ABSTRACT

We present a study of kinematic asymmetries from the integral field spectroscopic surveys MAGPI and SAMI. By comparing the asymmetries in the ionsied gas and stars, we aim to disentangle the physical processes that contribute to kinematic disturbances. We normalise deviations from circular motion by S_{05} , allowing us to study kinematic asymmetries in the stars and gas, regardless of kinematic temperature. We find a similar distribution of stellar asymmetries in galaxies where we do and do not detect ionised gas, suggesting that whatever is driving the stellar asymmetries does not always lead to gas removal. In both MAGPI and SAMI, we find an anti-correlation between stellar asymmetry and stellar mass, that is absent in the gas asymmetries. After stellar mass and mean-stellar-age matching distributions, we find that at all stellar masses, MAGPI galaxies display larger stellar asymmetry compared to SAMI galaxies. In both MAGPI and SAMI galaxies, we find that star-forming galaxies with old mean-stellar-ages typically have larger asymmetries in their gas compared to their stars, whereas galaxies with young mean-stellar-ages have larger asymmetries in their gas. We suggest that this results from continuous, clumpy accretion of gas.

Key words: galaxies: kinematics and dynamics- galaxies: interactions

1 INTRODUCTION

In a Cold Dark Matter Universe with a cosmological constant (ACDM), dark matter haloes form from the collapse of primordial density perturbations (e.g., Zavala & Frenk 2019). Baryons are dragged into these haloes by gravity, gaining angular momentum through tidal torques from surrounding halos (Peebles 1969; White 1984). The baryons begin to cool, conserving angular momentum and falling further into the halo where they collapse and a rotating stellar disk begins to form (Fall & Efstathiou 1980; Mo et al. 1998).

This idea of galaxies beginning as rotating disk systems is supported by observations of galaxies having disks in place since z > 4 (Neeleman et al. 2020; Lelli et al. 2021; Ferreira et al. 2022; Tsukui et al. 2023), demonstrating significant rotation in their gas (Fraternali et al. 2021; Lelli et al. 2023) at $z \sim 3$, and stars at $z \sim 1$ (Newman

et al. 2018; Bezanson et al. 2018). However, the prevalence of rotational support in galaxies seems to change over cosmic time; at low redshift, massive and quiescent (non-star-forming) galaxies are more dispersion dominated and less disk-like (Emsellem et al. 2007; Cappellari 2016) whereas at high redshift, star-forming galaxies exhibit higher gas turbulence in rotating disks compared to their low redshift counterparts (characterised by smaller ratios of rotational to dispersion velocity, (V/σ) ; Kassin et al. 2012; Übler et al. 2019; Wisnioski et al. 2019; Pillepich et al. 2019; Rizzo et al. 2021).

Massive galaxies in the local Universe are thought to have formed most of their stellar mass through dissipative gas cooling before and during Cosmic Noon ($z \sim 2$; Dekel et al. 2009; Madau & Dickinson 2014; Förster Schreiber & Wuyts 2020; Emonts et al. 2023), becoming quiescent before continuing to grow in stellar mass from the accretion of lower mass, gas-poor satellites (Naab et al. 2009; Oser et al. 2010; van der Wel et al. 2014; Stockmann et al. 2021). Accretion is not only restricted to stars; galaxies can acquire new gas from gas-rich mergers (e.g., Di Teodoro & Fraternali 2014), along

[†] ARC DECRA Fellow

cold gas filaments (e.g., Kereš et al. 2009), or from the hot outer halo (e.g., Lagos et al. 2015). Galaxies can also re-accrete gas that has been expelled from their disk through 'galactic fountain' effects (Shapiro & Field 1976; Spitoni et al. 2008; Marinacci et al. 2010). Indeed, some form of new gas accretion has to be invoked to explain the Star Formation Rates (SFRs) and cold gas masses seen at high redshift (Burkert et al. 2016; Scoville et al. 2017; Tacconi et al. 2018) as well as the growth of stellar mass over cosmic time (e.g., Walter et al. 2020)

The angular momentum of this accreted material is not necessarily aligned with the spin axis of the existing stellar disk, consequently, if this newly accreted gas can form stars, there may be a kinematic misalignment, (i.e., an offset between the kinematic position angles of the ionised gas and stars). This transitory state is sometimes observed at low redshift (Bryant et al. 2019). If the accretion rate of this event is sufficiently low, it is unlikely to cause a significant disturbance in the gas or stellar kinematics, since the existing stellar disk will provide a torque on the accreted gas, aligning it into a similar configuration as the stars (this includes counter-rotating disks, e.g., McDermid et al. 2006; Osman & Bekki 2017; Bryant et al. 2019; Duckworth et al. 2019). But if the accreted gas came in a 'clumpy' fashion (i.e. a merger event), or if there was very little gas present in the galaxy, to begin with, there would be significant disturbances in ionised gas kinematics. This phenomenon has been found in both high and low redshift merging galaxies (Shapiro et al. 2008; Bloom et al. 2018; Feng et al. 2020). Along with heavily disturbing the ionised gas, the stellar kinematics also become disturbed in merging galaxies (Bois et al. 2011; Lagos et al. 2022; D'Eugenio et al. 2023b).

Signatures of disturbed kinematics in the stars and ionised gas can be quantified in different ways. Commonly for spatially resolved spectroscopy surveys (radio and optical), this is done by computing deviations from circular motion that are captured by higher-order terms in a Fourier Series fitted to concentric ellipses (or projected tilted rings) on a velocity map (Krajnović et al. 2008, 2011; Di Teodoro & Peek 2021; Genzel et al. 2023). Disturbances to kinematics will cause the velocity profile around these ellipses to appear asymmetric, and these 'asymmetries' can be quantified by how much power is in the fitted higher order Fourier coefficients (e.g., Krajnović et al. 2006). Velocity asymmetries in the ionised gas and stars have been linked to aspects of galaxy evolution such as non-axisymmetric disk features (e.g., bars), stellar mass and local environment (Barrera-Ballesteros et al. 2014; Bloom et al. 2017, 2018; van de Sande et al. 2021).

