¹University of Oxford ²Technion - Israel Institute of Technology

Message Passing Neural Networks (MPNNs) are a staple of graph machine learning. MPNNs iteratively update each node's representation in an input graph by aggregating messages from the node's neighbors, which necessitates a memory complexity of the order of the number of graph edges. This complexity might quickly become prohibitive for large graphs provided they are not very sparse. In this paper, we propose a novel approach to alleviate this problem by approximating the input graph as an intersecting community graph (ICG) – a combination of intersecting cliques. The key insight is that the number of communities required to approximate a graph does not depend on the graph size. We develop a new constructive version of the Weak Graph Regularity Lemma to efficiently construct an approximating ICG for any input graph. We then devise an efficient graph learning algorithm operating directly on ICG in linear memory and time with respect to the number of nodes (rather than edges). This offers a new and fundamentally different pipeline for learning on very large non-sparse graphs, whose applicability is demonstrated empirically on node classification tasks and spatio-temporal data processing.

1. Introduction

The vast majority of graph neural networks (GNNs) learn representations of graphs based on the message passing paradigm [21], where every node representation is synchronously updated based on an aggregate of messages flowing from its neighbors. This mode of operation hence assumes that the set of all graph edges are loaded in the memory, which leads to a memory complexity bottleneck. Specifically, considering a graph with N nodes and E edges, message-passing leads to a memory complexity that is linear in the number of edges, which quickly becomes prohibitive for large graphs especially when $E \gg N$. This limitation motivated a body of work with the ultimate goal of making the graph machine learning pipeline amenable to large graphs [22, 12, 13, 7, 57].

In this work, we take a drastically different approach to alleviate this problem and design a novel graph machine learning pipeline for learning over large graphs with memory

complexity linear in the number of nodes. At the heart of our approach lies a graph approximation result which informally states the following: every undirected graph with node features can be represented by a linear combination of intersecting communities (i.e., cliques) such that the number of communities required to achieve a certain approximation error is independent of the graph size for dense graphs. Intuitively, this results allows us to utilize an "approximating graph", which we call intersecting community graph (ICG), for learning over large graphs. Based on this insight — radically departing from the standard message-passing paradigm — we propose a new class of neural networks acting on the ICG and on the set of nodes from the original input graph, which leads to an algorithm with memory and runtime complexity that is linear in the number nodes.

Our analysis breaks the traditional dichotomy of approaches that are appropriate either for small and dense graphs or for large and sparse graphs. To our knowledge, we present the first rigorously motivated approach allowing to efficiently handle graphs that are both large and dense. The main advantage lies in being able to process a very large non-sparse graph without excessive memory and runtime requirements. The computation of ICG requires linear time in the number of edges, but this is an offline pre-computation that needs to be performed *once*. After constructing the ICG, learning to solve the task on the graph — the most computation demanding aspect — is very efficient, since the architecture search and hyper-parameter optimization is linear in the number of nodes.

Context. The focus of our study is graph-signals: undirected graphs with node features, where the underlying graph is given and fixed. This is arguably the most common learning setup for large graphs, including tasks such as semi-supervised (transductive) node classification. As we allow varying features, our approach is also suitable for spatiotemporal tasks on graphs, where a single graph is given as a fixed domain on which a dynamic process manifests as time-varying node features. Overall, our approach paves the way for carrying out many important learning tasks on very large and relatively dense graphs such as social networks that typically have $10^8 \sim 10^9$ nodes and average node degree of $10^2 \sim 10^3$ [18] and do not fit into GPU memory.

Challenges and techniques. There are two fundamental technical challenges to achieve the desired linear complexity, which we discuss and elaborate next. How to construct the ICG efficiently with formal approximation guarantees? Our answer to this question rests on an adaptation of the Weak Regularity Lemma [19, 33] which proves the existence of an approximating ICG in cut metric – a well-known graph similarity measure ¹. Differently from the Weak Regularity Lemma, however, we need to construct an approximating ICG. Directly minimizing the cut metric is numerically unstable and hard to solve². We address this in Theorem 3.1, by proving that optimizing the error in Frobenius norm, a much easier optimization target, guarantees a small cut metric error. Hence, we can approximate uniformly "granular" adjacency matrices by low-rank ICGs in cut metric.

¹[19] proposed an algorithm for finding the ICG, but it has impractical exponential runtime (see Section 7).

²The definition of cut metric involves maximization, so minimizing cut metric is an unstable min-max.

