Abstract

Spinodal decomposition in multicomponent alloys has attracted increasing attention due to its beneficial effect on their mechanical and functional properties and potential applications. Both based on the Cahn-Hillard equation, the reference element method (REM) and the projection matrix method (PMM) are the two main methods to predict the occurrence of spinodal decomposition in multicomponent alloys. In this work, it is mathematically proven that the two methods are equivalent, and therefore the advanced results based on one method can be applied to the other. Based on these methods, the $Fe_{15}Co_{15}Ni_{35}Cu_{35}$ multicomponent alloy is designed as a case study. Experimental results confirm the spinodal decomposition in the heat-treated alloy, and its strength and ductility are simultaneously enhanced. This work can be the pavement for further theoretical and experimental studies on the spinodal decomposition in multicomponent alloys.

Keywords

Multicomponent alloy; spinodal decomposition; reference element method; projection matrix method; high entropy alloy

Introduction

Multicomponent alloys, including high entropy alloys (HEAs), have recently gained significant and increasing attention due to their novel and vast compositional space and excellent mechanical and functional properties[1-7]. The microstructure is of critical importance to their properties, and spinodal decomposition is found to be a common and effective process in multicomponent alloys to alter their microstructures and thus properties[8-15]. Spinodal decomposition refers to the process in which a homogeneous phase becomes unstable and decomposes to usually two phases with the same crystal structure but distinct compositions. Such a process is usually described by the Cahn-Hilliard equation, and the criterion of the occurrence of the spinodal decomposition can be obtained from this equation[16-20]. Although the occurrence of the spinodal decomposition may also be predicted or explained by the phase-field [21-28], molecular dynamic [29-33] or ab initio [34-36] methods, the spinodal decomposition criterion derived from the Cahn-Hilliard equation is still helpful since the cost for its calculation is much lower than other methods, and the required input information is easily and readily available, which makes the high-throughput calculation on the novel and vast compositional space of the multicomponent alloys possible[11].

A critical part of the criterion is that the spinodal decomposition criterion must consider the sum of the mole composition fraction of all the components is always equal to one, which limits the possible compositional directions. A simple and widely applied method to realize it is by substituting the composition fraction of one element (denoted as the reference element hereafter) by one minus the sum of the composition fractions of all other elements. For most properties, this treatment can give results independent of the selection of the reference element[37]. However, it is found that such treatment is not rigorous since the absolute value of the calculated driving force of the spinodal decomposition would be dependent on the selection of the reference element[37]. Recently, a more advanced method (denoted as the Reference Element Method (REM) hereafter) has been introduced, where the compositional change is transformed from the Gibbs space into the Cartesian space during the analysis, and it can produce results independent of the selection of the reference element[37-41]. Another method, denoted as the Projection Matrix Method (PMM), can also avoid this "reference element problem" [42-48]. In PMM, a projection matrix is applied to the driving force of the spinodal decomposition to eliminate the component of the driving force that would drive the composition to violate the conservation of mass. Therefore, the conservation of mass is always obeyed, and there is no need to select a reference element. Comparing the two methods, the REM is mainly used in the materials science field, and it has been realized in the PandatTM 2022 software[38, 49] recently, while the PMM is mainly used in the mathematical physics and applied mathematics fields for its more straightforward form and easier mathematical treatment. The two methods are supposed to give the same results since they are both valid and they describe the same phenomenon. In a recent work, the authors have shown that alloys with 2 to 10 elements would have the same driving force for spinodal decomposition if the decomposition directions were the same [11]. However, such a result is not satisfying, and a rigorous mathematical proof is still lacking. Therefore, the equivalence of the two methods is not guaranteed, and the advanced theoretical or calculation results based on one method can not be directly transferred to the other. In this work, the equivalence of the two spinodal decomposition criteria is mathematically proven, as schematically shown in Fig. S1. Then, the Fe15Co15Ni35Cu35 multicomponent alloy is designed based on the criteria and

investigated as a case study for illustration.

