. This critical inquiry is not made with the aim to claim any ineffectiveness or faulty design of equal shares on these aspects, although alternative aggregation methods that optimize for other qualities are plausible. It is also not made to claim that fairness is anyhow a necessary condition for impact loss. Instead, with this inquiry we aim to provide new insights to citizens, city authorities and designers of participatory budgeting campaigns about the proposed projects and their selection to be put for voting such that voting outcomes by equal shares are even more legitimate, impactful and mitigate for any potential (cost) biases, see Section 3. These insights, missing so far, are critical and timely, and they are expected to significantly strengthen the adoption of methods that promote fairness, such as equal shares. As Cho points out, political fairness is a complex phenomenon, and requires compromise and balancing competing interests so that members of all groups are represented [17]. For instance, infrastructure planning and investments to meet net-zero targets in cities can be costly [18, 19]. To what extent is it likely for equal shares to disadvantage such projects because of their inherently costly nature, resulting in biases affecting sustainability? Or is it likely that multiple such type of projects have more chances to materialize when they have a more localized scope and collectively build, in a more bottom-up way, a sustainability impact at city scale? Do such biases over impact areas also affect in turn the voting turnout within different groups? For instance, Stewart et al. have highlighted the case of participatory budgeting held in Chicago’s 49th ward on how a biased voter-turnout resulted in the selection of low-priority projects favouring only specific population demographics [20]. All these are some key questions that this study tackles for the first time and which come with significant policy implications.

On the challenge of measuring impact of voting outcomes. Measuring the impact and novelty of voting outcomes is by itself a complex long-standing challenge, and one that this paper addresses. The absence of a standard for impact evaluations on the outcomes of participatory budgeting processes is expected given the inherently ambiguous nature of the term *impact*. Impact is a multi-faceted concept and can be assessed differently by different stakeholders. The European Commission underscores the importance of conducting impact assessments for any public initiatives anticipated to yield substantial economic, social, or environmental modifications [21]. Campbell et al. have conducted a scoping review on the impact of participatory budgeting processes on health and well-being [22]. Beuermann and Amelina have presented their findings of experimental evaluation of a participatory budgeting model carried out in Russia, reporting an increased citizens’ engagement in public decision making and raised revenue in the local tax collection [23]. Hajdarowicz has conducted a qualitative analysis on the empowerment of women from participatory budgeting processes [24]. Cabannes presents case studies of participatory budgeting instances in four cities across Latin America on the initiatives to involve children and young people in the local governance of their cities [25]. There is a significant body of literature assessing the impacts of participatory processes [26, 27, 28, 29], however such work has focused on the impact of overall participatory processes and no existing work evaluates the impact loss or gain by the winning outcomes of different voting aggregation methods. A recent work by Nelissen on the empirical analysis of the winning outcomes by equal shares and utilitarian greedy across 35 participatory

budgeting instances held in Amsterdam [30], is the most pertinent to our study. However, our work provides a much larger and more comprehensive empirical analysis, along with a novel impact framework to characterize the voting outcomes of equal shares and several new revealing insights stemming from the application of this framework.

A framework for measuring impact and novelty. We introduce a novel measurement framework of impact and novelty of voting outcomes in participatory budgeting, see Figure 1. It consists of the following elements: (i) The voting aggregation method that forms the voting outcomes. For this study, we focus on the utilitarian greedy (popularity-oriented) and the equal shares (fairness-oriented) methods. (ii) A number of impact areas (and beneficiaries) that characterize a proposed project. For instance, a new park with a playground is likely to create impact on the urban greenery and public space development, in particular for children and families. (iii) A number of metrics that characterize different qualities of voting outcomes related to the cost utilization and frequency of certain projects in the winning set. *By bringing these three elements together, it becomes possible to assess a number of metrics for the winning projects of a certain impact area and voting aggregation method.* We also distinguish for a certain impact area the exclusive winning projects of a particular aggregation method, these are, for instance, the projects of this impact area selected by equal shares but not by utilitarian greedy. Based on this principle of exclusivity, we introduce novelty metrics that can be applied to the cost and number of projects belonging in an impact area. For both impact and novelty metrics, the loss (or gain) of equal shares over utilitarian greedy is measured as their difference.

Impact metrics. The impact metrics characterize the cost and frequency utilization of the winning projects in an impact area by a voting aggregation method. Two metrics focus on the winning projects set: the cost and number of winning projects in a certain impact area out of the total cost and number of winning projects (*budget share* and *winning rate* respectively). Two other metrics focus on the representation of the proposed projects from an impact area in the winning set: the cost and number of winning projects in a certain impact area out of the total cost and number of proposed projects in this impact area (*cost representation* and *project representation* respectively). Last but not least, two metrics focus on the proportionality of projects of an impact area in the set of winning and proposed projects: the cost and number of winning/proposed projects in an impact area over the cost and number of all winning/proposed projects (*cost proportionality* and *project proportionality* respectively). Mathematical formulations are given in Section 4.

Novelty metrics. They characterize how unique the winning projects of a voting aggregation method are. Two notions of novelty are distinguished: *within-impact-area novelty* that measures the cost or number of exclusive winning projects in an impact area by a voting aggregation method, out of the total cost or number of *winning projects in this impact area*. In contrast, *between-impact-areas novelty* measures the cost or number of exclusive winning projects in an impact area by a voting aggregation method, out of the total cost or number of *exclusive winning projects in all impact areas*. Mathematical formulations are given in Section 4.

Analysis of biases in 345 participatory budgeting elections. To acquire evidence for any potential impact and novelty loss of equal shares, we apply the proposed framework to 345 out of 810 participatory budgeting elections data collected from the PABULIB [31] repository. These participatory budgeting instances are the ones that contain information about the impact areas and beneficiaries of the voted projects. Each project has one or more labels for the following 9 impact areas: *education, health, welfare, culture, public transit and roads, public space, urban greenery, environmental protection, sport*. Likewise, each project comes with one or more labels for the following 8 beneficiaries: *families with children, students, disabled people, children, adults, animals, youth, elderly*. To control for the factor of cost when assessing the impact and novelty loss, the following additional labels are assigned to each project based on the cost quartile it belongs: *very cheap, cheap, expensive or very expensive*. This allows us to distinguish between biases on project costs on which the method of equal shares relies for its calculations and biases on the project impact area. We also conduct a conjoint analysis [32] to explore causal evidence and explain how the impact areas represented in the winning projects explain the voting outcomes by different voting aggregation methods.

Real-world case studies of equal shares for impact loss mitigation. Note that all the studied par-