Uniformity here means that the number of communities Kof the ICG required for the error tolerance ϵ is $K = \epsilon^{-2}$, independently of on any property of the graph, not even its size N. This result allows us to design an efficient and numerically stable algorithm. Figure 1 shows an adjacency matrix with an inherent intersecting community structure. and our approximated ICG, which captures the statistics of edge densities, ignoring their granularity. How to effectively use ICG for efficient graph learning? We present a signal processing framework and deep neural networks based on the ICG representation (ICG-NN). As opposed to message-passing networks that require $\mathcal{O}(E)$ memory and time complexity, ICG-NNs operate in only $\mathcal{O}(N)$ complexity. They involve node-wise operations to allow processing the small-scale granular behavior of the node features, and community operations that account for the large-scale structure of the graph. Notably, since communities have large supports, ICG-NN can propagate information between far-apart nodes in a single layer.

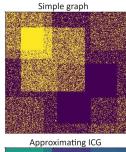

Figure 1: **Top**: adjacency matrix of a simple graph. **Bottom**: approximating 5 community ICG.

Contributions. Our contributions can be summarized as follows:

- We present a novel graph machine learning approach for large and non-sparse graphs which enables an $\mathcal{O}(N)$ learning algorithm on ICG with one-off $\mathcal{O}(E)$ pre-processing cost for constructing ICG.
- Technically, we prove a constructive version of Weak Regularity Lemma in Theorem 3.1 to efficiently obtain ICGs, which could be of independent theoretical interest.
- We introduce ICG neural networks as an instance of a signal processing framework, which applies neural networks on nodes and on ICG representations.
- Empirically, we validate our theoretical findings on semi-supervised node classification and on spatio-temporal graph tasks, illustrating the scalability of our approach, which is further supported by competitive performance against strong baseline models.

2. A primer on graph-signals and the cut-metric

Graph signals. We are interested in undirected (weighted or simple), featured graphs $G = (\mathcal{N}, \mathcal{E}, \mathbf{S})$, where \mathcal{N} denotes the set of nodes, \mathcal{E} denotes the set of edges, and \mathbf{S} denotes the node feature matrix, also called the signal. We will write N to represent the *number of nodes* and E to represent the *number of edges*. For ease of notation, we will assume that the nodes are indexed by $[N] = \{1, \ldots, N\}$. Using the graph signal

³Note that the optimal Frobenius error is not uniformly small, since adjacency matrices of simple graphs are $\{0,1\}$ -valued, typically very granular, so they cannot be approximated well by low-rank \mathbb{R} -valued ICG matrices. Nevertheless, if we find an approximate Frobenius minimizer, we are guaranteed a small cut metric error.

processing convention, we represent the graphs in terms of a graph-signal G = (A, S), where $A = (a_{i,j})_{i,j=1}^N \in \mathbb{R}^{N \times N}$ is the adjacency matrix, and $S = (s_{i,j})_{i \in [N], j \in [d]} \in \mathbb{R}^{N \times D}$ is the D-channel signal. We assume that the graph is undirected, meaning that A is symmetric. The graph may be unweighted (with $a_{i,j} \in \{0,1\}$) or weighted (with $a_{i,j} \in [0,1]$). We additionally denote by S_n^{\top} the n-th row of S, and denote $S = (s_n)_{n=1}^N$. By abuse of notation, we also treat a signal S as the function $S : [N] \to \mathbb{R}^D$ with $S(n) = s_n$. We suppose that all signals are standardized to have values in [0,1].

In general, any matrix (or vector) and its entries are denoted by the same letter, and vectors are seen as columns. The *i*-th row of the matrix \mathbf{A} is denoted by $\mathbf{A}_{i,:}$, and the *j*-th column by $\mathbf{A}_{:,j}$. The Frobenius norm of a square matrix $\mathbf{B} \in \mathbb{R}^{N \times N}$ is defined by $\|\mathbf{B}\|_{\mathrm{F}} = \sqrt{\frac{1}{N^2} \sum_{n,m=1}^{N} |b_{n,m}|^2}$, and for a signal $\mathbf{S} \in \mathbb{R}^{N \times D}$ by $\|\mathbf{S}\|_{\mathrm{F}} = \sqrt{\frac{1}{N} \sum_{n=1}^{N} \sum_{j=1}^{D} |s_{n,j}|^2}$. The Frobenius norm of a matrix-signal, with weights a, b > 0, is defined to be $\|(\mathbf{B}, \mathbf{S})\|_{\mathrm{F}} := \sqrt{a \|\mathbf{B}\|_{\mathrm{F}}^2 + b \|\mathbf{S}\|_{\mathrm{F}}^2}$. We define the degree of a weighted graph as $\deg(\mathbf{A}) := N^2 \|\mathbf{A}\|_{\mathrm{F}}^2$. In the special case of an unweighted graph we get $\deg(\mathbf{A}) = E$. The pseudoinverse of a full rank matrix $\mathbf{B} \in \mathbb{R}^{N \times K}$, where $N \geq K$, is $\mathbf{B}^{\dagger} = (\mathbf{B}^{\top} \mathbf{B})^{-1} \mathbf{B}^{\top}$.

