Key points:

- Machine learning is explored as a replacement for geochemical simulators in reactive transport for faster and accurate computations.
- Machine learning surrogates excel in isolated predictions but require modifications to avoid failure in successive time-step predictions.
- Physics-based constraints & tailored datasets are key to enhancing machine learning surrogate accuracy in successive time-step predictions.

Abstract

Reactive transport in porous media plays a pivotal role in subsurface reservoir processes, influencing fluid properties and geochemical characteristics. However, coupling fluid flow and transport with geochemical reactions is computationally intensive, requiring geochemical calculations at each grid cell and each time step within a discretized simulation domain. Although recent advancements have integrated machine learning techniques as surrogates for geochemical simulations, ensuring computational efficiency and accuracy remains a challenge. This chapter investigates machine learning models as replacements for a geochemical module in a reactive transport in porous media simulation. We test this approach on a well-documented cation exchange problem. While the surrogate models excel in isolated predictions, they fall short in rollout predictions over successive time steps. By introducing modifications, including physics-based constraints and tailored dataset generation strategies, we show that machine learning surrogates can achieve accurate rollout predictions. Our findings emphasize that, when judiciously designed, machine learning surrogates can substantially expedite the cation exchange problem without compromising accuracy, offering significant potential for a range of reactive transport applications.

1 Introduction

Reactive transport within porous media occurs in a range of subsurface processes including geothermal energy extraction, hydrocarbon recovery, CO_2 storage, and groundwater flow. These phenomena

can significantly affect the fluid dynamics, as well as the petrophysical and geochemical properties of the reservoirs [Appelo and Postma, 2004, Fan et al., 2012, Kala and Voskov, 2020, Molins et al., 2012, Nogues et al., 2013, Oliveira et al., 2019, Soulaine et al., 2021, Yekta et al., 2021]. Nonetheless, simulating fluid flow and transport coupled with chemical reactions is highly computationally intensive, due to the necessity of computing chemical reactions within each discrete element of the simulation grid, which can range from hundreds to millions of elements in size.

Two predominant methodologies exist for solving transport and reaction processes together: the sequential method [Oliveira et al., 2019, Soulaine et al., 2021, Yekta et al., 2021] and the fully coupled (or simultaneous) method [Fan et al., 2012, Kala and Voskov, 2020, Seigneur et al., 2023]. In the sequential method, transport and chemical reactions are solved in a stepwise manner. The fully coupled method, on the other hand, simultaneously resolves both transport and reaction equations, iterating until convergence is achieved. Both methodologies necessitate executing geochemical calculations on a per-grid-block basis, which remains the primary contributor to the computational time. Even worse for the fully coupled scheme, where the calculations need to be performed for each iteration within a time step (until convergence).

The use of machine learning to address complex engineering challenges has paved the way for advancements in reactive transport simulations. The trend of using machine learning as a substitute for conventional geochemical simulators is on the rise [De Lucia and Kühn, 2021, Demirer et al., 2023, Guérillot and Bruyelle, 2020, Jatnieks et al., 2016, Leal et al., 2020, Li et al., 2019, Sprocati and Rolle, 2021], although ensuring computational efficiency and prediction accuracy remains an open challenge. Mainly, when we consider the accumulation of error through time steps (rollout), since the solution of one time iteration is the input for the next one. Thus, any small deviation from the correct solution can be amplified and generate unbounded errors during the simulation run. Furthermore, to the best of the author's knowledge, a detailed evaluation of machine learning models, training set sampling procedures, and the incorporation of physical constraints are still lacking for building surrogates of geochemical simulators.