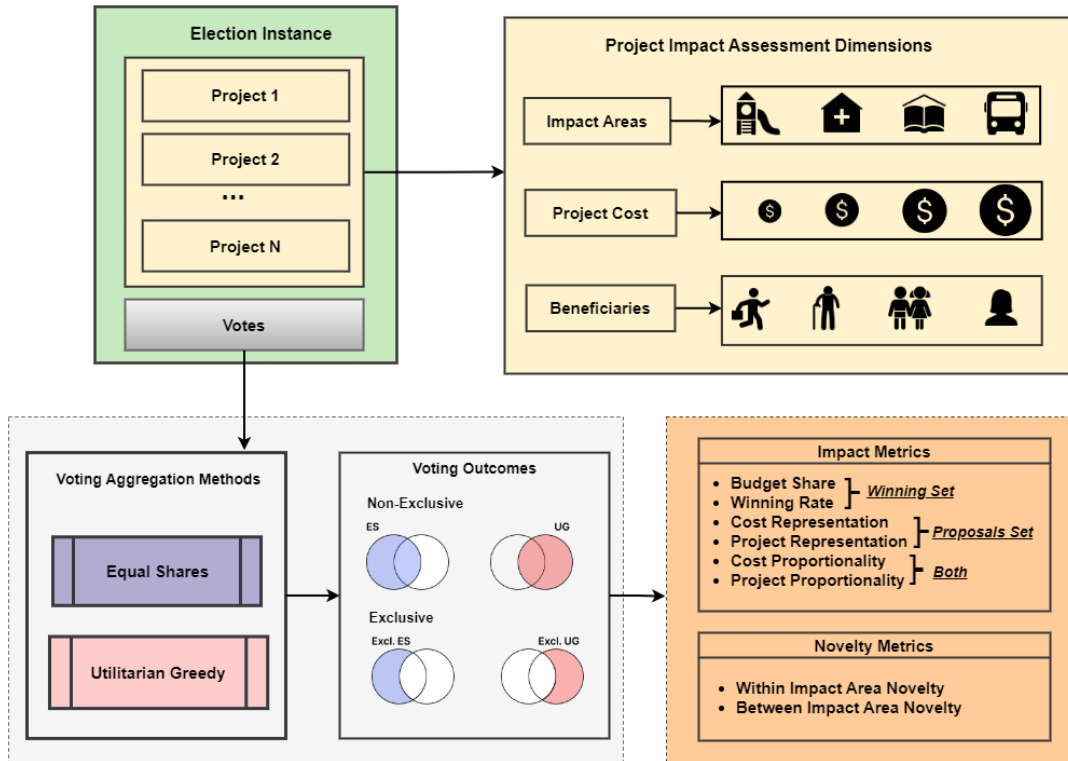

Figure 1: **Impact and novelty assessment framework for voting outcomes of participatory budgeting as a result of using different voting aggregation methods.** The framework consists of a number of impact metrics applied to different impact areas, project cost levels and beneficiaries. The metrics characterize the winning set (budget share and winning rate), the proposals set (cost and project representation) and both (cost and project proportionality). The novelty methods are distinguished between within-impact-area and between-impact-areas measurements, see Section 4 for more information. The impact assessments rely on non-exclusive winners, while the novelty assessments on exclusive winners between two voting aggregation methods.

participatory budgeting elections used utilitarian greedy. It is likely that if another voting aggregation method was used, the projects and even the choices of voters would be different, for instance, lower-cost project would be proposed and likely in different impact areas. To address this threat of validity, we pick up the public voting outcomes [16, 33] of two real-world participatory budgeting processes designed to run with the method of equal shares: (i) *Green Million (Wieliczka)* and (ii) *City Idea (Aarau)*. We study these voting outcomes as case studies and hypothesize that they mitigate part of the overall impact and novelty loss.

2 Results

Five key results are illustrated in this paper – (i) Equal shares results in voting outcomes with an impact loss in several infrastructural and sustainable development projects and an impact gain in welfare, education and culture. Strikingly, impact loss for such infrastructural and sustainable development projects is more frequent, while impact gain in welfare, education and cultural projects is larger in scale. (ii) Equal shares results in novelty gain in terms of unique winning projects within each impact area. It also results in novelty

gain for the unique winning projects of welfare, education and culture out of all unique winning projects. In all other cases, equal shares shows novelty loss. (iii) Equal shares creates low under-representation for the impact area of public transit and an over-representation for education and culture. However, it contributes to a significant reduction in the over-representation of urban greenery, environmental protection and public space by the utilitarian greedy. (iv) Equal shares results in impact loss that originates from both high and low cost projects for the impact areas of infrastructural and sustainable development projects. Strikingly, high-cost sport projects show impact loss, while low-cost ones show impact gain. (v) The application of equal shares in two real-world participatory budgeting campaigns mitigates impact loss in public space, urban greenery, sport and, for one of the campaigns, in public transit. Culture and education show lower impact gain than anticipated.

2.1 Impact loss and gain of equal shares

Equal shares has an impact loss in infrastructural and sustainable development projects. Figure 2 shows the impact loss from utilitarian greedy to equal shares measured with the four metrics distinguished by different impact areas. Projects related to infrastructural and sustainable development such as public space, public transit, urban greenery and environmental protection show higher impact loss. For instance, the highest mean loss of budget share is 7% for public space, 6% for urban greenery and 5% for public transit projects. The voting instances with the budget share losses are 54%, 36% and 38% respectively. The voting instances with the winning rate loss are 57%, 60% and 48% respectively for these impact areas. For cost and project representation, these are 56%, 40%, 41% and 8%, 15%, 14% respectively.

Equal shares has an impact gain for culture, education and welfare. Unlike infrastructural and sustainable development projects, there is a net impact gain (as signified by negative values of mean loss) for culture, education and welfare projects across all 4 impact metrics. For instance, the mean loss of cost representation is -25%, -20% and -15% for welfare, culture and education. Moreover, the number of voting instances with impact losses is as few as 4%, 9%, 16% respectively for both metrics of cost representation and budget share in such impact areas. Similarly, the voting instances with winning rate losses and project representation losses are 14%, 14% and 13% and 1%, 1% and 2% respectively, which is the lowest among other impact areas.

2.2 Novelty loss and gain of equal shares

Novelty gain of equal shares: Figure 3 illustrates the within and between novelty loss (and gain) across different impact areas. *Within-impact area novelty gain is observed across all impact areas.* The within novelty gain is prominent for the impact areas of education, culture and welfare. For instance, in terms of winning costs and winning projects, the within novelty loss is -39%, -52%, -75% and -48%, -56%, -76% respectively. This means that of the winning costs that are allocated to these impact areas, an additional 39%, 52% and 75% of winning costs for respective impact areas can be attributed to exclusively winning projects by the equal shares which ultimately results in a net impact gain. *Equal shares also exhibits between novelty gain but of lower magnitude for the same impact areas of education, culture and welfare* i.e. in terms of winning costs and winning projects, the novelty losses are -30%, -28%, -13% and -36%, -33% and -13% respectively.

Figure 2: Equal shares results in voting outcomes with an impact loss in infrastructural and sustainable development projects and an impact gain in welfare, education and culture. Strikingly, for sustainable infrastructure projects impact loss is more frequent, while impact gain is larger in magnitude for culture, education and welfare projects. For each of the four depicted impact metrics i.e. (A) budget share, (B) winning rate, (C) cost representation and (D) project representation, positive loss (Y-axis, $UG - ES$) in an impact area (colored lines) shows outperformance by utilitarian greedy (UG), while negative loss shows outperformance by equal shares (ES). The X-axis denotes election instances sorted according to impact loss. A circular marker is placed for each line to easier distinguish the number of voting instances with positive/negative loss. The four numbers next to each impact area denote the (i) % of voting instances with positive loss, (ii) the mean ‘~’, (iii) mean positive ‘+’ and (iv) mean negative ‘-’ impact loss. Two additional numbers with the prefixes ‘+’ and ‘-’ placed on each of the metrics signify the overall mean positive and negative impact loss respectively across all impact types.