Cut-metric. The *cut metric* is a graph similarity, based on the *cut norm*. We show here the definitions for graphs of the same size; the extension for arbitrary pairs of graphs is based on graphons (see Appendix B.2). The definition of matrix cut norm is well-known, and we normalize it by a parameter $E \in \mathbb{N}$ that indicates the characteristic number of edges of the graphs of interest, so cut norm remains within a standard range. The definition of cut norm of signals is taken from [28].

Definition 2.1. The matrix cut norm of $\mathbf{B} \in \mathbb{R}^{N \times N}$, normalized by E, is defined to be

$$\|\boldsymbol{B}\|_{\square} = \|\boldsymbol{B}\|_{\square;N,E} := \frac{1}{E} \sup_{\mathcal{U},\mathcal{V}\subset[N]} \Big| \sum_{i\in\mathcal{U}} \sum_{j\in\mathcal{V}} b_{i,j} \Big|.$$
 (1)

The signal cut norm of $\mathbf{Z} \in \mathbb{R}^{N \times D}$ is defined to be

$$\|\mathbf{Z}\|_{\square} = \|\mathbf{Z}\|_{\square;N} := \frac{1}{DN} \sum_{i=1}^{D} \sup_{w \in [N]} \Big| \sum_{i \in w} z_{i,j} \Big|.$$
 (2)

The matrix-signal cut norm of $(\boldsymbol{B}, \boldsymbol{Z})$, with weights $\alpha > 0$ and $\beta > 0$ s.t. $\alpha + \beta = 1$, is defined to be

$$\|(B, Z)\|_{\square} = \|(B, Z)\|_{\square; N, E} := \alpha \|B\|_{\square; N, E} + \beta \|Z\|_{\square; N}.$$
 (3)

Given two graphs A, A', their distance in *cut metric* is the *cut norm* of their difference, namely

$$\|\boldsymbol{A} - \boldsymbol{A}'\|_{\square} = \frac{1}{E} \sup_{\mathcal{U}, \mathcal{V} \subset [N]} \left| \sum_{i \in \mathcal{U}} \sum_{j \in \mathcal{V}} (a_{i,j} - a'_{i,j}) \right|. \tag{4}$$

The right-hand-side of (15) is interpreted as the difference between the edge densities of \mathbf{A} and \mathbf{A}' on the block on which these densities are the most dissimilar. Hence, cut-metric has a probabilistic interpretation. Note that for simple graphs, $\mathbf{A} - \mathbf{A}'$ is a granular function: it has many jumps between the values -1, 0 and 1. The fact that the absolute value in (4) is outside the integral, as opposed to being inside like in ℓ_1 norm, means that cut metric has an averaging effect, which mitigates the granularity of $\mathbf{A} - \mathbf{A}'$. The graph-signal cut metric is similarly defined to be $\|(\mathbf{A}, \mathbf{S}) - (\mathbf{A}', \mathbf{S}')\|_{\square}$.

Cut metric in graph machine learning. The cut metric has the following interpretation: two (deterministic) graphs are close to each other in cut metric iff they look like random graphs sampled from the same stochastic block model. The interpretation has a precise formulation in view of the Weak Regularity Lemma [19, 33] discussed below. This makes the cut metric a natural notion of similarity for graph machine learning, where real-life graphs are noisy, and can describe the same underlying phenomenon even if they have different sizes and topologies. Moreover, [28] showed that GNNs with normalized sum aggregation cannot separate graph-signals that are close to each other in cut metric. In fact, cut metric can separate any non-isomorphic graphons [32], so it has sufficient discriminative power to serve as a graph similarity measure in graph machine learning problems. As opposed to past works that used the cut norm to derive theory for existing GNNs, e.g., [41, 35, 28], we use cut norm to derive new methods for a class of problems of interest. Namely, we introduce a new theorem about cut norm – the constructive weak regularity lemma (Theorem 3.1) – and use it to build new algorithms on large non-sparse graphs.