In this work, we explore machine learning techniques to develop a rapid surrogate model for the geochemical simulator PHREEQC, a specialized geochemical code that function independently or in conjunction with flow and transport simulators [Parkhurst and Wissmeier, 2015, Parkhurst et al., 1999, 2013]. The aim is to facilitate an efficient integration with flow and transport simulators while reducing computational overhead. Our efforts concentrate on modelling cation exchange reactions between an aqueous solution and a rock surface in a porous medium scenario, a topic well documented in the literature [Appelo and Postma, 2004, Parkhurst et al., 2013, Silva et al., 2022, Yekta et al., 2021]. We assess various machine learning and deep learning strategies to determine their suitability for geochemical computations. We also investigate how the error evolves when multiple time steps are considered (rollout), the effect of different dataset sampling procedures on the prediction error, and how prior information or physical knowledge of the problem can help improve prediction accuracy. Our findings suggest that, with careful design, machine learning surrogates can effectively substitute the reaction module in PHREEQC for the cation exchange problem. This paves the way for broad applications in rapid reactive transport modelling, potentially extending to a variety of phase equilibrium models in diverse transport scenarios.

The remainder of this paper is structured as follows. In Section 2, we describe the geochemical simulator, flow and transport simulator, coupling procedure, the cation exchange problem, and the machine learning/deep learning surrogates. Following that, we detail the results for the one-shot and rollout predictions in Section 3. Finally, a discussion and concluding remarks are provided in Section 4 and 5, respectively.

2 Method

In this section, we first describe the geochemical simulator (PHREEQC). Following that, we present the flow and transport simulator (IC-FERST) and the coupling procedure used to integrate PHREEQC into IC-FERST. Then we describe the cation exchange problem, and finally we present the machine learning/deep learning models used as surrogates.

2.1 Geochemical simulator

PHREEQC [Parkhurst et al., 1999] is a public-domain geochemical reaction package developed and maintained by the United States Geological Survey. PHREEQC simulates geochemical processes including ion exchangers, equilibrium between water and minerals, solid solutions, and gases. Specifically tailored for embedding reaction calculations into diverse flow and mass transport simulators, PHREEQCRM is structured as a C++ class. Its core function involves receiving component concentrations from the transport simulator's grid cells, executing geochemical reactions, and subsequently relaying the updated component concentrations back to the transport simulator. In this work, we use PHREEQCRM in the coupling with the flow and transport simulator (IC-FERST).

2.2 Flow and transport simulator

We present the equations for incompressible single-phase porous-media flow. The pressure and velocity in the porous space have a linear relationship given by Darcy's law as

$$\mathbf{u} = \frac{\mathbf{K}}{\mu} (-\nabla p + \rho g \nabla z),\tag{1}$$

where **u** is the Darcy velocity and μ is the viscosity. **K** is the permeability tensor, ρ is the density, p is the pressure, ∇z is the gravity direction, and g is the gravitational acceleration.

The continuity equation is given by

$$\nabla \cdot \mathbf{u} = 0. \tag{2}$$

We also include the transport equation for each species as

$$\phi \frac{\partial C_{\alpha}}{\partial t} + \nabla \cdot (\mathbf{u}C_{\alpha}) = Q_{\alpha}, \tag{3}$$

where Q_{α} is a volumetric source term of species α , C_{α} the concentration of species α , and ϕ is the porosity.

We use IC-FERST for the solution of the equations reported here [Jackson et al., 2015, Salinas et al., 2017, Silva et al., 2021]. IC-FERST is a next-generation three-dimensional reservoir simulator that uses surface-based modelling to represent the different petrophysical properties and unstructured meshes to discretize the domain. In surface-based modelling, the petrophysical properties are defined using discrete values bounded by surfaces [Jacquemyn et al., 2019]. In this approach, geological representation and the mesh used to discretize the domain are independent. IC-FERST uses for the space discretization a double control volume finite element method (DCVFEM) [Salinas et al., 2017], which is an improvement from the control volume finite element method (CVFEM) [Durlofsky, 1993, Gomes et al., 2017, Jackson et al., 2015]. Time is discretized using a θ -method where θ varies between 0.5 (Crank-Nicholson) and 1 (implicit order) based on the total variational diminishing (TVD) criterion [Pavlidis et al., 2014].

Figure 1: Coupling between the flow and transport simulator (IC-FERST) and the geochemical simulator (PHREEQC).