Gas and stars can be thought of as fundamentally different fluids; with gas considered collisional, whereas stars are collisionless (Jog & Solomon 1984). By being a collisional fluid, gas within a galaxy will be able to correct from induced kinematic disturbances faster than stars would be able to. As such, if we were to compare disturbances in both the stars and gas, we would expect the disturbance to last in the stellar kinematics, possibly long after the gas has resettled (e.g., Eggen et al. 1962). Comparison of gas and stellar disturbances can be used to isolate specific drivers behind kinematic asymmetries, which can be difficult to discern when only considering the ionised gas (Bagge et al. 2023), or even different gas phases (Watts et al. 2023).

In this work, we study the source of kinematic disturbances in galaxies by comparing the kinematic asymmetries between stars and ionised gas to disentangle what is driving kinematic asymmetries in each. We also look for evidence of dynamical evolution in these asymmetries at different redshifts. To this end, we draw a sample of galaxies from the Middle Ages Galaxy Properties in IFS (MAGPI; Foster et al. 2021) and the SAMI Galaxy Survey Data Release 3

(Croom et al. 2021a). We use KINEMETRY (Krajnović et al. 2006) to model the stellar and ionised gas velocity maps and use the asymmetry to measure the amount of disturbance in each. The structure of this paper is as follows; §2.2 gives a brief overview of the MAGPI survey and data products we use in this work, §2.3 describes our method of sample selection in both the MAGPI and SAMI surveys, §3.1.1 describes how we use KINEMETRY in our analysis of the stellar and ionised gas velocity maps. In §3, we show our results and discuss possible interpretations, before offering our conclusions in §4. We adopt a Planck Collaboration et al. (2020) cosmology for this work; explicitly a flat Universe with $H_0 = 67.7$ kms⁻¹ Mpc⁻¹, $\Omega_M = 0.31$ and $\Omega_{\Lambda} = 0.69$. All correlations quoted are measured using Pearson correlation coefficients.

2 DATA

2.1 The MAGPI Survey

The MAGPI survey is an ongoing MUSE/VLT Large Program (Program ID: 1104.B-0536) targeting 56 (42 completed as of January 2024) 1 × 1 arcmin fields from the Galaxy and Mass Assembly (GAMA; Driver et al. 2011) fields G12, G15 and G23. MAGPI is currently collecting spatially resolved spectra of stars and ionised gas at a redshift of $0.28 \le z < 0.35$. MAGPI also includes archival observations of legacy fields Abell 370 and Abell 2744. When observations are completed, MAGPI's entire dataset will include 60 spatially resolved 'primary' targets ($M_* > 7 \times 10^{10} M_{\odot}$) and ~ 100 spatially resolved 'secondary' targets ($M_* \ge 10^9 M_{\odot}$) at $z \sim 0.3$.

Data was collected using MUSE Wide Field Mode in the nominal wavelength range (4650 Å - 9300 Å) with a spectral sampling of 1.25 Å. Ground Level Adaptive Optics (GLAO) are employed to mitigate the effect of atmospheric seeing, resulting in a 270 Å-wide gap between 5780 Å and 6050 Å due to the GALACSI laser notch filter. Each MAGPI field has a field-of-view (FOV) equal to 1×1 square arcmin with spatial sampling of 0.2'' pixel⁻¹ and average image quality of 0.65''. A detailed discussion of the data reduction will be presented in the first data release (Mendel et. al., in prep).

For this work, stellar masses are derived using the SED-fitting code PRoSPECT (Robotham et al. 2020) with 9-band u- K_s (KiDS and VIKING imaging) photometry pixel-matched to the MAGPI cubes, where forced photometry is based on the MAGPI segmentation maps. The implementation of PRoSPECT applied is consistent with the method used to derive stellar masses for GAMA (Bellstedt et al. 2020; Driver et al. 2022). A truncated skewed-normal parametrisation is used for the star-formation history, with a linearly evolving metallicity evolution implemented to ensure a chemical build-up that follows the stellar mass build-up in the galaxy. A Chabrier (2003) Initial Mass Function (IMF) is assumed, and the Bruzual & Charlot (2003) stellar population templates are used.

Stellar kinematic maps for MAGPI galaxies are obtained using PPXF, which models the stellar continuum as a linear superposition of input stellar templates. A subset of the reduced IndoUS stellar-template library (Valdes et al. 2004) is used. Detailed description is provided in (D'Eugenio et al. 2023a). Briefly, all stellar kinematics are obtained by fitting their stellar templates on a spaxel-by-spaxel basis using additive Legendre polynomials of degree n = 12. Regions of possible nebular emission and the strongest sky-lines are masked. Additionally, and for MAGPI only, the spectral region affected by the AO laser is also masked. A first round of fitting is completed on a set of elliptical annuli to derive a subset of optimal stellar templates to be used to fit the spectrum of individual spaxels. Starting from the centre,

Figure 1. Histograms of the mass (left), $R_e/FWHM$ (middle) and mean stellar population age (right) distributions for our MAGPI (blue) and SAMI (orange) subsamples. The bin sizes for stellar mass and mean stellar population age are 0.25 dex, and the bins sizes for $R_e/FWHM$ is 0.25. Our MAGPI subsample is skewed towards more massive galaxies, while our $R_e/FWHM$ and mean stellar population age distributions are similar.

the procedure creates a series of elliptical annuli, using only spaxels with nominal SNR \geq 3. Each annulus is grown in steps of one halfpixel (0.1") until either the target SNR = 25 is (nominally) reached, or until there are no more valid spaxels to merge. A minimum of one (elliptical) bin is required to proceed; galaxies with insufficient SNR are immediately failed. The procedure then fits the stellar kinematics of each spaxel, by restricting the pool of input templates to the subset used to create the best-fit model spectrum of the annular bin(s) that the current spaxel intersects, plus one more external annulus bin (if present) and one more internal annulus (if present).

 λ_{Re} is the spin parameter proxy defined by Emsellem et al. (2007). Explicitly, λ_{Re} is,

$$\lambda_{Re} = \frac{\sum_{i=1}^{N} F_i R_i |V_i|}{\sum_{i=1}^{N} F_i R_i \sqrt{V_i^2 + \sigma_i^2}}$$
(1)

where *N* is number of spaxels in the chosen aperture, F_i is the flux within the *i*-th spaxel, V_i is the line-of-sight velocity, σ_i is the line-of-sight velocity dispersion, and R_i is the galactocentric radius to the *i*-th spaxel. The computation of λ_{Re} will be described in detail in Derkenne et al., in prep., but are briefly described here. Apertures are first constructed using a Multi-Gaussian Expansion (Cappellari 2002) fit to a mock *r*-band image of the galaxy. Using that aperture, λ_{Re} is computed following Eqn. 1 and corrected for seeing following Harborne et al. (2020).