3. Approximation of graphs by intersecting communities

3.1. Intersecting community graphs

Given a graph G with N nodes, for any subset of nodes $\mathcal{U} \subset [N]$, denote by $\mathbb{1}_{\mathcal{U}}$ its indicator (i.e., $\mathbb{1}_{\mathcal{U}}(i) = 1$ if $i \in \mathcal{U}$ and zero otherwise). We define an *intersecting community graph-signal (ICG)* with K classes (K-ICG) as a low rank graph-signal (C, P) with adjacency matrix and signals given respectively by

$$\boldsymbol{C} = \sum_{j=1}^{K} r_j \mathbb{1}_{\mathcal{U}_j} \mathbb{1}_{\mathcal{U}_j}^{\top}, \qquad \boldsymbol{P} = \sum_{j=1}^{K} \mathbb{1}_{\mathcal{U}_j} \boldsymbol{b}_j^{\top}$$
 (5)

where $r_j \in \mathbb{R}$, $\mathbf{b}_j \in \mathbb{R}^D$, and $\mathcal{U}_j \subset [N]$. In order to allow efficient optimization algorithms, we relax the $\{0,1\}$ -valued hard affiliation functions $\mathbb{1}_{\mathcal{U}}$ to functions that can assign soft affiliation values in \mathbb{R} . Letting χ denote the set of all indicator functions of the form $\mathbb{1}_{\mathcal{U}}$, for subsets $\mathcal{U} \in [N]$, we can formally define soft affiliation models as follows.

Definition 3.1. A set Q of functions $q : [N] \to \mathbb{R}$ that contains χ is called a soft affiliation model.

Definition 3.2. Let $d \in \mathbb{N}$. Given a soft affiliation model \mathcal{Q} , the subset $[\mathcal{Q}]$ of $\mathbb{R}^{N \times N} \times \mathbb{R}^{N \times D}$ of all elements of the form (rqq^{\top}, qb^{\top}) , with $q \in \mathcal{Q}$, $r \in \mathbb{R}$ and $b \in \mathbb{R}^D$, is called the soft rank-1 intersecting community graph (ICG) model corresponding to \mathcal{Q} . Given $K \in \mathbb{N}$, the subset $[\mathcal{Q}]_K$ of $\mathbb{R}^{N \times N} \times \mathbb{R}^{N \times D}$ of all linear combinations of K elements of $[\mathcal{Q}]$ is called the soft rank-K ICG model corresponding to \mathcal{Q} .

ICG models can be written in matrix form as follows. Given $K, D \in \mathbb{N}$, any intersecting community graph-signal $(C, P) \in \mathbb{R}^{N \times N} \times \mathbb{R}^{N \times D}$ in $[\mathcal{Q}]_K$ can be represented by a triplet of community affiliation matrix $\mathbf{Q} \in \mathbb{R}^{N \times K}$, community magnitude vector $\mathbf{r} \in \mathbb{R}^K$, and community feature matrix $\mathbf{F} \in \mathbb{R}^{K \times D}$. In the matrix form, $(C, P) \in [\mathcal{Q}]_K$ if and only if it has the form

$$oldsymbol{C} = oldsymbol{Q} \operatorname{diag}(oldsymbol{r}) oldsymbol{Q}^{ op} \quad ext{and} \quad oldsymbol{P} = oldsymbol{Q} oldsymbol{F},$$

where $\operatorname{diag}(\mathbf{r})$ is the diagonal matrix in $\mathbb{R}^{K\times K}$ with \mathbf{r} as its diagonal elements.

3.2. The Constructive Graph-Signal Weak Regularity Lemma

The following theorem is a semi-constructive version of the Weak Regularity Lemma for intersecting communities. It is semi-constructive in the sense that the approximating graphon is not just assumed to exist, but is given as the result of an optimization problem with an "easy to work with" loss, namely, the Frobenius norm error. The theorem also extends the standard weak regularity lemma by allowing soft affiliations to communities instead of hard affiliations.