Proof of the equivalence of the two spinodal decomposition criteria

For a multicomponent alloy with n elements, the composition **c** shall be denoted as

$$\mathbf{c} = \begin{bmatrix} c_1 & c_2 & \cdots & c_n \end{bmatrix}^T, \tag{1}$$

where c_i is the composition fraction of the i^{th} element, and the upper right corner mark ^{*T*} indicates the transpose action. For PMM, the Cahn-Hilliard equation is written as

$$\frac{\partial}{\partial t}\mathbf{c} = \Delta(-\varepsilon^2\Delta\mathbf{c} + f(\mathbf{c})) \quad in \quad \Omega \tag{2}$$

$$\nabla \mathbf{c} \cdot \mathbf{n} = 0 \quad and \quad \nabla(\Delta \mathbf{c}) \cdot \mathbf{n} = 0 \quad on \quad \partial \Omega, \tag{3}$$

where *t* is the time, $f(\mathbf{c})$ is a function of the composition related to the driving force of the spinodal decomposition, Ω is the geometric space of the alloy (or mathematically, the inner space of the alloy), $\partial\Omega$ is the boundary of the alloy, the *n* is the normal vector of the boundary, and ε^2 is a small positive parameter [42]. The Eq. (2) has been normalized, and the diffusion term is not explicitly expressed. The *f*(**c**) is related to the Gibbs free energy of the alloy as[42]

$$f(\mathbf{c}) = P \frac{d}{d\mathbf{c}} G(\mathbf{c}) \tag{4}$$

where *P* is the projection matrix and $G(\mathbf{c})$ is the Gibbs free energy as a function of composition of the alloy. The *P* matrix is given as

$$P = I_{n \times n} - \frac{1}{n} J_{n \times n},\tag{5}$$

where $I_{n\times n}$ is an identity matrix with dimension $n \times n$, and $J_{n\times n}$ is an all-ones matrix with dimension $n \times n$. The *P* matrix is applied to project the driving force of the spinodal decomposition to the space perpendicular to the vector $[1]_n = [1,...,1] \in R_n$ (orthogonal complement of $\{[1]_n\}$) by substracting the component vector parallel to $[1]_n$. Then, it can be deduced that the criterion for the occurrence of the spinodal decomposition is that the smallest eigenvalue of the following matrix $B_{n\times n}$ (denoted as λ_{\min}^B) is negative[17, 39, 42, 50], where *B* is defined as

$$B = P \frac{d^2}{d\mathbf{c}^2} G(\mathbf{c}).$$
(6)

The driving force of the spinodal decomposition would be proportional to $-\lambda_{\min}^B$, and the compositional direction of the spinodal decomposition would be the eigenvector ν_{\min}^B corresponding to the λ_{\min}^B . It should be noted that the $[\frac{d^2}{dc^2}G(\mathbf{c})]^{-1}[1]_n$ is always an eigenvector of *B* with no physical meaning, and it has been excluded from the discussion.

As for the REM, we shall take the n^{th} element as the reference element, and the Gibbs free energy shall be given as

$$G(\mathbf{c}) = G(c_1, \dots, c_{n-1}, 1 - \sum_{i=1}^{n-1} c_i).$$
(7)

Then, the fluctuations of the composition in the current Gibbs space are converted to the Cartesian space through a matrix T, and the compositional direction and the driving force of the spinodal decomposition in the Cartesian space would be given by the eigenvalue $\lambda^{\widehat{G}}$ and eigenvector $\nu^{\widehat{G}}$ of the matrix \widehat{G} , which is given by

$$\widehat{G} = T^T \frac{d^2 G(\mathbf{c})}{d\mathbf{c}_{n-1}^2} T.$$
(8)

where c_{n-1} denotes the first n-1 terms of the composition. Then, the eigen-

vectors are transformed back to the Gibbs space by

$$\nu^R = T \nu^{\widehat{G}},\tag{9}$$

while the eigenvalues are not changed. It should be noted that the v^R is the compositional direction of the first n-1 elements, and the composition direction v^{Rn} with n elements should be

$$\nu^{Rn} = \begin{bmatrix} I_{n-1 \times n-1} & [0]_{n-1} \\ [-1]_{n-1}^T & 1 \end{bmatrix} \begin{bmatrix} \nu^R \\ 0 \end{bmatrix} = \begin{bmatrix} \nu^R \\ -\sum_{i=1}^{n-1} \nu_i^R \end{bmatrix}.$$
 (10)