2.3 Coupling procedure

We use a sequential approach to couple PHREEQC and IC-FERST in a non-iterative framework, see Figure 1. The sequential non-iterative approach is a commonly used coupling scheme in reactive transport modelling [Oliveira et al., 2019, Soulaine et al., 2021, Yekta et al., 2021]. Here, the geochemical reactions (cation exchange) do not affect the characteristics of the rock or the flow behavior of the fluid. For other scenarios where the reactions can alter the porosity and permeability in the porous space or the viscosity of the fluids for example, a fully coupled scheme would be required [Fan et al., 2012, Kala and Voskov, 2020, Seigneur et al., 2023].

In the coupling, IC-FERST controls the fields associated with the flow and transport, this includes pressure, velocity, saturation, and concentrations. Geochemical reactions are addressed by PHREEQC. Specifically, PHREEQC retrieves component concentrations from each grid cell within IC-FERST, processes the geochemical reactions, and then returns the updated component concentrations back to IC-FERST. The coupling is performed as follows:

- 1. Configure the simulation domain and the related transport and chemical parameters initializing IC-FERST and PHREEQC. Set the boundary and initial conditions.
- 2. IC-FERST updates pressure, velocity, and concentration (transport step in Figure 1).
- 3. PHREEQC computes the new concentration values for each grid cell (geochemical step in Figure 1).
- 4. Advance to the next time level and repeat the procedure until the final time level is achieved.

2.4 Cation exchange problem

The cation exchange problem is a single-phase flow and reactive (cation exchange) transport case used to evaluate several reactive transport models in the literature [Appelo and Postma, 2004, Parkhurst et al., 2013, Silva et al., 2022, Yekta et al., 2021]. The aim is to simulate solute transport in a saturated domain. We are interested in the advection of ionic species in the porous space containing a cation exchanger. Figure 2 shows a schematic of the cation exchange in part of the porous space. The inputs of interest for the geochemical reaction are the concentration of the elements Ca^{2+} , Na^+ , K^+ in the inflow solution and in the exchanger. The outputs are the new concentrations in the equilibrated aqueous solution, as shown in Figure 3.

To simulate this process, we use a two-dimensional domain shown in Figure 4, alongside the mesh. We use the same model set up as in Yekta et al. [2021]. A calcium-chloride (CaCl₂) solution is flushed into the porous space at a constant rate of 2.78×10^{-7} m/s from left boundary, while the resulted solution is produced from the right boundary. The other boundaries are closed to flow. Table 1 shows the ion concentrations in the initial and injected solutions.

Figure 2: Schematic of the cation exchange in a small portion of the porous space. The outflow from the schematic will be the inflow in the next portion of the domain in the next time step.

Figure 3: Inputs and outputs of the geochemical reaction in the cation exchange problem. The reaction is performed for each grid cell at each time step.

Table 1: Initial and injected solution concentrations. The concentrations are reported in milimoles per kilogram of water (mmol/kgw).

Solution	Na^+	K^+	Ca^{2+}	$\mathrm{NO_3}^-$	Cl^-
Initial Injected	$\begin{array}{c} 1.0 \\ 0.0 \end{array}$	$0.2 \\ 0.0$	$\begin{array}{c} 0.0 \\ 0.6 \end{array}$	$\begin{array}{c} 1.2 \\ 0.0 \end{array}$	$0.0 \\ 1.2$

In this scenario, as CaCl₂ is introduced into the porous space, calcium (Ca²⁺) replaces sodium (Na⁺) and potassium (K⁺) from the solution and exchanger. As long as Na⁺ remains on the exchanger, the introduced Ca²⁺ will continue to elute it. When Na⁺ is depleted, K⁺ is released from the exchanger, with its dissolved concentration rising to counterbalance the introduced Cl⁻. Eventually, the Ca²⁺ concentration stabilizes, matching the concentration of the incoming solution once all K⁺ has been discharged. Figure 5 shows the outflow (right boundary) of Ca²⁺, Na⁺, and K⁺, over the reactive transport simulation, generated by the coupling between IC-FERST and PHREEQC, as in Yekta et al. [2021]. Because there is no exchange of anions, they are only transported within the domain, we do not show them here.