Theorem 3.1. Let $1 \leq p \leq 2$. Let $(\boldsymbol{A}, \boldsymbol{S})$ be a D-channel graph-signal of N nodes, where $\deg(\boldsymbol{A}) = E'$. Let $K \in \mathbb{N}$, $\delta > 0$, and \mathcal{Q} be a soft affiliation model. Consider the matrix-signal cut norm with weights $\alpha, \beta \geq 0$ not both zero, and the matrix-signal Frobenius norm with weights $\|(\boldsymbol{B}, \boldsymbol{X})\|_F := \sqrt{\alpha \frac{N^2}{E} \|\boldsymbol{B}\|_F^2 + \beta \|\boldsymbol{X}\|_F^2}$. Let m be sampled uniformly from [K], and let $R \geq 1$ such that $K/R \in \mathbb{N}$.

Then, in probability $1 - \frac{1}{R}$ (with respect to the choice of m), for every $(C^*, P^*) \in [Q]_m$,

if
$$\|(A, S) - (C^*, P^*)\|_{F} \le (1 + \delta) \min_{(C, P) \in [Q]_m} \|(A, S) - (C, P)\|_{F}$$

then
$$\|(\boldsymbol{A}, \boldsymbol{S}) - (\boldsymbol{C}^*, \boldsymbol{P}^*)\|_{\square; N, E'} \le \frac{3N}{2\sqrt{E'}} \sqrt{\frac{R}{K} + \delta}.$$
 (6)

The proof of Theorem 3.1 is given in Appendix B, where the theorem is extended to graphon-signals. Theorem 3.1 means that we need not consider a complicated algorithm for estimating cut distance. Instead, we can optimize the Frobenius norm, which is much more direct (see Section 4). The term δ describes the stability of the approximation, where a perturbation in (C^*, P^*) that corresponds to a small relative change in the optimal Frobenius error, leads to a small additive error in cut metric.

3.3. Approximation capabilities of ICGs

ICGs vs. Message Passing. Until the rest of the paper we suppose for simplicity that the degree of the graph E' is equal to the number of edges E up to a constant scaling factor $0 < \gamma \le 1$, namely $E' = \gamma E$. Note that this is always true for unweighted graphs, where $\gamma = 1$. The bound in Theorem 3.1 is closer to be uniform with respect to N the denser the graph is (the closer E is to N^2). Denote the average node degree by d = E/N. To get a meaningful bound in (6), we must choose $K > N^2/E$. On the other hand, for signal processing on the ICG to be more efficient than message passing, we require K < d. Combining these two bounds, we see that ICG signal processing is guaranteed to be more efficient than message passing for any graph in the semi-dense regime: $d^2 > N$ (or equivalently $E > N^{3/2}$).

Essential tightness of Theorem 3.1. In [2, Theorem 1.2] it was shown that the bound (6) is essentially tight in the following sense⁴. There exists a universal constant c (greater than 1/2312) such that for any N there exists an unweighted graph $\mathbf{A} \in \mathbb{R}^{N \times N}$ with $\deg(\mathbf{A}) = E$, such that any $\mathbf{B} \in \mathbb{R}^{N \times N}$ that approximates \mathbf{A} with error $\|\mathbf{A} - \mathbf{B}\|_{\square;N,E} \le 16$ must have rank greater than $c\frac{N^2}{E}$. In words, there are graphs of E edges that we cannot approximate in cut metric by any ICG with $K \ll \frac{N^2}{E}$. Hence, the requirement $K \gg N^2/E'$ for a small cut metric error in (6) for any graph is tight.

ICGs approximations of sparse graphs. In practice, many natural sparse graphs are amenable to low rank intersecting community approximations. For example, a simplistic model for how social networks are formed states that people connect according to shared characteristics (i.e. intersecting communities), like hobbies, occupation, age, etc [53]. Moreover, since ICGs can have negative community magnitudes r_k , one can also construct heterophilic components (bipartite substructures) of graphs with ICGs⁵. Hence, a social network can be naturally described using intersecting communities, even with $K < N^2/E$. For such graphs, ICG approximations are more accurate than their theoretical bound (6). In addition, Figure 5 in Appendix F.3 shows that in practice the Frobenius local minimizer, which does not give a small Frobenius error, guarantees small cut metric error even if $K < N^2/E$. This means that Frobenius minimization is a practical approach for fitting ICGs also for sparse natural graphs. Moreover, note that in the experiments in Tables 2 and 1 we take $K < N^2/E$ and still get competitive performance with SOTA message passing methods.

4. Fitting ICGs to graphs

Let us fix the soft affiliation model to be all vectors $\mathbf{q} \in [0, 1]^N$. In this subsection, we propose algorithms for fitting ICGs to graphs based on Theorem 3.1.