Stellar ages are computed using PPXF to fit MILES single stellar population templates to $1R_e$ integrated spectra with emission lines included in the fit. We use light-weighted stellar ages, as opposed to mass-weighted stellar ages.

Ionised gas velocity maps are obtained from continuum-subtracted spectra using GIST (Galaxy IFU Spectroscopy Tool; Bittner et al. 2019), a PYTHON wrapper of PPXF (Cappellari & Emsellem 2004; Cappellari 2017) and GANDALF (Sarzi et al. 2006; Falcón-Barroso et al. 2006). Briefly, a set of 22 single-component Gaussians are fit to spectral lines ranging from [O II] 3727Å to [S II] 6733 Å where the widths and relative velocities are all tied to one line (see Foster et al. (2021) for more details). A detailed description of the emission line products will be present in Battisti et al., in prep. We use [S II] 6718,33 Å integrated fluxes within $1R_e$ to classify each of the galaxies in our sample into star-forming and AGN galaxies.

2.2 The SAMI Galaxy Survey

The Sydney-AAO Multi Integral field (SAMI) Galaxy Survey is an integral field spectroscopic survey of galaxies within the local Universe (0.004 < z < 0.095), probing galaxies over a large stellar mass range of $10^7 < M_* < 10^{12}$ M_{\odot}, morphology and galactic environments (Bryant et al. 2015; Owers et al. 2017; Brough et al. 2017). Spectral cubes were obtained using the SAMI instrument (Croom et al. 2012) on the 3.9m Anglo-Australian Telescope connected to the AAOmega spectrograph (Sharp et al. 2006). The SAMI instrument has 13 hexabundles and 26 sky fibres over a 1-degree field-of-view. Each hexabundle consists of 61 fibers with a diameter of 1.6 arcsec, giving each hexabundle a diameter of 15 arcsec. Data products used in this work (gas velocity maps, emission line fluxes, stellar populations), barring the stellar masses, are computed similarly to the MAGPI data products previously discussed and are described, in detail, in the SAMI Galaxy Survey Data Release papers (Green et al. 2018; Scott et al. 2018; Croom et al. 2021a). Stellar masses for SAMI galaxies are computed using extinction-corrected g - i colors from the GAMA catalogue, following Eqn. 3 in Bryant et al. (2015). SAMI stellar kinematics are derived in a similar manner to aforementioned MAGPI stellar kinematics and a detailed description is provided in van de Sande et al. (2017).

2.3 Sample Selection

To select MAGPI galaxies, we only select those that have R_e /FWHM > 1 and are at a redshift of 0.2 < z < 0.4. We further select those galaxies where the minimum H α SNR/spaxel >20 and stellar continuum SNR/spaxel >3 within $2R_e$. Galaxies that met the stellar continuum criterion, but not the H α criterion are included as ionised gas non-detections. Similarly, galaxies that met the H α criterion, but not the stellar continuum criterion are included as stellar non-detections. Finally, we use [S II]-BPT diagnostic plot with integrated $1R_e$ fluxes to classify our sample into star-forming and AGN galaxies following the criteria stipulated in (Kewley et al. 2006). The [S II]-BPT was used as it allows a cleaner separation between star-forming, AGN and LINER galaxies, than the [N II]-BPT alone (Kewley et al. 2001; Belfiore et al. 2016; Law et al. 2021). Galaxies that host AGN/LINER are removed from the sample. This yields a MAGPI subsample of 95 galaxies.

To select SAMI galaxies, we employ the same SNR, spatial resolution (R_e /FWHM>1), and ionisation source requirements on galaxies

Figure 2. v_{asym} against λ_R for MAGPI galaxies. v_{asym} normalised by S_{05} is shown on the left, while v_{asym} normalised by k_1 is shown on the right. v_{asym} measured in the stars is shown in blue, while v_{asym} measured in the gas is in orange. Stellar non-detections are shown as orange triangles. When normalising by S_{05} , we see that v_{asym} is largely independent of whether the galaxy is rotating slowly (small λ_{Re}) or fast (large λ_{Re}), whereas if we normalise by k_1 , the v_{asym} value, for slow rotating galaxies begins to diverge. 7 galaxies are not shown due to no λ_{Re} values being available, and 16 galaxies are not shown due to the measured λ_{Re} being unphysical (i.e., $\lambda_{Re} > 1$). These galaxies would be considered fast rotating galaxies ($\lambda_{Re} > 0.6$) prior to seeing correction.

in SAMI Data Release 3 (Croom et al. 2021a). We do not place any redshift selection for SAMI galaxies, for which the median redshift is 0.04. As of writing, MAGPI does not include any cluster galaxies in its master catalogue, because of this we exclude cluster galaxies within SAMI from the analysis. Our final subsample contains 802 galaxies.

Distributions of the stellar mass, R_e /FWHM and mean-stellarages are shown in Fig. 1. Due to the large difference in sample sizes between SAMI and MAGPI, we seperately match the stellar mass, R_e /FWHM and mean stellar population age distributions between surveys, and discuss this in Sect. 3.3. The median seeing for our SAMI subsample is coarser compared to our MAGPI subsample, ~ 2" versus ~ 0.7", respectively. These seeing conditions correspond to a similar physical spatial resolution of ~ 3 kpc for MAGPI, and ~ 1.5 kpc for SAMI.