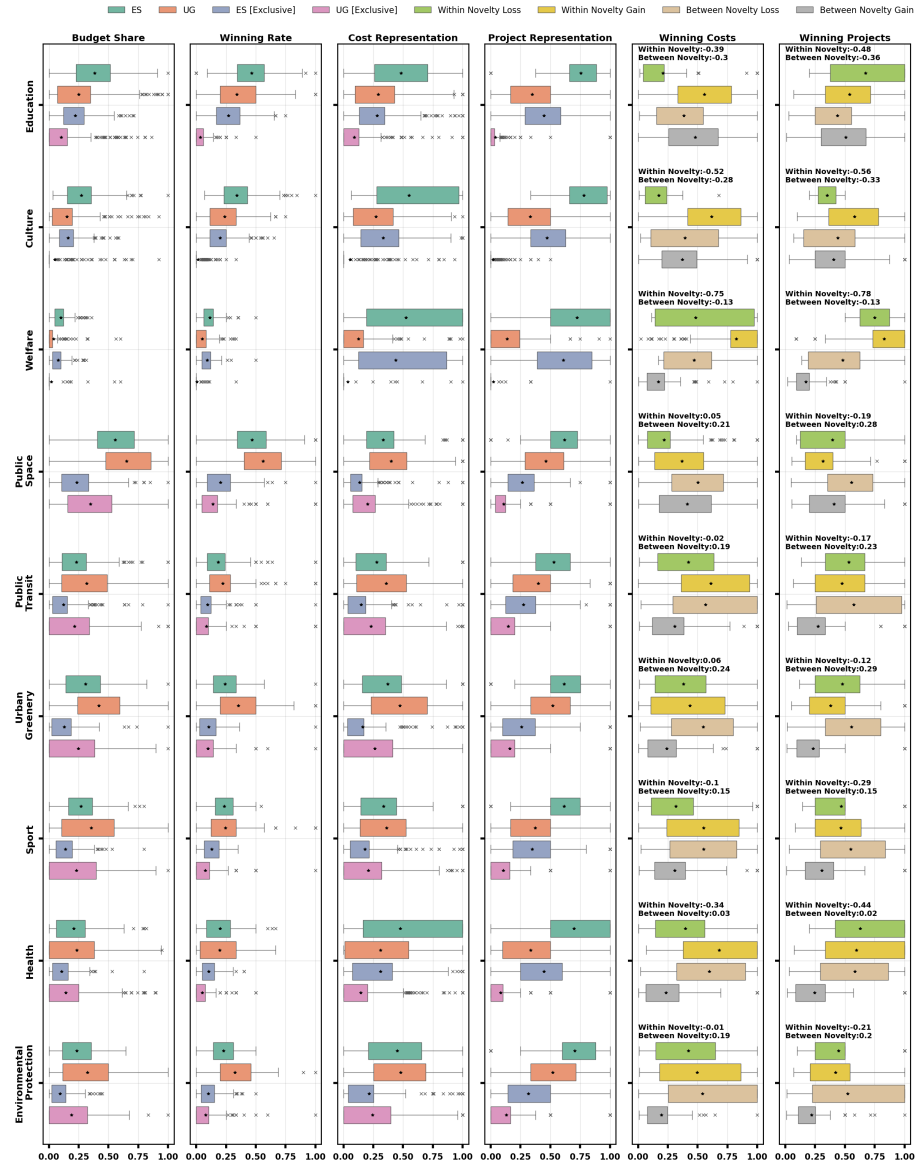

Figure 3: Equal shares has an impact loss in all impact areas besides education, culture, welfare and in all impact metrics besides winning rate, which shows a universal impact gain for equal shares. Equal shares also shows within novelty gain in almost all of the impact areas and between novelty gain in the areas of education, culture and welfare, in which it also shows impact gain. In all other impact areas, equal shares shows loss of between novelty. Within novelty comes with larger gains than losses, while between novelty comes with larger losses than gains. The figure shows different impact areas (Y-axis) for different impact and novelty metrics (X-axis). They compare the impact (first four columns) of exclusive vs. non-exclusive winning projects in equal shares (ES) and utilitarian greedy (UG). They also compare the novelty gain and loss (last two columns) of equal shares over utilitarian greedy in two different ways: (i) *within-impact-area novelty*, which measures the share of cost and number of exclusively winning projects within a single impact area out of the total cost and number of winning projects for that impact area and (ii) *between-impact-area novelty*, which measures the share of cost and number of exclusively winning projects for a given impact area out of the total cost and number of exclusive winning projects across all impact areas. The overall within and between novelty losses of each impact area is also shown.

Novelty loss of equal shares: *Equal shares shows between novelty losses for impact areas of public transit, public space, urban greenery, sport and environmental protection.* For instance, in terms of winning costs, the between novelty losses for urban greenery, public space, public transit and environmental protection is 24%, 21%, 19% and 19% respectively. This means that out of the total exclusively winning costs by respective aggregation methods, equal shares reduces the cost allocation on exclusively winning projects by 24%, 21%, 19% and 19% for such impact areas respectively. Likewise, in terms of winning projects, the between novelty losses for the same impact areas are 29%, 28%, 23% and 20% respectively.

2.3 Proportionality in representation of impact areas by equal shares

Equal shares introduces a proportional representation of diverse project types. Figure 4 illustrates the performance of equal shares and utilitarian greedy for projects across different impact areas in terms of project proportionality. This impact metric measures the proportionality of representation of a given impact area in winning outcomes with respect to the initial distribution of proposed projects. We find that winning outcomes by equal shares are more proportionally represented compared to utilitarian greedy. A value of project proportionality greater than 1 for an impact area means that the impact area is over-represented in the winning outcome while a value less than 1 signifies under-representation. Particularly, equal shares increases the proportionality in representation of under-represented impact areas such as education, culture and welfare, while slashing over-representation of urban greenery and environmental protection. Since the value of the project proportionality metric by equal shares across all impact areas roughly aligns around a fair representation value of $y = 1$, a diverse set of project types are proportionately represented in the winning outcome. The equal shares method also improves the project representation for specific beneficiaries. Table 1 shows that across all beneficiaries, the project representation by equal shares increases significantly compared to utilitarian greedy. *The increase in project representation for population beneficiaries and more proportional representation of various impact areas comes at the expense of sacrificing ambitious projects for less expensive ones* (see Figure 1 in SI).

Table 1: **Equal shares results in selection of projects that increases project representation across all target beneficiaries compared to utilitarian greedy.** Table shows the overall number of proposed projects across all instances targeted towards specific beneficiaries and the corresponding values for project representation by utilitarian greedy and equal shares.

Beneficiaries	Total Projects	UG Project Representation	ES Project Representation
Families	2625	47.6	66
Students	366	44.3	72.1
Disabled People	4266	28.3	61.9
Children	7062	33.7	65
Adults	7656	35.3	66.6
Seniors	6239	33.8	65.7
Animals	313	67.1	80.8
Youth	6943	33	65.5

2.4 Impact loss across impact areas and different cost levels

Our findings so far suggest that impact is lost by equal shares for infrastructural and sustainable development projects while impact is gained for projects related to education, culture, welfare. Moreover, on account of equal distribution of budget among all voters by the equal shares, expensive projects are discouraged while