Figure 4: Two-dimensional domain and mesh used to represent the cation exchange problem (as in Yekta et al. [2021]). We show a snapshot in time of the concentration of K^+ .

Figure 5: Cation exchange results generated by the coupling between IC-FERST and PHREEQC.

2.5 Machine learning surrogates

In this work, we replace the geochemical simulator (PHREEQC) in the reactive transport by a machine learning surrogate, as shown in Figure 6. The reaction calculations usually take the majority of the computational cost of the coupling between the numerical solution of flow and transport and the chemical reactions (up to 99% in some cases) [De Lucia and Kühn, 2021, Demirer et al., 2023, Jatnieks et al., 2016, Leal et al., 2020, Li et al., 2019, Sprocati and Rolle, 2021, Yekta et al., 2021]. The reaction calculations need to be performed for each grid cell of the discretized domain and for each iteration of the coupling procedure. Here, since we use a sequential non-iterative approach the chemical reactions are performed at each time step (and for all grid cells).

We compare several machine learning models to determine which is most suitable for the cation exchange problem. Despite the success of deep learning in the last decades, "classical" machine learning methods still outperform neural network and deep learning methods for tabular data [Borisov et al., 2022, Grinsztajn et al., 2022, Shwartz-Ziv and Armon, 2022]. Tabular data can be

Figure 6: Coupling between the flow and transport simulator (IC-FERST) and the machine learning surrogate.

described as data that is organized in columns and rows in a table format, for example, the data in this work is tabular but not an image, text, or song. Hence, we decided to test "classical" machine learning methods, such as linear regression, decision trees, random forest, and gradient boosting. Very recently, some deep learning architectures based on the attention mechanism [Vaswani et al., 2017] have also demonstrated good results for tabular data, for example, tabnet [Arik and Pfister, 2021] and ft-transformer [Gorishniy et al., 2021]. Thus, we will test them along with a commonly used neural network, the multilayer perceptron. Below there is a brief description of each one of these methods.

Linear regression: A linear regression makes a prediction by simply computing a weighted sum of the input features plus a constant [Géron, 2019, Hastie et al., 2009]. The output of a linear regression is a linear function of the input. We use the linear regression implementation of Pedregosa et al. [2011].

Decision tree: Decision trees have a hierarchical tree structure, which consists of nodes and branches. They can be seen as a way to divide the feature space into a set of rectangles and then assign a simple model (a constant) in each one. They are simple but powerful and are the building blocks of random forest and gradient boosting algorithms [Géron, 2019, Hastie et al., 2009]. The decision tree is implemented here using Pedregosa et al. [2011].

Random forests: Random forests, proposed by Breiman [2001], are an ensemble of decision trees trained on samples from the dataset, either with or without replacement. During tree construction, the optimal split at each node is identified from a random subset of the inputs. These randomness elements reduce the estimator's variance [Breiman, 2001, Breiman et al., 1998]. Essentially, each tree is built using a randomly chosen subset of features and samples, and the final output is derived by averaging the predictions from all trees We use Pedregosa et al. [2011] to implement the random forest.

XGBoost: eXtreme Gradient Boosting (XGBoost) is a model based on gradient-boosted decision trees (GBDT) [Chen and Guestrin, 2016]. GBDT works by sequentially adding decision trees to an ensemble, each one correcting its predecessor. The xgboost extends GBDT by a number of improvements, such as adding regularization, and has achieved very good performance in many datasets Borisov et al. [2022], Grinsztajn et al. [2022], Shwartz-Ziv and Armon [2022]. Xgboost is one of the most popular machine-learning models for tabular data. The xgboost library [Chen and Guestrin, 2016] also provides a random forest implementation. Here, we test both the xgboost and xgboost random forest models.

Multilayer perceptron: A multilayer perceptron is a fully connected feed-forward artificial neural network, consisting of fully connected neurons with a nonlinear activation function, and with at least three layers: input, hidden layers, and output [Goodfellow et al., 2016, Hastie et al., 2009]. We use Abadi et al. [2015] to implement the multilayer perceptron in this work.