2.4 Kinemetric Analysis

KINEMETRY (Krajnović et al. 2006) is an algorithm that extends photometric analysis commonly used in surface brightness photometry to higher order moments of the line-of-sight-velocity-distribution (e.g., mean velocity, dispersion; Gerhard 1993; van der Marel & Franx 1993). KINEMETRY constructs models of the line-of-sight-velocitydistribution (LOSVD) moments by fitting a series of concentric ellipses with position angle (PA) and axial ratio q = b/a, where b and a are the semi-minor and semi-major axes, respectively. Like other tilted-ring fitting algorithms (Rogstad et al. 1974; Begemann 1987; Spekkens & Sellwood 2007; Di Teodoro & Fraternali 2015), KINEMETRY fits a Fourier Series along the ellipse,

$$K(a,\theta) = A_0 + \sum_{m=1}^{m=N} A_m \sin(m\theta) + B_m \cos(m\theta), \qquad (2)$$

where *a* is the semi-major axis of the ellipse, θ is the azimuth along the ellipse with respect to the semi-major axis, A₀ is the zeroth harmonic term and A_m and B_m are the *m*th additional harmonic terms. KINEMETRY determines the best fitting PA and *q* by minimising the harmonic coefficients that are in the series. Eqn. 2 can be represented more compactly as,

$$K(a,\theta) = A_0 + \sum_{m=1}^{m=N} k_m \cos(m[\theta - \phi_m(a)]),$$
(3)

where $k_m = \sqrt{A_m^2 + B_m^2}$ and $\phi_n = \arctan \frac{A_m}{B_m}$. The k_m parameters describe the kinematics of the galaxy while PA and q describe the geometry of the ellipse. A thin disk galaxy rotating with perfect circular motion can be described with a single cosine term in Eqn. 2 (i.e., $V(\theta) = B_1 \cos \theta$) which is a symmetrical function of azimuth around θ =180. Any deviation from non-circular motion results in an asymmetric function, and these asymmetries are encoded as power to higher-order coefficients. If one used KINEMETRY on a velocity map (1st moment), k_1 would represent the rotational velocity, V_{rot} at that ellipse. In the instance one used KINEMETRY on a dispersion map (2nd moment), A_0 , would represent the σ at that ellipse.

2.4.1 Defining kinematic asymmetry

In the literature, asymmetry in velocity maps for galaxies is usually defined as the higher order (up to n = 5) coefficients in Eqn. 3, normalised to k_1 (Krajnović et al. 2011; Bloom et al. 2017; Feng et al. 2020). For this study, we use a different formalism, where we normalise the higher order coefficients with the S_{05} parameter instead where $S_{05} = \sqrt{0.5V_{rot}^2 + \sigma^2}$, (Weiner et al. 2006a,b; Cortese et al. 2014; Barat et al. 2019). Where V_{rot} is the rotational velocity taken where the rotational curve reaches its maximum, and σ is the light-weighted average dispersion within $1R_e$. V_{rot} is corrected for inclination by $V_{obs}/\sin i$, where V_{obs} is the fitted k_1 value, and i is inclination of the galaxy.

Explicitly, the new asymmetry parameter is,

$$v_{\text{asym}} = \frac{k_2 + k_3 + k_4 + k_5}{4S_{05}} \tag{4}$$

 S_{05} is calculated for both the stars and ionised gas and used separately. Both V_{rot} and σ are measured using KINEMETRY where we fix the PA and q for all radii to their *i*-band photometric values.

We now discuss our motivation for changing our asymmetry parameter. If we normalise the higher order coefficients by k_1 measured in galaxies that are slowly rotating, not rotating at all, or are dispersion dominated we would be dividing by a small number (i.e., $k_1 \rightarrow$

0). This would artificially enhance v_{asym} , which would not necessarily be a true indication of how disturbed the kinematics are in those galaxies. To avoid this issue, k_1 (i.e., V_{rot}) is removed and replaced by S_{05} , which has been shown to have a tight relation with stellar mass in galaxies of all Hubble types (e.g., Es, Sp, S0s; Cortese et al. 2014) and be an effective tracer of gravitational potential well depth (Kassin et al. 2012). Including σ in the normalisation of the higher order terms captures the full kinematic 'budget' of the galaxy, and prevents the asymmetry value from diverging in slower rotating or dispersion-dominated galaxies. We discuss the impact of changing this normalisation in Sect. 3.1.1.

When measuring the kinematic asymmetries for both MAGPI and SAMI galaxies, we run KINEMETRY on the stellar and ionised gas velocity maps where kinematic position angle is allowed to vary between 0° and 360°. Kinematic axial ratio $q_{\rm kin}$ is set to vary between $q_{\text{phot}} \pm 0.1$. We opted for tight limits on q given our spatial resolution and not selecting galaxies on inclination (See Sect. 2.2 of Shapiro et al. 2008 and Sect. 4.2 of van de Sande et al. 2017). Spaxels on the stellar velocity maps with SNR/spaxel<3 are masked. A similar criterion is used for ionsied gas velocity maps where spaxels with SNR (H α)/spaxel<3 are masked. We run KINEMETRY out to 1 R_e and take the measured v_{asym} at $1R_e$. For MAGPI and SAMI galaxies, the distance between each ellipse is set to half the estimated seeing, ~ 0.3" and ~ 1", respectively. Uncertainties for v_{asym} are estimated using 100 Monte Carlo realisations, where we re-run KINEMETRY on the velocity map with Gaussian noise injected into each spaxel corresponding to the error in the velocity measurements. The final vasym values and uncertainties correspond to the mean and standard deviation of the Monte Carlo distribution, respectively.

2.4.2 Impact of seeing on λ_{Re} and KINEMETRY asymmetries

Galaxy kinematic measurements can be negatively impacted by atmospheric seeing conditions, where poor seeing conditions can decrease the measured rotation amplitude, while increasing the measured velocity dispersion. This can prove to be problematic when investigating slow and fast rotator fractions in IFS surveys, and corrections are necessary to ensure λ_{Re} is correctly measured in fastrotating galaxies (van de Sande et al. 2017; Greene et al. 2018; Graham et al. 2018). The λ_{Re} values used in this work are corrected using the empirical relation in Harborne et al. (2020), which considers how resolved the galaxy is (σ_{PSF}/R_e), its Sérsic index *n*, and ellipticity ϵ (Derkenne et al., in prep.). The mean amplitude of this corrections is 0.18 and standard deviation of 0.16.

In contrast, the effect of seeing on kinematic asymmetries is such that as the seeing degrades, complex kinematic features progressively are washed out and velocity fields become more regular, decreasing the asymmetry. This effect was investigated in App 2.2 of van de Sande et al. (2017), who degraded ATLAS^{3D} kinematics maps to see how recoverable the kinematic asymmetry was. The authors report that poor seeing reduced the kinematic asymmetry in those galaxies that had large kinematic asymmetry, but found little correlation between this impact and angular size of the galaxies. So while the complex kinematic features in galaxies that are very resolved are likely retained, these features are harder to measure in less resolved galaxies, leading to an underestimate of the true asymmetry.