Similar to the PMM method, the criterion for the occurrence of the spinodal decomposition would be the smallest eigenvalue of $\lambda^{\widehat{G}}$ being negative, and the compositional direction of the spinodal decomposition would be the transformed eigenvector corresponding to that eigenvalue. Previous numerical results indicate that the minimal eigenvalues of the two methods have $\lambda_{\min}^{Rn} = 2\lambda_{\min}^{B}$, while the corresponding eigenvectors are identical $(\nu_{\min}^{Rn} = \nu_{\min}^{B})[11]$. To prove the equivalence of the two methods, we shall prove that such a relationship is valid for all eigenvalues and eigenvectors, which would be a natural result if we can prove that the matrixes of the two methods are equivalent after some transformation. First, we shall start from the side of REM. Taking the Eq. (7) into the $\frac{d^2G(\mathbf{c})}{dc_{n-1}^2}$ in Eq. (8), and by the chain rule, we have

$$\frac{d^2 G(\mathbf{c})}{dc_i dc_j} = \frac{\partial^2 G(\mathbf{c})}{\partial c_i \partial c_j} - \frac{\partial^2 G(\mathbf{c})}{\partial c_j \partial c_n} - \frac{\partial^2 G(\mathbf{c})}{\partial c_i \partial c_n} + \frac{\partial^2 G(\mathbf{c})}{\partial c_n^2}.$$
(11)

For simplicity, we shall divide the $\frac{d^2G(\mathbf{c})}{d\mathbf{c}^2}$ matrix into 4 parts as

$$\frac{d^2 G(\mathbf{c})}{d\mathbf{c}^2} = \begin{bmatrix} \left[\frac{d^2 G(\mathbf{c})}{dc_i dc_j} \right]_{i,j=1,\dots,n-1} & \left[\frac{d^2 G(\mathbf{c})}{dc_i dc_n} \right]_{i=1,\dots,n-1} \\ \left[\frac{d^2 G(\mathbf{c})}{dc_j dc_n} \right]_{j=1,\dots,n-1} & \frac{d^2 G(\mathbf{c})}{dc_n^2} \end{bmatrix} = \begin{bmatrix} \ddot{G}_A & \ddot{G}_C \\ \ddot{G}_C^T & \ddot{G}_n \end{bmatrix}, \quad (12)$$

where the symmetry of the $\frac{d^2G(\mathbf{c})}{d\mathbf{c}^2}$ matrix is used. Then, together with the Eq. (11), the $\frac{d^2 G(\mathbf{c})}{d\mathbf{c}_{n-1}^2}$ can be given as

$$\frac{d^2 G(\mathbf{c})}{d\mathbf{c}_{n-1}^2} = \ddot{G}_A + [-1]_{n-1} \ddot{G}_C^T + \ddot{G}_C [-1]_{n-1}^T + \ddot{G}_n J_{n-1 \times n-1}.$$
 (13)

Then, from Eqs. (8), (9) and (10), we can get $\widehat{G}\nu^{\widehat{G}} = \widehat{G}T^{-1}\nu^{R} = \lambda^{\widehat{G}}\nu^{\widehat{G}} = \lambda^{\widehat{G}}T^{-1}\nu^{R}$, and therefore

$$T\widehat{G}T^{-1}\nu^R = \lambda^{\widehat{G}}\nu^R.$$
(14)

The Eqs.(8) and (13) can be taken into Eq.(14), and the result will be compared to the matrix in the side of PMM later. On the PMM side, we shall have the following equation from Eqs. (6) and (10)

$$\begin{bmatrix} I_{n-1\times n-1} & 0\\ [1]_{n-1}^T & 1 \end{bmatrix} P \begin{bmatrix} \ddot{G}_A & \ddot{G}_C\\ \ddot{G}_C^T & \ddot{G}_n \end{bmatrix} \begin{bmatrix} I_{n-1\times n-1} & 0\\ [-1]_{n-1}^T & 1 \end{bmatrix} \begin{bmatrix} \begin{bmatrix} \nu^B \end{bmatrix}_{n-1}\\ 0 \end{bmatrix} = \lambda^B \begin{bmatrix} \begin{bmatrix} \nu^B \end{bmatrix}_{n-1}\\ 0 \end{bmatrix},$$
(15)

where $\begin{bmatrix} \nu^B \end{bmatrix}_{n-1}$ denotes the first n-1 terms of ν^B and the $\begin{bmatrix} I_{n-1\times n-1} & [0]_{n-1} \\ [1]_{n-1}^T & 1 \end{bmatrix} \begin{bmatrix} I_{n-1\times n-1} & [0]_{n-1} \\ [-1]_{n-1}^T & 1 \end{bmatrix} = I_{n\times n}$ is applied. By taking the Eq. (5) into Eq. (15)