Tabnet: Tabnet is a deep learning model for tabular data proposed by Arik and Pfister [2021].

It uses a sequential attention mechanism to choose which features to reason from at each step in the sequential architecture. The feature selection is instance-wise, which means it can be different for each input. The tabnet is implemented here using Paszke et al. [2019].

FT-transformer: The FT-transformer is a simple adaptation of the transformer architecture [Vaswani et al., 2017] for tabular data, proposed by Gorishniy et al. [2021]. It uses a parallel attention mechanism (from the transformer architecture) and a module embedding for categorical and numerical features. In a broader view, it transforms all features into embeddings and apply a stack of transformer layers. We use Paszke et al. [2019] to implement the ft-transformer.

2.5.1 Residual connection

Residual neural networks have achieved great success in computer video [He et al., 2016] and recently in natural language processing (used in the transformer architecture) [Vaswani et al., 2017]. The main idea is to create a direct path from the input to the output (skip/residual connection). The layers in the machine learning model learn a residual function with respect to the input. Then we add the output of the layers to their input to generate the final results. This facilitates the training process and gradient propagation in neural networks [He et al., 2016]. Here, we adapt the residual connections to the cation exchange problem by training some machine learning models to generate the change in concentration (delta) between the output and the injected solution (Figure 3). Then to generate a prediction, we add the delta (output of the trained machine learning model) to the concentrations in the input (injected solution).

2.6 Hardware

We run all experiments in a workstation with two AMD EPYC 7452 processors (32 cores each), 256 GB RAM memory, NVIDIA QUADRO RTX 4000 video card. During the training and inference of the machine learning models, we use all the cores available on the CPU or GPU (when supported). We report the prediction times for all machine learning models using only the CPU. This is because the machine learning surrogate needs to be integrated into the flow and transport simulator, that runs only on a CPU.

3 Results

3.1 One-shot prediction

In this section, we evaluate the performance of the machine learning models described in Section 2.5, considering a one-shot prediction. This means that we are not considering, in this section, the accumulation of error through time steps.

3.1.1 Machine learning model

We compare several machine learning models (linear regression, decision tree, random forest, xgboost random forest, xgboost gradient boosting, multilayer perceptron, tabnet, and ft-transformer) to find the most suitable surrogate for the geochemical simulator PHREEQC. We run a hyperparameter optimization using a grid search with a 3-fold cross-validation for all machine learning models. We normalise all inputs using a min-max scaling between -1 and 1. The mean square error (MSE) is used as a loss function in all cases.

We start using a dataset that comprises 100,000 instances generated by running the PHREEQC with each input sampled from a uniform distribution, as in Silva et al. [2022]. We use 80% of the

Figure 7: Root mean square error for different machine learning models.

Figure 8: Prediction time for different machine learning models.

dataset instances for the training and 20% for testing. Figure 7 shows the root mean square error (RMSE) between the machine learning models and PHREEQC for the cation exchange problem. The minimum RMSE is from the ft-transformer, but xgboost gradient boosting and the multilayer perceptron achieve a similar value. Figure 8 presents the prediction (inference) time of the models for different numbers of instances. The prediction was performed by calling the corresponding function in each model passing one two-dimensional array with the specified number of instances. For each model and number of instances, we run the prediction 1,000 times and average the resulting prediction time. We can notice that linear regression, decision tree, xgboost gradient boosting, and multilayer perceptron generate the best prediction times. The prediction time of one instance using PHREEQC is roughly 10 milliseconds. Considering that the goal is to replace the PHREEQC in

Figure 9: Comparison between the machine learning models with and without a residual connection.

Figure 10: Prediction versus ground truth using the xgboost gradient boosting with residual connection. Each plot shows the 20,000 points in the test set. The coefficient of determination is $R^2 = 0.993$.

order to speed-up the reactive transport simulation, all machine learning models accomplish this goal since their prediction times are lower than the one from PHREEQC.