However, a correction similar to that applied for λ_{Re} in fast-rotating galaxies cannot be performed since we do not know *a-priori* if a low-asymmetry galaxy is intrinsically a high-asymmetry galaxy that has had its asymmetry washed out by seeing, or if it has intrinsically low-asymmetry. We plot ν_{asym} against R_e /FWHM for MAGPI and SAMI galaxies in Fig. A1, and find no trend. The highest correlation

Figure 3. v_{asym} measured in the stars against v_{asym} measured in the ionised gas for MAGPI galaxies. The histograms above and to the right show the distributions of detections and non-detections in the ionised gas and stars, respectively. Galaxies with non-detections in either stars or gas are shown in orange. The black dot-dashed line is the 1:1 to delineate between galaxies with larger gas or stellar kinematic asymmetries. The average size of the error bars is shown in the bottom right corner. The distributions of stellar asymmetries with gas detections and gas non-detections are similar. If interactions and mergers are driving the stellar asymmetries, the similar distribution between the two suggests that interactions or mergers do not always remove the gas in galaxies.

coefficient is ρ =-0.23 with a p-value of 0.09 for stellar asymmetry. We also measure how v_{asym} varies as a function of the number of pixels that are along the ellipse. Again, we find only a weak correlation with the highest correlation coefficient being ρ =-0.20 with a p-value of 0.03. We leave this as caveat of our analysis.

3 RESULTS AND DISCUSSION

In this section we compare v_{asym} in the stars and the ionised gas that was normalised by k_1 and normalised by S_{05} , discuss the physical drivers behind the asymmetries in the stars and ionised gas for MAGPI galaxies and the possible dynamical evolution of galaxies from MAGPI to SAMI.

3.1 Stellar and Ionised Gas Kinematic Asymmetries for MAGPI Galaxies

3.1.1 Normalisation

Fig. 2 shows the v_{asym} measured in the stars and ionised gas against λ_R . We see that when normalising by k_1 , galaxies will typically exhibit larger asymmetry values with comparatively enhanced scatter at low λ_{Re} (i.e., slower rotating galaxies). Conversely, when normalising by S_{05} , v_{asym} appears largely independent of λ_{Re} . This confirms our hypothesis that changing the normalisation will minimise diverging for slower rotating systems. Adopting v_{asym} to be v_{asym} , S_{05} we show in Fig. 3 v_{asym} measured in stars against v_{asym} measured in the gas. There is no clear correlation between asymmetry in the stars and asymmetry in the stars and gas is not coupled. The lack of a

Figure 4. For MAGPI galaxies, stellar v_{asym} against stellar mass (*top left*), ionised gas v_{asym} against stellar mass (*top right*), stellar v_{asym} against stellar age (*bottom left*), and ionised gas v_{asym} against stellar age (*bottom right*). Ionised gas and stellar non-detections are shown in green and orange, respectively. There is a anti-correlation between stellar asymmetries and stellar mass (ρ =-0.51,p<10⁻⁹), that is much weaker (ρ =0.29,p=0.29), and more scattered in the ionised gas. We interpret this as the gas 'washing out' asymmetries faster than the stars, a consequence of the collisional nature inherent to the gas.

correlation could also be due to the gas being able to return to low asymmetry through collisional processes, which stars cannot do. We find that most of our sample demonstrates larger stellar asymmetries (i.e., are below the dashed line). This is not unexpected, as stellar velocity disturbances could remain present in the kinematics for a longer time, compared to velocity disturbances in the gas. The distribution of stellar asymmetries between galaxies detected in ionised gas and those where we do not detect ionised gas is also similar, albeit with tail towards large stellar asymmetries. A Kolmogorov–Smirnov (KS)-test suggests that they could be different distributions (t=0.49, p=0.0001).

3.2 Physical Drivers of Kinematic Asymmetries in MAGPI Galaxies

3.2.1 Stellar Mass and Gravitational Potential

Higher stellar mass galaxies will have a larger gravitational potential, and be able to provide a larger restoring force to kinematic disturbances. Since both stars and gas respond to the same gravitational potential of the galaxy, both stellar and gas asymmetries should exhibit an anti-correlation with stellar mass since S_{05} traces this potential, regardless if it was measured in the stars or gas. Fig. 4 shows the asymmetries in the stars and gas plotted against stellar mass. Including non-detections, there is a strong anti-correlation between stellar mass and stellar asymmetry (ρ =-0.59,p<10⁻⁵); however this anti-correlation is weaker when considering the gas asymmetries in both the stellar detections and non-detections (ρ =-0.30,p=0.006), and is entirely absent when considering the stellar detections and

MNRAS 000, 1–12 (2023)

non-detections separately. Excluding gas non-detections increases the strength of the correlation between stellar asymmetries and stellar mass (ρ =-0.69,p<10⁻⁵).

The absence of a correlation between gas asymmetries and stellar mass is contrary to previous findings in the literature (Bloom et al. 2017; Feng et al. 2022; Bagge et al. 2023). These asymmetries, however, were normalised to k_1 , not S_{05} , hence it is likely these lower mass galaxies were slower rotating, causing the v_{asym} to diverge. Normalising by S_{05} should not remove a physical anti-correlation between dynamical disturbances and mass, as a tight S_{05} vs. stellar mass correlation has been shown to be independent of whether V_{rot} and σ are measured in the stars or gas (Cortese et al. 2014, but see Barat et al. 2019, 2020). For completeness, we check this by calculating $S_{05, stars}/S_{05, gas}$ for each galaxy, and find that this value is close to 1 across the sample, with a mean of 0.87 and standard deviation of 0.27. We conclude that this absence of an anti-correlation between v_{asym} in the gas and stellar mass is not an artefact of normalising by S_{05} measured in different phases.

The lack of a correlation between stellar mass and ionised gas asymmetries suggests that gas can recover from induced asymmetries independent of the restoring force provided by the gravitational potential. This is possibly a result of ionised gas being able to dissipate energy and transfer angular momentum faster than the stars are able to through collisional processes. The additional restoring pathways available to the gas mean the asymmetries in the gas may be dissipated on shorter timescales, while still persisting in the stars. However, this is assuming that the gas and stellar asymmetries were induced in the galaxy at the same time, which we can not confirm

Figure 5. Stellar v_{asym} against ionised gas v_{asym} coloured by stellar age for MAGPI galaxies. Gas non-detections are shown at the bottom, stellar non-detections are shown on the left. When galaxies with old mean-stellar-ages also have gas, they tend to have larger asymmetries in their gas, rather than asymmetries in their stars. Galaxies with younger mean-stellar-ages tend to have larger stellar asymmetries, regardless if they have gas or not. Markers with red circles indicate galaxies shown in Fig. 6.