(5) into Eq. (15), we can have

$$((I_{n-1\times n-1} - \frac{1}{n}J_{n-1\times n-1})(\ddot{G}_A + \ddot{G}_C[-1]_{n-1}^T) - \frac{1}{n}[1]_{n-1}(\ddot{G}_C^T + \ddot{G}_n[-1]_{n-1}^T))[\nu^B]_{n-1} = \lambda^B [\nu^B]_{n-1}$$
(16)

The equivalence of the two methods requires $\{\nu^R\} = \{[\nu^B]_{n-1}\}$ and $\{\lambda^{\widehat{G}}\} = \{2\lambda^B\}$, and by comparing the Eq. (16) with Eq. (14), this can be obtained if

$$(I_{n-1\times n-1} - \frac{1}{n}J_{n-1\times n-1})(\ddot{G}_A + \ddot{G}_C[-1]_{n-1}^T) - \frac{1}{n}[1]_{n-1}(\ddot{G}_C^T + \ddot{G}_n[-1]_{n-1}^T) = \frac{1}{2}T\widehat{G}T^{-1}.$$
(17)

Taking Eqs. (8) and (13) into Eq. (17) with the lemma (see Supplementary Note 1) that

$$TT^{T} = 2(I_{n-1 \times n-1} - \frac{1}{n}J_{n-1 \times n-1}),$$
(18)

it can be found that both sides of the Eq. (17) equation equal to

$$(I_{n-1\times n-1} - \frac{1}{n}J_{n-1\times n-1})\ddot{G}_{A} + (I_{n-1\times n-1} - \frac{1}{n}J_{n-1\times n-1})\ddot{G}_{C}[-1]_{n-1}^{T},$$

$$-\frac{1}{n}[1]_{n-1}\ddot{G}_{C}^{T} + \frac{1}{n}J_{n-1\times n-1}\ddot{G}_{n}$$
(19)

and therefore the equivalence of two spinodal decomposition criteria is proven. The equivalence of the two methods broadens the possible choice of methods for material scientists and mathematicians, and the conclusions based on one method can now be applied to the other method directly. For example, based on the PMM method, it has been derived that the condition for spinodal decomposition to produce 3 phases is $\lambda_{\min}^B \approx \lambda_{second smallest}^B < 0[42]$, and this result has been used to explain why spinodal decomposition into 3 phases is rare[11]. With this proof of the equivalence of the two methods, this condition can be tested by the smallest and the second smallest eigenvalues obtained from the REM method directly.

Application of the two criteria to the $Fe_{15}Co_{15}Ni_{35}Cu_{35}$ multicomponent alloy

To numerically and experimentally illustrate the criteria, the $Fe_{15}Co_{15}Ni_{35}Cu_{35}$ multicomponent alloy is designed as an example. To apply the two criteria to actual alloys, we shall obtain the expression of the $G(\mathbf{c})$ term first. Taking pure elements as references, the $G(\mathbf{c})$ can be given by the regular solution model as

$$G(\mathbf{c}) = H(\mathbf{c}) - T_{Temp}S(\mathbf{c}), \tag{20}$$

where

$$H(\mathbf{c}) = \sum_{i=1}^{n} \sum_{j=1}^{n} 2H^{i-j} c_i c_j,$$
(21)

$$S(\mathbf{c}) = -R \sum_{i=1}^{n} c_i \ln(c_i), \qquad (22)$$

 $H(\mathbf{c})$ is the mixing enthalpy, $S(\mathbf{c})$ is the mixing entropy, T_{Temp} is the temperature, H^{i-j} is the mixing enthalpy per mole between the i^{th} element and j^{th} element (note $H^{i-j} = 0$ if i = j), and R is the ideal gas constant. Although the regular solution model has been widely used in HEAs [51-53] for its simple form and high data availability, the model has also been criticized, and it may not be widely effective[54]. It should be noted that our proof does not depend on the exact expression of $G(\mathbf{c})$, and extra terms, such as the magnetism term, and other expressions or modifications of $H(\mathbf{c})$ and $S(\mathbf{c})$ can be applied[55]. The values of the H^{i-j} can be given by the Miedema's model[55], and the H^{i-j} between the elements in the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy is shown in Fig. S2, where the Cu element shows a positive mixing enthalpy with other elements, which may lead to spinodal decomposition. With the expression of the $G(\mathbf{c})$ term, the two criteria can be applied to the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy. As for the PMM, based on the Eqs.(20), (21) and (22), the $\frac{d^2}{dc^2}G(\mathbf{c})$ term can be given as