The xgboost gradient boosting and multilayer perceptron achieved the best compromise between prediction error and inference time. They can predict at least 10 times faster than PHREEQC. The ft-transformer has produced the lowest root mean square error, although a higher prediction time. In the next section, we will perform further investigations using these three machine learning models.

3.1.2 Residual connection

Figure 9 shows a comparison between the three machine learning models selected in the previous section with and without a residual connection. The xgboost and multilayer perceptron have reduced their prediction error by using the skip connection, while the ft-transformer produced the same result. The ft-transformer already has residual connections in its original architecture [Gorishniy et al., 2021] which explains the same error value. Considering the prediction error and inference time, we selected the xgboost gradient boosting with residual connection to continue the experiments. Figure 10 shows the ground truth (PHREEQC) versus the xgboost predictions for the test set. The machine learning surrogate seems to accurately predict the cation concentrations.

Figure 11: Simulation results comparing the coupling between PHREEQC (circles) and the machine learning surrogate (lines) with IC-FERST. Although the quality of the fit for the one shot prediction is good (Figure 10), during the rollout the concentration of K^+ generated by the machine learning surrogate explodes.

3.2 Rollout prediction

In the previous section, we generated a machine learning surrogate for the geochemical simulator (PHREEQC) but only considered a one-shot prediction. However, during the numerical simulation the results from the geochemical reactions from one time step are used as inputs for the reactions in the next time iteration, and so on and so forth. We call this a rollout prediction. The difference between the ground truth and the surrogate over the time steps, we call rollout error. The rollout error appears because a prediction from one time step is used as a starting point for the prediction in the next time step. Hence, a small error or perturbation that occurs at the beginning of the simulation, can easily result in an unbounded rollout error.

We show in Figure 11 the simulation (rollout) comparing the results from the flow and transport simulator (IC-FERST) coupled with the machine learning surrogate and PHREEQC. We notice that even though the machine learning surrogate (xgboost with residual connection) performed well for the one-shot prediction ($R^2 = 0.993$ in Figure 10), when we consider the rollout, the simulation error escalates (the results are similar or worse when considering other machine learning models). Given these results, we decided to perform a thorough investigation of the rollout prediction using the machine learning surrogate.

3.2.1 Dataset generation

In the works from Demirer et al. [2023], Jatnieks et al. [2016], they mention the importance of the sampling procedure used to generate the dataset for the accuracy of the results in the coupling between transport and reactions. However, they do not give more details about this statement.

Figure 12: Comparison of different sampling procedures and dataset sizes.

Here, we will investigate different ways to generate the dataset, and the effect of the dataset size on the rollout/simulation error. One design choice was to not use the coupled simulation between IC-FERST and PHREEQC to generate the dataset, since the goal is to use the machine learning surrogate to replace PHREEQC in the coupled simulation. The dataset used in the previous section was generated using Monte Carlo simulation and a uniform distribution with the same fixed range for all the input variables (see Section 3.1.1). In this section, we test the following sampling procedures to generate the inputs for the datasets:

- 1. Using Monte Carlo to sample the inputs from a uniform distribution with the same fixed range (concentrations from 0.0 to 0.0015 mol/kgw). We will call this "vanilla" sampling.
- 2. Using Monte Carlo to sample the inputs from uniform distributions but using the concentration ranges from Figure 5.
- 3. Using Monte Carlo to sample the inputs from a uniform distribution with the same fixed range and randomly enforcing the concentration zero in 30% of the sample inputs. We did this because looking at Figure 5, we see that most of the time one or more cations have zero concentration during the simulation.
- 4. Using Monte Carlo to sample the inputs from uniform distributions but using the concentration ranges from Figure 5, and randomly enforcing the concentration zero in 30% of the sample inputs.
- 5. Using Monte Carlo to sample the inputs from a given covariance matrix. The assumption here is that we know the relation between the inputs and can provide the corresponding covariances.