Figure 6. 3 colour (g, i, r) images of MAGPI1501224275 (left) and MAGPI2310199196 (right). Both galaxies display larger gas asymmetries, compared to their stars, but only MAGPI2310199196 appears to be undergoing a significant merger event. We suspect MAGPI1501224275 is instead accreting gas that is independent of a merger or interaction. The faint source above MAGPI1501224275 is unconfirmed to be a nearby galaxy.

given there is little correlation between the v_{asym} in the stars and v_{asym} in the gas.

3.2.2 Gas Accretion

Fig. 5 shows the stellar asymmetries plotted against the ionised gas asymmetries for MAGPI galaxies with the points coloured by mean-stellar-age. When kinematic asymmetry is measured in galaxies with old mean-stellar-ages (log (Stellar Age/yr)>9), they typically demonstrate larger asymmetries in their gas, rather than their stars. The reverse is true for galaxies with young mean-stellar-ages, which demonstrate larger asymmetries in their stars.

Galaxies can accrete stars and gas from mergers, or they can accrete gas from the circumgalactic or intergalactic medium. Accreted gas may enter the disk with a range of angular momenta and orientation, and the dynamics of this gas will be dependent on the timescale of the accretion event. If the accretion happens over a long enough timescale where the incoming gas' angular momentum becomes aligned to the already present gas through collisions, it may not result in kinematic asymmetry. However, if the accretion event is shorter than the time it would take to realign the gas, it is likely the gas will display some kinematic asymmetry. It should also be said that this is only true for a galaxy that has an existing reservoir of gas. If a gas-poor galaxy accretes gas, the new gas would not be able to realign itself through collisions with existing gas. The accreted gas would only be able to align itself to the bulk motion of the galaxy through the torque provided by the stellar component, which would take a much longer time than if gas is present in the galaxy (more than 5 dynamical times , van de Voort et al. 2015; Davis & Bureau 2016).

We considered whether the gas asymmetries in systems with old mean-stellar-ages could be due to a misaligned disk that was in the process of being rebuilt during an accretion episode (Davis et al. 2011; Ristea et al. 2022), however we do not find these galaxies to have large stellar-gas kinematic misalignment in their position angles ($|\Phi| < 10^{\circ}$). Misaligned disks can be formed in galaxies that have rebuilt a disk after experiencing a major merger (McDermid et al. 2006). In this secnario, the incoming angular momentum of accreted gas that is misaligned is sufficiently above the torque provided by the pre-existing stellar disk, preventing the rebuilt gas disk from realigning with the stellar component (van de Voort et al. 2015). If accretion is responsible for the gas asymmetries, the absence of a misaligned disk would imply that the accretion rate is very low.

We postulate that the galaxies in our sample with old mean-stellarages, aligned gas and stellar kinematics, large gas asymmetries and low stellar asymmetries are driven by recent slow gas accretion. Accretion rather than outflows is a more likely explanation for the asymmetries in these systems since outflows occur in highly star-forming galaxies, and these old galaxies have low specific star formation rate $(sSFR < 10^{-10} \text{ yr}^{-1})$. We suggest two possible scenarios for this gas accretion. Firstly, the increased gas asymmetries could arise during a gas-rich, minor merger. MAGPI2310199196 (right panel of Fig. 6), is one of the galaxies in our sample with old mean-stellar-ages and large gas asymmetries that is seemingly stripping the gas from the smaller, neighbouring galaxy (M*,neigh/M*,primary=0.28). Accretion of gas through minor gas-rich merger would be clumpy, explaining the elevated gas asymmetries in MAGPI2310199196. Simulations of Milky Way-like galaxies have shown that gas stripping and accretion during a minor merger can persist for up-to, and longer than 1 Gyr (Tepper-García & Bland-Hawthorn 2018; Tepper-García et al. 2020). This suggests that accretion of gas from a merger over an extended period could thus be clumpy enough that it causes kinematic asymmetries, but slow enough that it does not result in a kinematic misalignment.

Alternatively, the gas could been accreted externally, independent of a merger. MAGPI1501224275 (left panel of Fig. 6) also has large gas asymmetries compared to it stars, but it is relatively isolated and is not obviously interacting with a gas-rich galaxy. MAGPI1501224275 may instead be slowly accreting gas from the outer halo. Its old stellar population and red colour confirms that it is relatively gas-poor, and whatever little accreted gas is leading to the star formation in this system is taking longer to align with the stars due to there being no existing gas in the galaxy, resulting in larger gas kinematic asymmetries. We also considered accretion through galactic fountains; however, in this scenario, the angular momentum of the accreting gas should match that of the disk from which it was expulsed in the first place, which would not result in the asymmetries observed. Disentangling possible scenarios for the origin of high gas asymmetries in old galaxies requires careful analysis of simulations, which will be the subject of a subsequent paper.

Figure 7. Histograms of $k_m/(k_2 + k_3 + k_4 + k_5)$, no one mode typically ever dominates over modes in v_{asym} . The dashed black line in each plot indicate a threshold of 0.25. No galaxies have m = 3 as their largest mode, suggesting bar or oval-like asymmetries are not what is driving the asymmetry in our sample, given our spatial resolution.