$$\frac{d^2}{d\mathbf{c}^2}G(\mathbf{c}) = \frac{d^2}{d\mathbf{c}^2}H(\mathbf{c}) - T_{Temp}\frac{d^2}{d\mathbf{c}^2}S(\mathbf{c}),$$
(23)

where 1, 2, 3, and 4 denote Fe, Co, Ni, and Cu elements, respectively. The projection matrix P from Eq.(5) is

$$P = I_{4\times4} - \frac{1}{4}J_{4\times4}.$$
 (24)

Taking Eqs. (23) and (24) into Eq.(6), and taking the $T_{Temp} = 1100K$ as an example, the *B* matrix can be calculated as shown in Supplementary Note 2, and the eigenvalues and the corresponding eigenvectors of the *B* matrix are calculated as

$$\left\{\lambda^B\right\} = \{-19984.68, \, 41778.32, \, 67854.93\} \tag{25}$$

and

$$\{\nu^{B}\} = \{[0.470, 0.195, 0.178, -0.843], \\ [-0.224, -0.523, 0.819, -0.072] .$$
(26)
$$[0.692, -0.662, -0.217, 0.187]\}$$

The negative λ_{\min}^{B} indicates the spinodal decomposition would occur, and the corresponding eigenvector indicates the spinodal decomposition would produce a Cu-rich phase and a Fe, Co, and Ni-rich phase, as schematically illustrated in Fig. 1a. The second smallest eigenvalue $\lambda^B_{second smallest}$ is positive, which indicates that the spinodal decomposition would produce two phases like most other multicomponent alloys[11, 42]. The λ_{min}^{B} and the $\lambda_{sec ond smallest}^{B}$ as a function of temperature are plotted in Fig. 1b, which indicates a possible spinodal decomposition start temperature at 1739 K. It should be noted that this temperature is very likely to be higher than the melting point of the alloy, and it actually may indicate a decomposition of the liquid phase. The eigenvector corresponding to λ_{\min}^{B} , which indicates the compositional direction of the decomposition, is shown in Fig. 1c as a function of temperature. It shows that the two phases are Cu-rich and Fe, Co, and Ni-rich within the whole temperature range. As for the REM method, we shall use the same expression of $G(\mathbf{c})$ in Eq.(20), and calculate the spinodal decomposition criterion at $T_{Temp} = 1100K$. Cu is chosen as the reference element first, and the \widehat{G} matrix can be calculated by Eq.(8) (see Supplementary Note 2), and the eigenvalues $\{\lambda^{\widehat{G}}\}$ and the transformed eigenvectors $\{v^R\} = \{Tv^{\widehat{G}}\}$ are

$$\{\lambda^{\widehat{G}}\} = \{-39969.36\ 83556.64\ 135709.86\}$$
(27)
$$\{\nu^{R}\} = \{[-0.664, -0.275, -0.252], \\ [0.316, 0.740, -1.158], . (28) \\ [0.979, -0.936, -0.307]\}$$

It can be verified that the values of $\{\lambda^{\widehat{G}}\}\$ is indeed twice the values of $\{\lambda^B\}$, and the $\{\nu^R\} = \{T\nu^{\widehat{G}}\}\$ is the same as $\{\nu^B\}\$ after adding the Cu component and normalization. The Fe, Co, or Ni element can also be chosen as the reference element, and the results are listed in Supplementary Note 2. It can be seen that the $\{\lambda^{\widehat{G}}\}\$ and the normalized transformed eigenvectors $\{\nu^R\}\$ are not affected by the selection of the reference element. These results numerically confirm the equivalence of two spinodal decomposition criteria and predict the spinodal decomposition of the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy at 1100 K.