For each one of these sampling procedures, we train the xgboost with residual connection using different dataset sizes, ranging from 4,000 to 500,000 instances. Figure 12 shows the rollout/simulation error for all these cases. We notice that as more information/physics is added to the training samples (input space) better the result. The "vanilla" sampling produces the worst results, and the process

Figure 13: Simulation results comparing the coupling between PHREEQC (circles) and the machine learning surrogate (lines) with IC-FERST. We train the machine learning using the dataset enforcing the zeros.

of enforcing zeros is the best one. We can also see that if we do not have enough information about the input space, adding more instances to the dataset can definitely improve the results. On the other hand, for the cases where we enforce the zeros a much smaller dataset can be used for training. The case using the covariance matrix does not produce great results, this indicates that the manifold (in the input space) generated by the physically plausible inputs cannot be described only using the covariances.

Figure 13 shows the simulation results, but now training the xgboost with residual connections with the dataset enforcing the zeros (one of the lowest errors in Figure 12). We train the machine learning model using 100,000 instances in the dataset. The results from Figure 13 are better (in terms of squared error) than Figure 11; however, the machine learning surrogate is still not able to replace the geochemical simulator. For the remainder of the paper, we are going to use the dataset enforcing the zeros.

3.2.2 Physical constraints

In the previous section, we observed that the more information/physics we add to the training samples, the lower the simulation/rollout error will be. Based on this, we decided to include more prior knowledge to the coupling procedure. The idea is to enhance the coupling between IC-FERST and the machine learning surrogate with the physics of the problem. Below, we list the modifications to the coupling procedure:

1. When the concentrations of the cations in one grid cell is equal to the concentrations in the inflow of that same cell, we do not call the surrogate. We assume that the output (final

Figure 14: Adding the prior/physics knowledge into the coupling procedure. If we apply the modifications in a different order, the charge balance still generates the greatest decrease in error followed by the periodic geochemical simulator call. We still need the three modifications to achieve the lowest level of mismatch.

solution) has the same concentrations. No geochemical reaction will occur in this case because the solution is in equilibrium.

- 2. Every n-1 time steps (here n = 10), we use the geochemical simulator instead of the machine learning surrogate in a new time step. This procedure enable us to correct any small deviation in the solution caused by the surrogate. In terms of computational cost, we are still replacing PHREEQC in 90% of the callings.
- 3. We enforce the charge balance (cations will not be created or destroyed unphysically) in the output of the machine learning surrogate, as a post-processing step (see Figure 16). We linearly rescale the concentrations in the output to match the same charge in the input solution.

We show in Figure 14, the RMSE of the coupling between IC-FERST and the machine learning surrogate adding each one of these modifications. For the first modification, we observe a small decrease in the error. Figure 15a shows the simulation results comparing the coupling between PHREEQC and the machine learning surrogate with IC-FERST, considering that we do not call the surrogate (or PHREEQC) when the inflow cation concentrations are equal to the concentrations already in the grid cell. We can notice in this case that the cation concentrations at the beginning of the simulation match the ground truth. Because we inject on the left of the domain and produce on the right (see Figure 4), in the first time steps the concentration in the output will be equal to the initial one, which means no geochemical reactions need to be performed. For the second modification, we see a higher decrease in the error in Figure 14. We show in Figure 15b the simulation results considering the two modifications. These results are much closer to the ground truth, although not yet being able to replace it.

We also notice from Figure 15b that the amount of K^+ is much higher when we use the machine learning surrogate rather than the PHREEQC. It indicates that the surrogate is generating mass, in other words, creating more K^+ than what was injected or present in the domain. Considering this, we add a mass balance (here in the form of charge balance) as a post-processing step of the machine learning surrogate, as shown in Figure 16. We just rescale the output concentrations to conserve

(b) Adding modifications 1 and 2.

Figure 15: Simulation results comparing the coupling between PHREEQC (circles) and the machine learning surrogate (lines) with IC-FERST.

the charge balance in the solution. We see from Figure 14 that the difference in error due to the charge balance is the greatest one, the error is almost one order of magnitude lower than the other ones. Figure 17 shows the simulation results after adding the three modifications. We can see a good match between the coupling using the machine learning surrogate and the PHREEQC. If we remove any one of the three modifications, we do not generate a good match. It is worth noticing that the surrogate (xgboost with residual connection) runs 10 times faster than PHREEQC and that we replace the latter in 90% of the callings.