3.2.3 Non-axisymmetric disk features

Bars or 'oval' distortions perturb the axisymmetric gravitational potential galaxies, which can contribute to the kinematic asymmetry (Athanassoula 1992; Schoenmakers et al. 1997). Typically, this manif ests as increased power to the m = 2 and m = 3 modes in Eqn. 3 (Wong et al. 2004; Gentile et al. 2005; Spekkens & Sellwood 2007; Stark et al. 2018; López-Cobá et al. 2022; Tsukui et al. 2024). Fig. 7 shows distributions of the individual contributions of each mode to the overall v_{asym} . To ascertain whether bars or oval distortions are driving kinematic assymetries in our sample, we identify galaxies where the m = 3 mode is the dominant contributor to v_{asym} (i.e., $k_3/(k_2 + k_3 + k_4 + k_5) > 0.25$). We find no galaxy in our sample where k_3 is the largest contributor to the asymmetry. We repeat this process for the k_2 mode and find 7 galaxies where k_2 is the largest contributor to vasymin either stars or gas. There are only 4 galaxies for which k_2 is the largest contributor for the gas v_{asym} . Visually inspecting the images of these galaxies, we find no indication of a bar, with most having a spheroidal-like morphology. However, we note that the spatial resolution of MAGPI images is limited, which makes it difficult to identify structures such as bars (Foster et al., in prep.). Identification of bars requires sufficiently resolved (2× FWHM; ~6 kpc given our spatial resolution) imaging (Erwin 2018). While there may be hidden bars, the above exercise suggests that they are not the main driver of the kinematic asymmetries in our sample. We have confirmed that our results and conclusions are robust against removing galaxies where k_2 is the main contributor to the asymmetry.

3.3 Dynamical Evolution from MAGPI to SAMI

The MAGPI survey was designed to observe galaxies at $z \sim 0.3$ with similar physical resolution to local IFS surveys (MAGPI: ~ 3

kpc, SAMI: ~ 1.5 kpc). We can leverage the higher lookback time of MAGPI galaxies (~4 Gyrs) against SAMI galaxies (~1 Gyr) to see if the trends we are finding in MAGPI galaxies are still present in SAMI. We investigate evolution in these trends by matching the distributions in stellar mass and mean-stellar-ages between SAMI and MAGPI galaxies. While this removes the effect of stellar mass selection between surveys, it does not eliminate progenitor bias (van Dokkum & Franx 2001; Croom et al. 2021b).

Looking at Fig. 8, we find that the trend of gas-rich galaxies with old mean-stellar-ages having larger ionised gas asymmetries compared to their stellar asymmetries is still present in SAMI galaxies. We also compare the relationship between stellar and gas asymmetries against stellar mass found in MAGPI galaxies with SAMI. Fig. 9 shows the same parameter spaces as Fig. 4 but for SAMI galaxies. We find similar results in SAMI galaxies; chiefly that there is a strong anti-correlation between stellar asymmetries and stellar mass, while the correlation between gas asymmetries and stellar mass is absent. The strength of the correlation between stellar asymmetry and stellar mass is similar to what we found in MAGPI (SAMI; ρ =- $0.58,p<10^{-9}$, MAGPI; $\rho=-0.59,p<10^{-5}$). In Fig. 4, when excluding gas non-detections, we find a strong anti-correlation between meanstellar-age and stellar v_{asym} (ρ =-0.49,p<0.01), though this could be driven by the larger scatter at younger mean-stellar-ages. Including the gas non-detections reduces the significance of the correlation to ρ =-0.28, p<0.05. Taking advantage of the larger number statistics available in SAMI, we find an anti-correlation of ρ =-0.36,p<10⁻⁹ These results are consistent with low stellar mass galaxies with young mean-stellar-ages being less dynamically relaxed. The top-right panel Fig. 4 also shows that, at fixed stellar mass, gas asymmetries tend to be larger in galaxies without stellar detections, however this is not apparent for SAMI galaxies. We suspect this is most likely due to low stellar mass, small, and thus low stellar continuum flux MAGPI galaxies not surviving our quality cuts/selection criteria.

From Fig. 10, after mass and mean-stellar-age matching MAGPI and SAMI, we find that for all stellar masses, the median stellar v_{asym} is 1σ higher in MAGPI than in SAMI galaxies. This result is not mirrored in the gas v_{asym} . Our results are unchanged if we also match distributions of Re/FWHM prior to the mass and mean-stellar-age matching. The cause of stellar kinematic asymmetries is nuanced, while effectively driven by interactions (McElroy et al. 2022), stellar asymmetries have also been found to have a stronger correlation with stellar surface density rather than environment in SAMI galaxies, when interacting/merging galaxies are excluded. Suggesting the internal mass distribution is also a significant driver (Zhong et al. 2023). The elevated kinematic asymmetries in MAGPI galaxies could be due to a lower stellar surface density, however, Derkenne et al. (2023) found little evolution in the internal mass distribution between MAGPI galaxies and ATLAS^{3D}. Our results, however, are consistent with findings in McElroy et al. (2022) and Pal et al., (in prep.) who studied the kinematic and photometric asymmetries in simulated merging galaxies, and MAGPI galaxies, respectively. Both report that kinematic asymmetries persist in post-merger remnants even after photometric asymmetries have dissipated.

4 CONCLUSIONS

We have conducted a study of the kinematic asymmetries in the stellar and ionised gas velocity maps for a subsample of MAGPI and SAMI galaxies to investigate the physical drivers behind kinematic asymmetries. Using KINEMETRY, we have quantified the asymmetry

Figure 8. The same as Fig. 5, but for SAMI galaxies. The left panel is the raw data, the stellar ages in the right panel have been LOESS smoothed using the algorithm in (Cappellari et al. 2013). The trend of galaxies with old mean-stellar-ages having larger ionised gas asymmetries, and galaxies with young mean-stellar-ages having larger stellar asymmetries we found in MAGPI galaxies persists in SAMI galaxies. If accretion is responsible, this would suggest that old galaxies will continue to accrete gas over 4 Gyrs.

Figure 9. The same as 4, but for SAMI galaxies. We find similar trends between MAGPI and SAMI galaxies. Namely, that there is a strong correlation between stellar asymmetries and stellar mass, that is absent for the gas asymmetries. We also find that star-forming, galaxies with old mean-stellar-ages will display larger asymmetries in their gas compared to the stars.

Figure 10. *Left*: Stellar v_{asym} vs. stellar mass for MAGPI (blue) and SAMI (red) after stellar mass and mean-stellar-age matching the distributions. *Right*: The same as *left*, but for the gas asymmetries. Solid points indicate medians measured from 0.5 dex bins of stellar mass, where the errorbars represent the standard error (SE= σ/\sqrt{N}). Downward facing triangles are bins with less than 10 galaxies. Non-detections are ignored when binning the data. At all stellar masses, the median v_{asym} is 1 σ higher for MAGPI galaxies compared to SAMI galaxies.

by normalising the higher order Fourier Coefficients in Eqn. 3 to S_{05} . Our findings are as follows:

• Normalising the higher order terms using only k_1 (i.e., V_{rot}) causes the v_{asym} to diverge in low mass, slow-rotating and more dispersion dominated galaxies. This effect is particularly prominent in the stellar asymmetries for low λ_R galaxies (Fig. 2). By normalising by $S_{05} = \sqrt{0.5V_{\text{rot}}^2 + \sigma^2}$ instead, we can measure kinematic asymmetries between the stars and ionised gas, in all galaxy types, regardless if it is a slow or fast rotator.