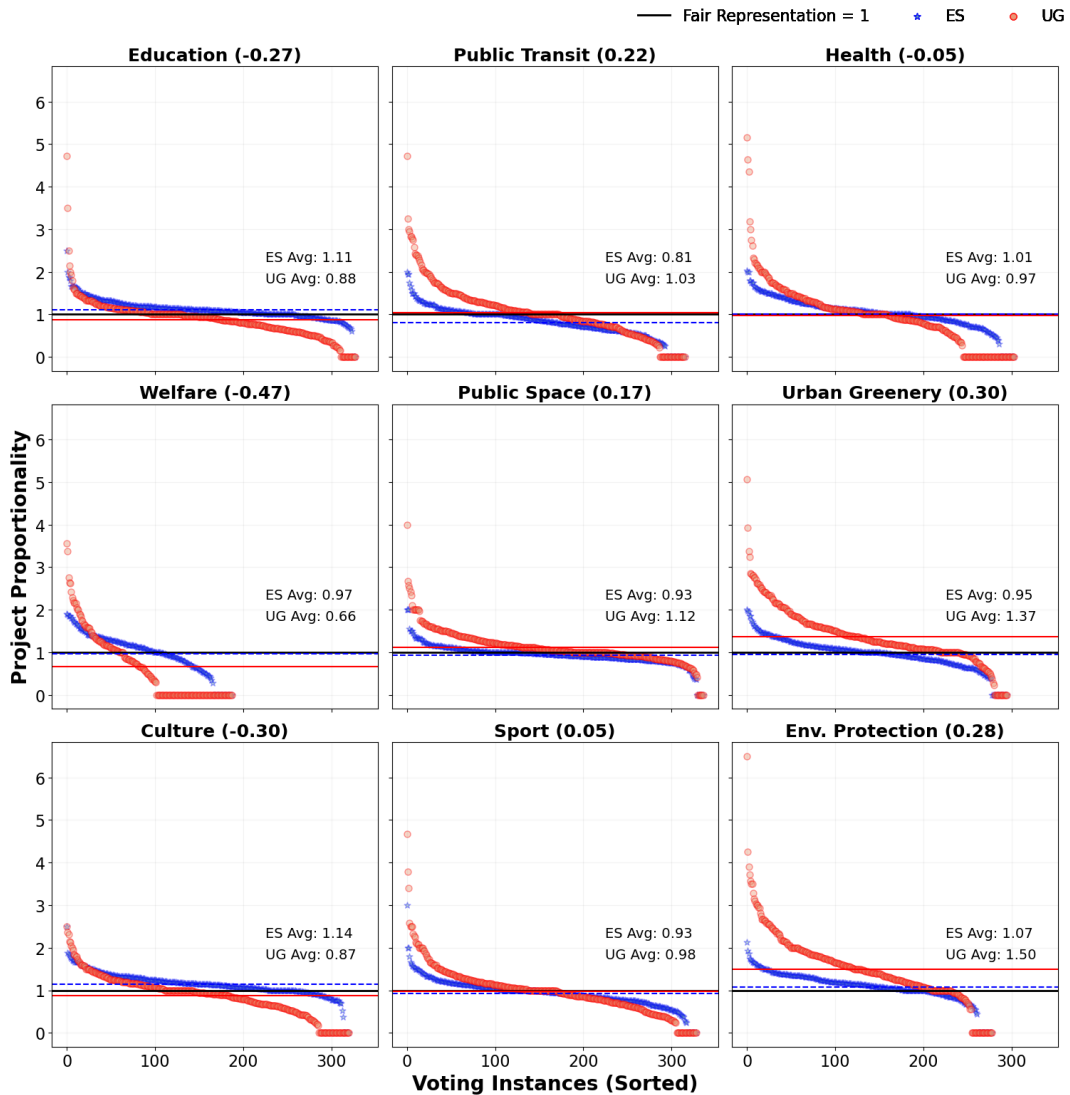

Figure 4: Equal shares (ES) shows impact gain in project proportionality for education, welfare, culture and health, with an impact loss in all other impact areas. Equal shares over-represents the impact areas of culture and education by 14% and 11% respectively, while it under-represents the area of public transit by 19%. In contrast, utilitarian greedy (EG) over-represents urban greenery, environmental protection and public space by 37%, 50% and 12% respectively, while under-representing welfare by 34%. For each of the nine depicted impact areas, a project proportionality (Y-axis) of '1' shows a fair representation of the projects, as the ratio of an impact area in the ballot of projects equals the ratio of this area in the winning projects. The X-axis denotes voting instances sorted according to impact loss. Values >1 denote over-representation and <1 under-representation. The numbers in the parentheses next to each impact area denote the impact loss measured by the difference of project proportionality between utilitarian greedy and equal shares with respect to the initial value of utilitarian greedy i.e., $(UG-ES) / UG$.

inexpensive projects are favored (see Figure 1, 2 in SI). We compare the impact loss or gain of equal shares for projects in different impact areas across multiple cost levels. Figure 5 illustrates the average impact performance of equal shares and utilitarian greedy and consequently the impact loss or gain of equal shares for projects in different impact areas across various cost levels.

Here we see that, despite the preference of low-cost projects by equal shares, very-cheap urban greenery projects exhibit an impact loss of 5% on average for both metrics of budget share and winning rate. However, in terms of cost and project representation, equal shares achieves an impact gain of 4% for both metrics. For very-expensive urban greenery projects, the impact loss of equal shares in terms of budget share and winning rate is minimal (0% and 1%) respectively, while loss in terms of cost and project representation is more significant (7% and 5% respectively). Similarly, for very cheap environmental protection projects, the impact lost in terms of budget share and winning rate by equal shares is 6% and 7% respectively. However, in terms of cost and project representation, equal shares achieves an impact gain of 5% and 5% respectively.

On the other hand, projects related to education and culture exhibit a different trends of impact across various cost levels. For very cheap education projects, impact is gained by equal shares for all metrics i.e. budget share, winning rate, cost and project representation by 7%, 7%, 23% and 21% respectively. For very cheap culture projects, the impact gained for these metrics are 4%, 4%, 15% and 14% respectively. However, for very expensive educational projects, impact is gained by equal shares in terms of budget share and winning rate by 6% and 6% respectively, while impact is slightly lost in terms of cost and project representation by 3% and 2% respectively. Despite very expensive projects in culture and welfare, equal shares results in an impact gain of 5%, 2% and 4%, 2% respectively in terms of budget share and winning rate. However, impact is lost by a marginal value of 1% for such very expensive projects in culture and welfare in terms of cost and project representation.

How impact areas and cost levels explain voting outcomes: a conjoint analysis. We have conducted a conjoint analysis to explore the causal relationship in determining the budget utilization rate of equal shares and utilitarian greedy using the attributes of impact areas and cost levels. Eight independent variables are used (4 variables for popular combination of project impact areas X 2 variables for cost levels). Table 2 tabulates the most frequently observed combination of project impact areas. These combinations of project impact areas group sustainable infrastructure projects, education & cultural projects separately. For each of these 4 independent variables with combinations of impact area labels, we further segregate them into two cost-price levels – low-cost and high-cost, resulting in a total of 8 independent variables.

Table 2: **Most frequently observed mutually-exclusive combination of labels for project impact areas**

Project Tags Combination	Number of Projects
Culture, Education	1227
Environmental Protection, Public Space, Urban Greenery	966
Public Space, Public Transit and Roads	755
...	...
Health, Public Space, Sport	261

Based on the presence or absence of winning projects with these combinations at two different cost levels in the winning outcomes of equal shares and utilitarian greedy, we model a choice-based conjoint analysis problem that contributes to the budget utilization (overall budget share). Our modeling results in a good fit for both equal shares and utilitarian greedy with $R^2 = 0.88$ and $R^2 = 0.82$ respectively with significant p-values for all independent variables (i.e. $p\text{-val} < 0.05$).

The relative importance (part-worth utilities) of different project impact areas and cost-price levels by equal shares and utilitarian greedy is shown in Figure 6. The conjoint analysis further reinforces the findings