Figure 16: Coupling between the flow and transport simulator (IC-FERST) and the machine learning surrogate. We add a post-processing step to guarantee mass/charge balance.

Figure 17: Simulation results comparing the coupling between PHREEQC (circles) and the machine learning surrogate (lines) with IC-FERST. Adding the prior knowledge/physics in modifications 1, 2 and 3.

4 Discussion

Our results indicate that machine learning surrogates when carefully designed, can successfully replace the reaction module in a reactive transport coupling. This opens up possibilities for a broader use of rapid reactive transport modelling and can potentially be applicable to a wide range of phase equilibrium models across different transport situations. We showed that the use of machine learning surrogates for the reactive transport cannot be seen as only fitting a good regression model. The rollout has a huge effect in the final result, and the physics of the problem need to be taken into account. For the geochemical calculations in the cation exchange problem, we could achieve a speed-up of at least 9 times which can enable the coupling for many reactive transport problems, since the reaction cost is a deterrent. We believe that for more complex geochemical calculations or for the fully coupled method the speed-up would be even greater. This is because the cost to predict using the machine learning surrogate would be almost the same.

We demonstrated that "classical" machine learning methods still outperform recently proposed deep learning architectures for tabular data, and that the xgboost produced the more accurate results. Also, adding a residual/skip connection improves the prediction accuracy. Although the machine learning surrogate produced low errors in the one-shot prediction ($R^2 = 0.993$ in Figure 10), when considering the coupling procedure and multiple time steps (rollout), the simulation using the surrogate fails (if nothing else is done). It seems that even small deviations in the surrogate outputs can be amplified during the rollout. We showed that the sampling procedure used to generate the dataset has a great impact on the simulation/rollout error. As much prior knowledge (physics) we add to the dataset better will be the results. Furthermore, incorporating this prior information into the training set can allow the use of much smaller dataset sizes than would be needed. On the other hand, if no prior knowledge is available including more data can reduce the simulation/rollout error.

Even using a more appropriate dataset and the best machine learning model, the surrogate was not able to replace the geochemical simulator for the rollout (without the physical constraints). The simulation error was still high. A crucial step for devising these surrogates is to incorporate the knowledge/physics into the modelling procedure. For the cation exchange problem, we demonstrated that adding three small changes into the simulation workflow, being the mass/charge balance the most important one (Figure 16), can make the machine learning surrogate able to replace the geochemical simulator. It is worth mentioning, that we also tested a physics-informed approach using a multilayer perceptron. However, the results were not as good as the physical constraints.

5 Conclusions

We evaluated machine learning models as replacements for the reaction module in a reactive transport simulation. The proposed approach is tested in a cation exchange problem. We compared several machine learning models, with xgboost with a residual/skip connection showing the best results in terms of prediction accuracy and being ten-fold faster than the geochemical simulator (PHREEQC). However, when considering the rollout prediction over multiple time steps, the machine learning surrogate alone failed to match the accuracy of the geochemical simulator. To address this, we introduced various modifications to improve the machine learning surrogate's performance in the rollout prediction: (i) not calling the surrogate when concentrations are in equilibrium, (ii) periodic validation against PHREEQC, and (iii) enforcing charge balance in the output. These modifications led to a significant reduction in the simulation error. Furthermore, the choice of dataset generation played a crucial role, highlighting the importance of incorporating prior knowledge or physics into the dataset sampling procedure. This work demonstrates that while machine learning surrogates can provide fast and accurate one-shot predictions, incorporating physics-based constraints and appropriate dataset generation strategies is essential for achieving reliable results in rollout predictions. By incorporating these modifications, we could replace PHREEQC for the cation exchange problem, while accelerating the geochemical calculations by at least nine times. This opens the way for broad applications in rapid reactive transport modelling, potentially extending to different types of phase equilibrium models in a variety of transport scenarios.

6 Data Availability Statement

The source code, data and hardware configuration used in this work are available at https://github.com/viluiz/react.