Experimental analysis of the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy

To experimentally confirm the predicted spinodal decomposition of the $Fe_{15}Co_{15}Ni_{35}Cu_{35}$ multicomponent alloy, the $Fe_{15}Co_{15}Ni_{35}Cu_{35}$ multicomponent alloy ingot is prepared by arc-melting and copper mould casting and analyzed (details in Supplementay Note 3). The X-ray diffraction (XRD) result shows that the as-prepared alloy has a single face-centered cubic (FCC) phase (a= 0.3592 nm) microstructure (Fig. 1d), and the single-phase microstructure is supposed to be caused by the fast cooling rate of the copper mould casting that dynamically prevents the spinodal decomposition process. To introduce the spinodal decomposition, the as-cast alloy was heat-treated at 1100 K for 1 hour, and the XRD result shows that the heat-treated alloy has two FCC

phases (Fig. 1d) with very close lattice parameters (a= 0.3615 nm and 0.3577 nm), which indicates that the spinodal decomposition happened as predicted. Scanning electron microscope (SEM) images show that these alloys keep a dendrite microstructure with a secondary dendrite arm spacing of $\sim 4 \ \mu m$ before and after the heat-treatment (Fig. S3). To observed the spinodal decomposition microstructure, the as-prepared and heat-treated alloys are observed by transmission electron microscopy (TEM) and energy dispersive spectroscopy (EDS) analysis. The heat-treated sample shows a maze-like microstructure with a spacing of ~40 nm (Fig. 2a), which is not observed in the TEM image of the as-prepared alloy (Fig. S4), and the selected area electron diffraction (SAED) image shows that both phases are FCC phases with indistinguishable lattice parameter and crystallographic orientation in TEM as confirmed by the coherent high-resolution TEM image (Fig. S5). These results show that the heat-treated alloy has a typical spinodal decomposition microstructure as predicted. The EDS line scan (Fig. S6) reveals that the spinodal decomposition produces a Cu-rich phase and a Fe, Co, and Ni-rich phase, which agrees with the prediction of the compositional direction. To better observe the composition fluctuation of the spinodal decomposition microstructure, the atom probe tomography (APT) analysis is applied to the heat-treated sample, as shown in Fig. 2c and d. The APT result clearly shows that the heat-treated sample has a Cu-rich phase and a Fe, Co, and Ni-rich phase with a transition region of \sim 7 nm (Fig. 2d). This result confirms the spinodal decomposition microstructure and the predicted compositional direction.

To show the effect of the spinodal decomposition on the properties, the tensile mechanical property of the as-prepared and heat-treated samples are tested as shown in Fig. 3a. The result shows that the spinodal decomposition slightly increases the yield strength (326.7 MPa to 327.5 MPa), while the ultimate ten-

sile strength (573.0 MPa to 583.7 MPa) and the elongation to failure (16.9 % to 19.5 %) are significantly increased. Similar increased strength has also been observed in other alloys with spinodal decomposition [12-14, 32, 56]. The increased strength is confirmed by the increased Vicker's hardness (178.1 ± 6.6 HV to 181.5 ± 4.0 HV). The strain-hardening rate curve (inset in Fig. 3a) shows that the heat-treated sample has a significantly higher strain-hardening rate at the initial stage of deformation, and it gradually decreases with more strain, while the strain-hardening rate of the as-prepared sample remains stable. The magnetic properties of the as-prepared and heat-treated samples are also analyzed by a vibrating sample magnetometer (VSM) as shown in Fig. 3b. The two samples show close saturation magnetization at ~795 Am²/kg, while the coercive force of the heat-treated sample (\sim 3.4 kA/m) is much higher than the as-prepared sample (~0.45 kA/m), which is supposed to be caused by the hindering effect of the Cu-rich phase on the arrangement motion of the magnetic domain wall[57-59]. A more detailed analysis would be beneficial for understanding the effect of spinodal decomposition on the properties, but it would be beyond the focus of this work. In short, we have experimentally confirmed the spinodal decomposition of the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy.

Conclusion

In summary, we have successfully demonstrated the equivalence of the reference element method and the projection matrix method for predicting spinodal decomposition in multicomponent alloys through rigorous mathematical proof. Then, the equivalence of the two methods is numerically verified, and the spinodal decomposition of the Fe₁₅Co₁₅Ni₃₅Cu₃₅ multicomponent alloy is predicted. Experimental results confirm the occurrence of the predicted spinodal decomposition, and the improved mechanical properties are observed. The proof in this work can link the results based on one method to the other, which is helpful for further theoretical and experimental studies, and the two criteria can function as powerful tools for further investigations.