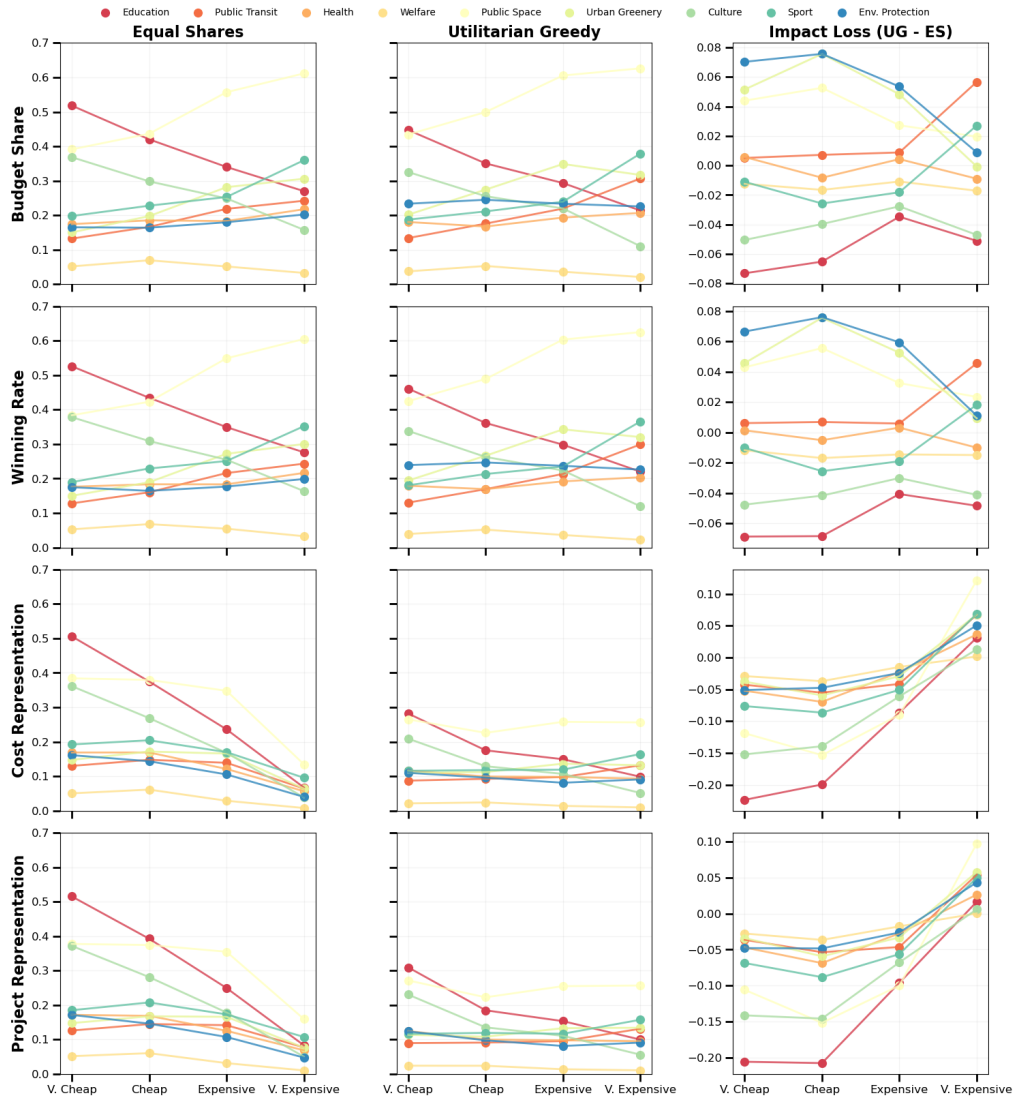

Figure 5: The impact loss of equal shares for public transit originates from very expensive projects in budget share (5%) and winning rate (5%). In contrast, the impact loss of equal shares for environmental protection, urban greenery and public space originates from very-cheap and cheap projects i.e. 7%, 5%, 4% and 8%, 7%, 6% respectively in terms of budget share and 7%, 4%, 4% and 7%, 7%, 6% respectively in terms of winning rate. Strikingly, sports projects that are very expensive show impact loss (3% and 2.5% respectively), while sports projects that are cheap and slightly expensive show impact gain (2.5% and 2.5% respectively). For cost and project representation, impact loss is observed for very expensive projects, while projects of any other cost level result in impact gain. Impact values (Y-axis) of equal shares (ES) and utilitarian greedy (UG) across different impact areas for (A) Budget Share, (B) Winning Rate, (C) Cost Representation and (D) Project Representation segregated at different cost levels (X-axis) is shown. The last column of plots depicts the respective impact loss values ($UG - ES$).

of our results. The figure illustrates that projects with the combination of *education, culture* at low-cost contribute the most to budget utilization by both equal shares and utilitarian greedy (relative importance of 71.6% and 52.5% respectively). However, the same combination of projects at higher cost ranges contributes negatively to the budget utilization rate in both aggregation methods. *Likewise, projects with combinations of environmental protection, public space and urban greenery across both cost ranges contribute positively to the budget utilization rate in the case of utilitarian greedy, whereas such projects contribute negatively in the case of equal shares. This observation is congruent with results that suggest impact is lost by equal shares for sustainable infrastructure related projects while impact is gained for projects related to culture, education and welfare.*

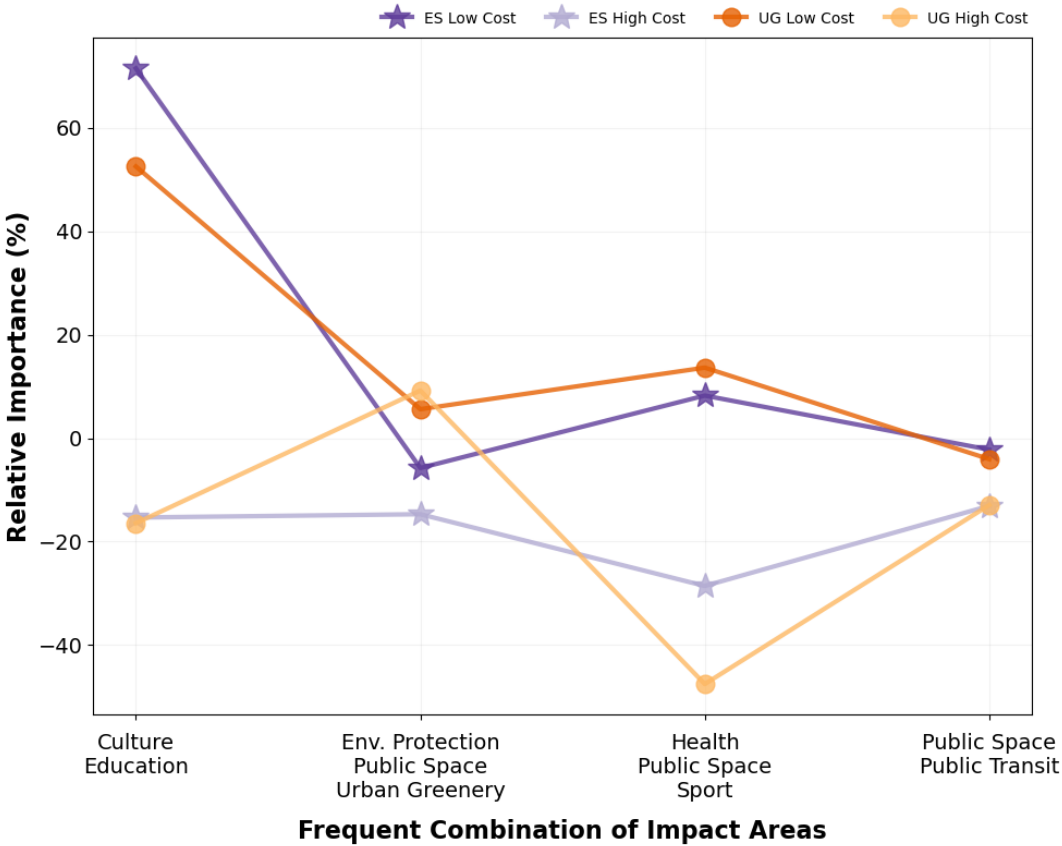

Figure 6: The impact areas of culture and education with low cost have the highest importance in both equal shares and utilitarian greedy, while for high costs, both of these impact areas come with negative importance. This pattern is also observed for the combinations of health, public space, sport and public space, public transit. In contrast, for the impact area of environmental protection, public space and urban greenery, the voting aggregation method is more important than the cost: positive importance for both cost levels of utilitarian greedy, negative importance for both costs of equal shares. Most frequent combinations of impact areas (X-axis) across cost levels and their relative importance (Y-axis, part-worth utilities) contributing to budget utilization rate by equal shares and utilitarian greedy is shown.

2.5 Equal shares in real world: the cases of City Idea & Green Million

Does equal shares mitigate impact loss in real world? Here we explore the impact loss and gain of equal shares across different impact areas for recently implemented participatory budgeting instances in Aarau (City Idea Project) and Wieliczka (Green Million), in which winning outcomes were determined using a variant of the equal shares method (*add1* using integral endowments for Green Million and *add1u* for City Idea). The impact loss (or gain) on the winning outcomes by equal shares for these two cases along with the mean values of overall voting instances is shown in Figure 7.

Figure 7: The application of equal shares in real-world mitigates impact loss in public space and urban greenery for budget share and winning rate, while an impact loss is observed in culture and education and impact gain in sport. A significant impact gain for public transit is observed in the Green Million campaign in Poland. Welfare in the City Idea campaign in Switzerland shows impact gain for budget share and winning rate. The impact loss (Y-axis) for different impact metrics across different impact areas (X-axis) for (i) all 345 voting instances (mean), (ii) the Green Million campaign in Wieliczka, Poland and (iii) the City Idea campaign in Aarau, Switzerland.