• 61% of star-forming galaxies (those that are detected in ionised gas) in MAGPI galaxies have larger stellar asymmetries compared to gas asymmetries. The distributions of stellar asymmetries in galaxies with gas detections and with non-detections are similar (Fig. 3), suggesting that what is driving the stellar asymmetries does not remove the gas within galaxies in our sample, or that whatever drove the stellar asymmetries happened after the galaxy was quenched. When investigating individual modes (k_2 and k_3), we find no evidence that bars or non-axisymmetric disk features are driving the asymmetry in our sample (Fig. 7).

• We find an anti-correlation ($\rho = -0.59$, $p < 10^{-5}$) between stellar asymmetry and stellar mass (top left panel of Fig. 4). We do not find an equivalent anti-correlation between ionised gas asymmetries and stellar mass (top right panel of Fig. 4). This is likely due to the gas asymmetries being removed independent of the restoring force provided from the gravitational potential (i.e., through collisional processes). The gas has more available paths to return to a state of low asymmetry than the stars do. Stars can only settle through gravitational processes (traced by their anti-correlation with S_{05}), resulting in the asymmetries lasting in the stars for longer.

• We find that star-forming galaxies with old stellar populations (log (Stellar Age/yr) > 9) have larger gas asymmetries, compared to their stars (Fig. 5). We also find that these galaxies have little to no kinematic misalignment between the stellar and ionised gas, we suggest that these galaxies are experiencing slow, but sustained gas accretion. Employing simulations will help disentangle the source of the accretion.

 Investigating kinematic asymmetries in SAMI and MAGPI, we find consistent trends in both surveys. Firstly, that galaxies with old stellar populations have larger gas asymmetries, compared to their stars. Secondly, a similar anti-correlation between stellar asymmetry and stellar mass that is absent in gas asymmetries. After stellar mass and mean-stellar-age matching the distributions between SAMI and

MNRAS 000, 1–12 (2023)

MAGPI, we find that at all stellar masses, MAGPI galaxies display larger stellar asymmetries compared to SAMI galaxies.

We have shown that comparing kinematic asymmetries across baryonic phases, in this case, stars and ionised gas, has helped delineate certain physical drivers behind the disturbances. This study only considered galaxies at $z \sim 0.01$ and $z \sim 0.3$ redshifts, but significant evolution is inferred to occur at higher redshifts from both simulations and observations (Lagos et al. 2022; D'Eugenio et al. 2023a). Applying these methods to spectroscopic surveys at higher redshifts as well as mock observations of simulated galaxies will provide further understanding of the dynamical evolution in galaxies.

ACKNOWLEDGEMENTS

We thank the referee for their helpful comments that prompted further exploration of our findings. Based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO program 1104.B-0536. We wish to thank the ESO staff, and in particular the staff at Paranal Observatory, for carrying out the MAGPI observations. MAGPI targets were selected from GAMA. GAMA is a joint European-Australasian project based around a spectroscopic campaign using the Anglo-Australian Telescope. GAMA is funded by the STFC (UK), the ARC (Australia), the AAO, and the participating institutions. GAMA photometry is based on observations made with ESO Telescopes at the La Silla Paranal Observatory under programme ID 179.A-2004, ID 177.A-3016. Part of this research was conducted by the Australian Research Council Centre of Excellence for All Sky Astrophysics in 3 Dimensions (ASTRO 3D), through project number CE170100013. CF is the recipient of an Australian Research Council Future Fellowship (project number FT210100168) funded by the Australian Government. CL, JTM and CF are the recipients of ARC Discovery Project DP210101945. APPENDIX A: SPATIAL RESOLUTION ACROSS SURVEYS

The median physical spatial resolution for MAGPI is roughly twice as coarse as the median physical spatial resolution for SAMI. We investigate the impact of physical spatial resolution differences on the robustness of our results. Fig. A1 shows the asymmetry in MAGPI galaxies as a function of R_e /FWHM, for MAGPI and SAMI galaxies. We find no significant trend between v_{asym} and R_e /FWHM in both the gas and stars. Since KINEMETRY relies of fitting Eqn. 3 to pixels along ellipses, we also investigate if there is a dependency on the number of pixels sampled N_{pix}. Reassuringly, we come to the same conclusion as with R_e /FWHM. Taking advantage of the larger number statistics in SAMI, we again do not find a significant trend between R_e/FWHM or N_{pix}.

As discussed in Sect. 2.4.2, a correction to v_{asym} similar to that for λ_{Re} cannot be applied since we do not know the intrinsic asymmetry in the galaxy, prior to the seeing removing some of the irregularity in the velocity map. When applying a correction to λ_{Re} , it can only be applied to fast-rotating galaxies, since we know *a-priori* that it is rotating, and we know how seeing affects rotating systems. Since we do not have this prior assumption for kinematic asymmetry in galaxies with R_e /FWHM, we cannot apply a correction. It is similar to how we can not correct slow-rotating/non-rotating systems for seeing since we do not know how beam smearing affects these systems.

This paper has been typeset from a T_EX/IAT_EX file prepared by the author.

Figure A1. *Top Row:* v_{asym} vs. R_e /FWHM for MAGPI, and SAMI galaxies. *Bottom Row:* v_{asym} vs. N_{rmpix} for MAGPI, and SAMI galaxies. We find there is little correlation between how resolved a galaxy is and the asymmetry measured, for both MAGPI and SAMI samples, and both stellar and gas kinematics. Medians of binned data are shown where the error bars are the standard error from each bin. The correlation coefficents and p-values are shown in the legends of the figures. The correlation is also absent when considering number of pixels KINEMETRY uses when computing asymmetries. SAMI, with its larger number statistics would also confirms this. Given that we find little correlation between how resolved a galaxy is and the measured asymmetry, we cannot see how one would correct for seeing, or if there is even an impact.