The winning outcomes by equal shares for the Green Million participatory budgeting instance is different from the expected winning outcomes of equal shares. Contrary to the expected equal shares outcome, it is seen that projects under impact areas of public transit, public space, urban greenery and environmental protection achieves an additional impact gain instead of expected impact loss for such projects. This is because the Green Million Project, as its name suggests, was particularly aimed at promoting eco-friendly "green" projects

such that most of the proposed projects were related to environmental protection, urban greenery and public space. Likewise, due to the absence of projects related to education, culture and welfare for this instance, an unexpected and significant impact loss is observed (in terms of all metrics) for such impact areas.

In case of the City Idea Project in Aarau, the winning outcomes by equal shares exhibit expected impact gains for welfare and expected impact loss for public transit and environmental protection related projects. However, unlike the expected impact gains for projects related to education by equal shares, a significant impact loss for educational projects is observed across all impact metrics. Also, a significant impact gain is observed for projects related to urban greenery. This is because, among the proposed project, only a single project (relatively expensive) was labeled under education while more number of projects (relatively cheaper than the cost of the single educational project) were assigned for urban greenery.

3 Discussion

The findings and key results comes with some significant implications. Equal shares gains momentum with radically different voting outcomes in participatory budgeting: a larger number of lower cost projects are elected (see Figure 1 in SI), often ‘replacing’ expensive popular projects, creating a fundamentally different impact for the society as a result of higher proportional representation of voters’ preferences. We show that there are some opportunities and risks here. In particular, infrastructural projects, especially ones related to sustainability, may be frequently disadvantaged by equal shares, as a result of their inherently costly nature but also beyond this, see Figure 5. On the other hand, equal shares strongly favors novel welfare, education and cultural projects, which is a likely result of their lower cost in the context of participatory budgeting.

The risk of a democratic deficit towards the endeavor of sustainability and net zero requires attention and mitigation. Apparently, letting infrastructural and sustainability projects planned in a top-down way is a major threat to legitimacy [34] by creating vulnerabilities for corruption and even green washing by large corporate organization with influence in governments. Preserving a capacity in participatory budgeting campaigns to materialize infrastructural and sustainability projects that fairly benefit the whole population is a key challenge to address in the future. Our new findings here suggest that participatory budgeting campaigns with projects of high cost discrepancies may be more effective when they are broken down into multiple campaigns with more local and synergistic effects in their implementation across different localities, for instance, low-cost incremental expansions of bike lines across a city, instead of centrally deciding the creation of a multi-million large bike lane network. The possibility of such substitution or complementarity effects among proposed projects is also discussed by Jain et al. [35].

We also show evidence from the first recent real-world participatory budgeting campaigns conducted using the method of equal shares that the mitigation of this impact loss is feasible. Awareness about how the voting aggregation method works and what it prioritizes results in different proposed projects, with different (lower) costs and, eventually, different preferences that yield impact recovery for public transit and sport, see Figure 7.

This study provides new insights for several beneficiaries: For *citizens and communities*, the results unravel new pathways for democratic social innovations and the preservation of capacity to innovate as such. They also provide further empirical evidence and understanding of more complex voting methods such as equal shares, and its effectiveness. For *policymakers*, the findings of this work can support a more effective design of participatory budgeting campaigns that mitigate for potential impact losses already at the stage of project proposals and feasibility checks. They also support them to align ambitious net zero policy agendas with citizens’ participation in their implementation and democratic legitimacy [29]. For the *academic community* of (computational) social choice and beyond, the insights of our study motivate for new axiomatic foundations to assess fairness, proportionality and voting methods. Last but not least, for *industry*, a more localized, distributed and synergistic implementation of infrastructural and sustainability projects with direct citizens’ engagements suggests the need for new business models aligned to democratic values.

4 Methods

4.1 Experimental Dataset

The data on participatory budgeting elections was collected in August 2023 from the PABULIB [31] open repository. The repository consists of multiple files which signify the details of a particular participatory budgeting voting instance defined by a standard .pb file. Such .pb files contain details on project costs, votes received, project description, and the total available budget. In reality, for all but two of the voting instances from the collected dataset, the winning outcomes were determined using utilitarian greedy. To determine the hypothesized winning outcomes by equal shares, we used the pabutools [36] library. While calculating the winning outcomes by equal shares, we added the conditions of arbitrary budget increments and utilitarian termination (*add1u*) to prevent non-exhaustive outcome and ensure higher utilization of budget.

The dataset consists of 810 participatory budgeting instances. Out of these, only 345 instances have information on project impact areas and population beneficiaries. Table 3 shows the overall and average distribution of projects across the 9 different impact areas, and Table 4 shows the overall and average distribution of project across 8 different beneficiaries. *For the participatory budgeting instances of City Idea, Aarau and Green Million, Wieliczka, the impact area labels for proposed projects were absent in the data collected from the repository. As such, the impact areas labels for proposed projects in these instances were assigned independently by multiple individuals to cross-validate the classification.*

Table 3: **Distribution of Proposed Projects Across Impact Areas**

Impact Areas	Total Projects	Avg. Num. Projects
Education	4336	13.3
Health	1408	4.6
Culture	3019	9.4
Sport	2760	8.4
Public Transit	1973	6.3
Welfare	783	4.2
Urban Greenery	2534	8.6
Public Space	5512	16.4
Environmental Protection	2093	7.5

Table 4: **Distribution of Proposed Projects Across Targeted Beneficiaries**

Beneficiaries	Total Projects	Avg. Num. Projects
Families	2625	7.7
Students	366	1.1
Disabled People	4266	12.4
Children	7062	20.5
Adults	7656	22.3
Seniors	6239	18.1
Animals	313	0.9
Youth	6943	20.2

4.2 Impact & Novelty Metrics

For a given participatory budgeting instance I and voting aggregation method f , Table 5 outlines the list of symbols and their meanings for defining the impact and novelty metrics. Based on these values, given aggregation method f , and label l , proposed impact and novelty metrics are calculated.

Table 5: **Symbols for project variables and measurement used in the formulation of impact metrics**

Symbol	Interpretation
f	Voting aggregation methods e.g. equal shares or utilitarian greedy i.e. $f = \text{ES}$ or $f = \text{UG}$
l	A distinct label for projects within a given impact area e.g. education, health, etc.
C	Cost of all proposed projects
N	Total number of all proposed projects
C_l	Cost of proposed projects within the impact area l
N_l	Number of proposed projects within the impact area l
C_w^f	Cost of all winning projects by the method f
N_w^f	Number of winning projects by the method f
$C_w^{f'}$	Cost of all winning projects exclusive to the method f
$N_w^{f'}$	Number of winning projects exclusive to method f
$C_{w,l}^f$	Cost of winning projects within the impact area l by the method f
$N_{w,l}^f$	Number of winning projects within the impact area l by the method f
$C_{w,l}^{f'}$	Cost of winning projects within the impact area l exclusive to the method f
$N_{w,l}^{f'}$	Number of winning projects within the impact area l exclusive to the method f
$R_{N,l}$	Ratio of number of projects in the impact area l over the total projects, i.e. $\frac{N_l}{N}$
$R_{C,l}$	Ratio of total cost of projects in the impact area l over the total cost of projects, i.e. $\frac{C_l}{C}$

Budget Share: Budget share impact $I_{\text{BS},l}^f$ for a given impact area l is the cost share of the winning projects for the impact area with respect to the total cost of all winning projects by the respective aggregation method f i.e. $\frac{C_{w,l}^f}{C_w^f}$. The exclusive budget share is calculated as the cost of exclusively winning projects for the impact area out of total cost of all winning projects by the respective aggregation method.

Winning Rate: Winning rate impact $I_{\text{WR},l}^f$ for a given impact area l denotes the fraction of winning projects in the impact area out of the total winning projects by the respective aggregation method f i.e. $\frac{N_{w,l}^f}{N_w^f}$. The exclusive winning rate is calculated as the number of exclusively winning projects for the impact area out of the total number of winning projects by the respective aggregation method.

Cost Representation: Cost representation impact $I_{\text{CR},l}^f$ for the impact area l is the cost fraction of proposed projects within the impact area that is represented in the winning outcome by the respective aggregation method f i.e. $\frac{C_{w,l}^f}{C_l}$. The exclusive cost representation is calculated as the cost of exclusively winning projects within the impact area out of the total cost of proposed projects for that impact area.

Project Representation: Project representation impact $I_{\text{PR},l}^f$ for the impact area l is the fraction of proposed projects within the impact area that is represented in the winning outcome by the respective aggregation

method f i.e. $\frac{N_{w,l}^f}{N_l}$. The exclusive project representation for the impact area is calculated as number of exclusively winning projects within the impact area out of the total number of proposed projects for that impact area.

Cost Proportionality: Cost proportionality impact $I_{CP,l}^f$ for an impact area l , measures if the cost of projects within the impact area is proportionately represented in the winning outcome of the method f with respect to the initial cost ratio of projects labeled under the impact area i.e. $\frac{I_{BS,l}^f}{R_{C,l}}$.

Project Proportionality: Project proportionality impact $I_{PP,l}^f$ for an impact area l , measures if projects within the impact area are proportionately represented in the winning outcome of the method f with respect to the initial ratio of projects labeled under the impact area i.e. $\frac{I_{WR,l}^f}{R_{N,l}}$.

Within-impact-area Cost Novelty: This metric denoted by $\nu_{P,l}^f$ for an impact area l by aggregation method f , measures the cost of winning projects with the label l that are exclusively winning in f out of the total cost of winning projects with label l by f i.e. $\frac{C_{w,l}^f}{C_{w,l}^f}$.

Within-impact-area Projects Novelty: This metric denoted by $\nu_{N,l}^f$ for an impact area l by aggregation method f , measures the number of winning projects with the label l that are exclusively winning in f out of the total number of winning project with the label l by f i.e. $\frac{N_{w,l}^f}{N_{w,l}^f}$.

Between-impact-areas Cost Novelty: This metric denoted by $\beta_{P,l}^f$ for an impact area l by aggregation method f , measures the cost of winning projects with the label l that are exclusively winning in f out of the total cost of exclusively winning projects in f i.e. $\frac{C_{w,l}^f}{C_w^f}$.

Between-impact-areas Projects Novelty: This metric denoted by $\beta_{N,l}^f$ for an impact area l by aggregation method f , measures the number of winning projects with the label l that are exclusively winning in f out of the total number of exclusively winning projects in f i.e. $\frac{N_{w,l}^f}{N_w^f}$.

For the listed metrics, impact and novelty values range between 0 and 1. Impact and novelty losses (or gains) are calculated as the difference in the metrics values between utilitarian greedy and equal shares as shown in Table 6.

Table 6: Impact loss or gain calculation for proposed metrics

Metric	Loss (or Gain)
Budget Share	$I_{BS,l}^{UG} - I_{BS,l}^{ES}$
Winning Rate	$I_{WR,l}^{UG} - I_{WR,l}^{ES}$
Cost Representation	$I_{CR,l}^{UG} - I_{CR,l}^{ES}$
Project Representation	$I_{PR,l}^{UG} - I_{PR,l}^{ES}$
Within-impact-area Cost Novelty	$\nu_{P,l}^{UG} - \nu_{P,l}^{ES}$
Within-impact-area Count Novelty	$\nu_{N,l}^{UG} - \nu_{N,l}^{ES}$
Between-impact-areas Cost Novelty	$\beta_{P,l}^{UG} - \beta_{P,l}^{ES}$
Between-impact-areas Count Novelty	$\beta_{N,l}^{UG} - \beta_{N,l}^{ES}$

Equal shares results in a dominant selection of very cheap and inexpensive projects but discourages selection of very expensive projects. Figure 1 illustrates the impact loss or gain by equal shares for projects grouped on the basis of cost-price levels in terms of the proposed impact metrics. The impact lost by equal shares method for very expensive projects is greater in magnitude compared to the impact gained for very cheap, cheap and slightly expensive projects in terms of budget share and winning rate. For instance, in terms of budget share and winning rate, the impact lost for very cheap, cheap and slightly expensive projects by equal shares is -5%, -10%, -11% and -4%, -5%, 2% respectively. The voting instances with budget share losses and winning rate losses for these cost-quartile projects are only as few as 3%, 5%, 12% and 16%, 22%, 39% respectively. On the other hand, the budget share losses and winning rate losses for very expensive projects is 26% and 14% respectively. Such losses for budget share and winning rate is observed in 70% and 74% of the election instances respectively.

This observed impact loss or gain by equal shares for different cost quartiles can be attributed to the novelty of exclusive selection by utilitarian greedy or equal shares method. Figure 2 illustrates the impact scores in terms of the proposed metrics for non-exclusive and exclusive winning outcomes as well as the novelty loss within and between groups of different cost-quartiles by the equal shares and utilitarian greedy methods. We observe that for very cheap, cheap and slightly expensive projects, the overall within and between-group novelty losses are negative, but for very expensive projects the within and between-group novelty losses are positive. For instance, in terms of budget share, the within novelty losses for very cheap, cheap and slightly expensive projects is -66%, -59% and -37% (i.e. novelty gain of 66%, 59% and 37%) respectively. This means that, out of the total winning costs for each of such cost-quartiles, an additional of 66%, 59% and 37% of the winning costs allocated to these cost quartiles are attributed to the exclusively winning projects by equal shares which results in the net impact gain for such cheap and slightly expensive projects. Likewise, in terms of budget share, the between-group novelty loss for very expensive projects is 88%. This means that out of the total exclusively winning projects by utilitarian greedy, an excess of 88% of such exclusively winning costs are allocated to very expensive projects which ultimately contributes in a net impact loss.

arXiv:2405.05085v2 [cs.MA] 9 May 2024

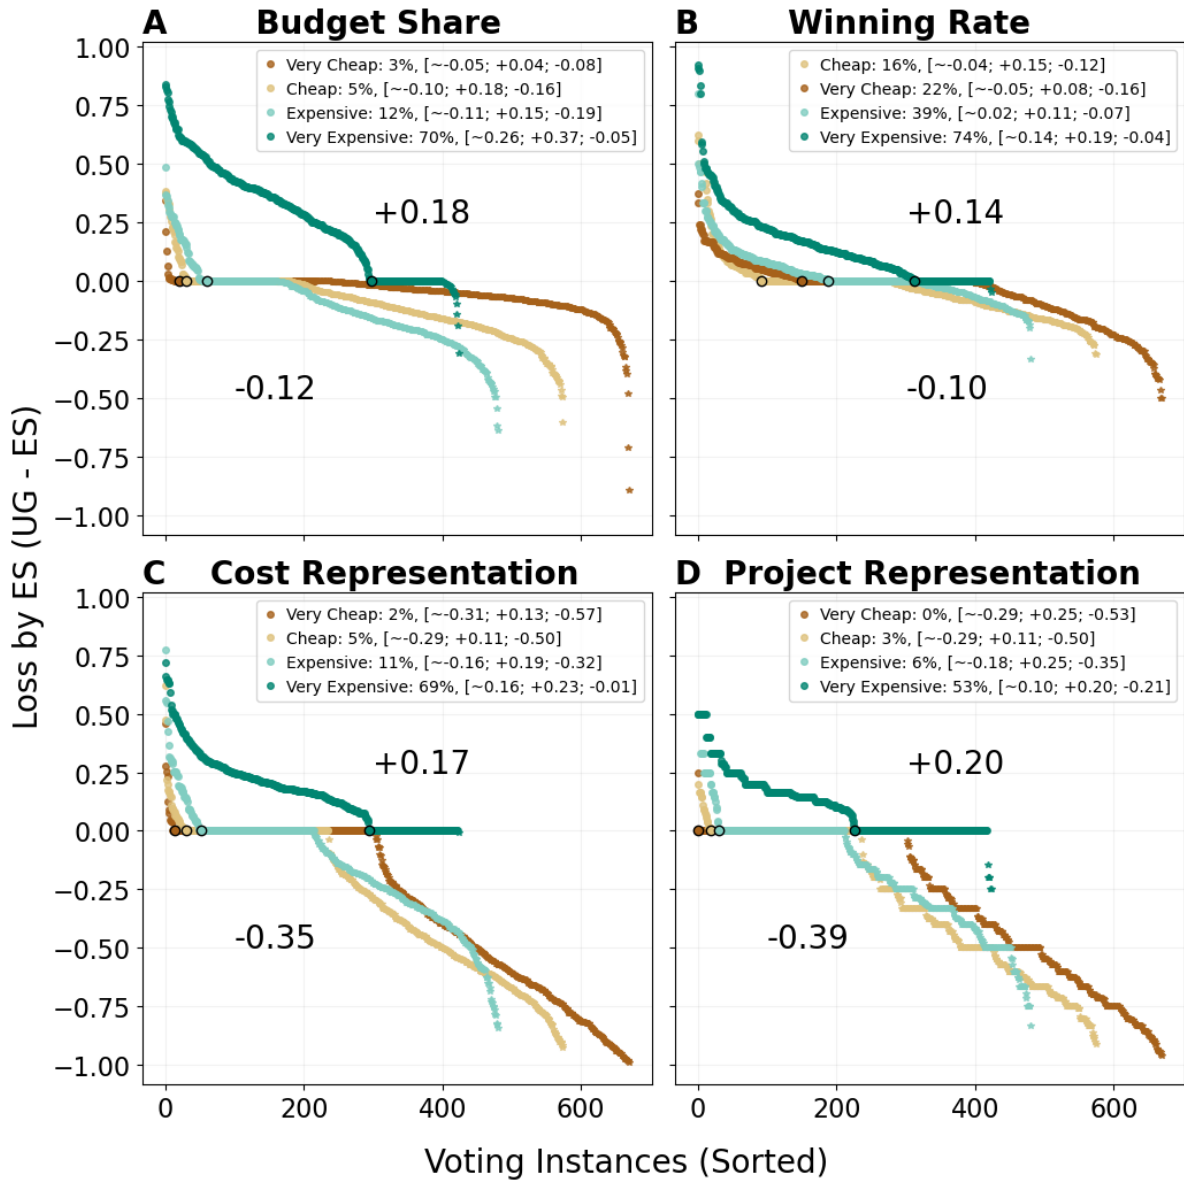

Figure 1: Equal shares results in voting outcomes with an impact loss in very expensive projects. Besides these projects, impact gain is more frequent and larger in scale for cost and project representation, while impact loss is larger in scale for budget share and project representation. For each of the four depicted impact metrics – (A) Budget Share, (B) Winning Rate (C) Cost Representation and (D) Project Representation, positive loss (Y-axis, $UG - ES$) in an impact cost quartile (colored lines) shows out-performance by utilitarian greedy (UG), while negative loss shows out-performance by equal shares (ES). The X-axis denotes voting instances sorted according to impact loss. A circular marker is placed along each line to easier distinguish the number of voting instances with positive/negative loss. The four numbers next to each cost level denote the (i) % of voting instances with positive loss, (ii) the mean ‘ \sim ’, (iii) mean positive ‘+’ and (iv) mean negative ‘-’ impact loss. Two additional numbers with the prefixes ‘+’ and ‘-’ placed on each of the metrics signify the overall positive and negative impact loss respectively across all project cost quartiles.

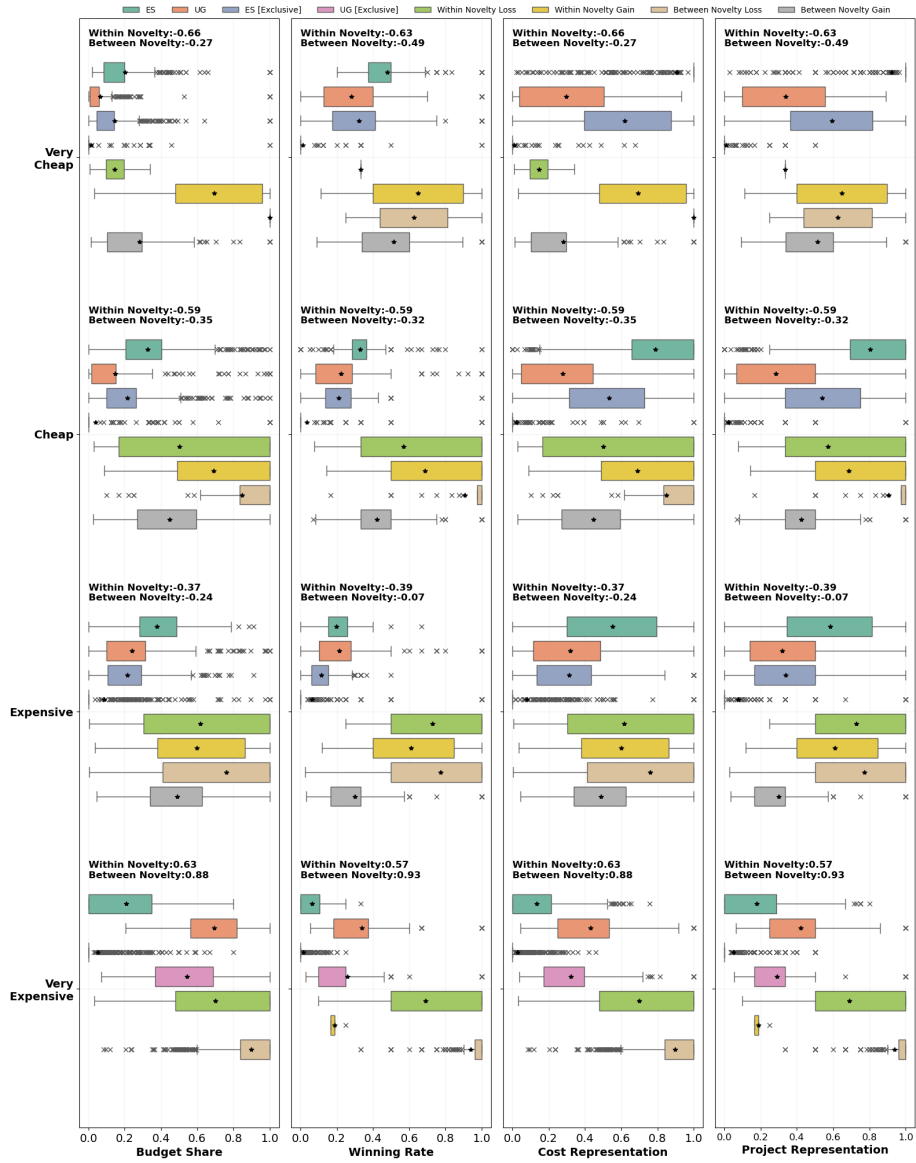

Figure 2: Equal shares exhibits impact gain for projects that lie in the cost-price ranges of very-cheap, cheap and slightly expensive projects whereas impact is lost for very-expensive projects. Equal shares also shows within-novelty and between-novelty gain for the very-cheap, cheap and slightly expensive projects. On the other hand, for very expensive projects, equal shares shows loss for both within-novelty and between-novelty. The within-novelty and between-novelty gain is the highest for very-cheap projects, and this magnitude of within-novelty and between-novelty gain is slightly reduced as the cost price of winning projects increases to cheap and expensive projects. For very expensive projects, within-novelty loss is as high as within-novelty gain for very cheap projects. Moreover, between-novelty loss for very-expensive projects is of the highest magnitude compared to others. The figure shows the performance of cost-price levelled projects (Y-axis) in terms of impact and novelty metrics (X-axis). The first four bars compare the impact of exclusive vs non-exclusive winning projects by equal shares (ES) and utilitarian greedy (UG). The next four bars compare the novelty gain and loss in two different ways: (i) *within novelty* and (ii) *between novelty*. The overall within and between novelty losses for each cost-price levels of projects is shown.