⁴We convert the result of [2] to our notations and definitions.

⁵Two sets of nodes (parts) $\mathcal{U}, \mathcal{V} \in [N]$ with connections between the parts but not within the parts can be represented by the ICG $(\mathbb{1}_{\mathcal{U} \cup \mathcal{V}} \mathbb{1}_{\mathcal{U} \cup \mathcal{V}}^{\top} - \mathbb{1}_{\mathcal{U}} \mathbb{1}_{\mathcal{U}}^{\top} - \mathbb{1}_{\mathcal{V}} \mathbb{1}_{\mathcal{V}}^{\top})$.

4.1. Fitting an ICG to a graph with gradient descent

In view of Theorem 3.1, to fit a soft rank-K ICG to a graph in cut metric, we learn a triplet $\mathbf{Q} \in [0,1]^{N \times K}$, $\mathbf{r} \in \mathbb{R}^K$ and $\mathbf{F} \in \mathbb{R}^{K \times D}$ that minimize the Frobenius loss:

$$L(\boldsymbol{Q}, \boldsymbol{r}, \boldsymbol{F}) = \left\| \boldsymbol{A} - \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{F}^{2} + \lambda \left\| \boldsymbol{S} - \boldsymbol{Q} \boldsymbol{F} \right\|_{F}^{2}, \tag{7}$$

where $\lambda \in \mathbb{R}$ is a scalar that balances the two loss terms. To implement $\mathbf{Q} \in [0,1]^{N \times K}$ in practice, we define $\mathbf{Q} = \operatorname{Sigmoid}(\mathbf{R})$ for a learned matrix $\mathbf{R} \in \mathbb{R}^{N \times K}$.

Suppose that A is sparse with K^2 , $Kd \ll N$. The loss (7) involves sparse matrices and low rank matrices. Typical time complexity of sparse matrix operations is O(E), and for rank-K matrices it is $O(NK^2)$. Hence, we would like to derive an optimization procedure that takes $O(K^2N + E)$ operations. However, the first term of (7) involves a subtraction of the low rank matrix Q diag $(r)Q^{\top}$ from the sparse matrix A, which gives a matrix that is neither sparse nor low rank. Hence, a naïve optimization procedure would take $O(N^2)$ operations. The next proposition shows that we can write the loss (7) in a form that leads to a $O(K^2N + KE)$ time and O(KN + E) space complexities.

Proposition 4.1. Let $\mathbf{A} = (a_{i,j})_{i,j=1}^N$ be an adjacency matrix of a weighted graph with E edges. The graph part of the Frobenius loss can be written as

$$\begin{aligned} \left\| \boldsymbol{A} - \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{\mathrm{F}}^{2} &= \frac{1}{N^{2}} \operatorname{Tr} \left((\boldsymbol{Q}^{\top} \boldsymbol{Q}) \operatorname{diag}(\boldsymbol{r}) (\boldsymbol{Q}^{\top} \boldsymbol{Q}) \operatorname{diag}(\boldsymbol{r}) \right) + \|\boldsymbol{A}\|_{\mathrm{F}}^{2} \\ &- \frac{2}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j}. \end{aligned}$$

Computing the right-hand-side and its gradients with respect to \mathbf{Q} and \mathbf{r} has a time complexity of $\mathcal{O}(K^2N + KE)$, and a space complexity of $\mathcal{O}(KN + E)$.

The proof is given in Appendix C. We optimize Q, r and F via gradient descent (GD) on (7) implemented via Proposition 4.1. After converging, we can further optimize the community features by setting them to $F = Q^{\dagger}S$.

4.2. Initialization

In Appendix D we propose a good initialization for the GD minimization of (7). Suppose that K is divisible by 3. Let $\Phi_{K/3} \in \mathbb{R}^{N \times K/3}$ be the matrix consisting of the leading eigenvectors of A as columns, and $\Lambda_{K/3} \in \mathbb{R}^{K/3 \times K/3}$ the diagonal matrix of the leading eigenvalues. For each eigenvector ϕ with eigenvalue λ , consider the three soft indicators

$$\phi_1 = \frac{\phi_+}{\|\phi_+\|_{\infty}}, \quad \phi_2 = \frac{\phi_-}{\|\phi_-\|_{\infty}}, \quad \phi_3 = \frac{\phi_+ + \phi_-}{\|\phi_+ + \phi_-\|_{\infty}}$$
 (8)

with community affiliation magnitudes $r_1 = \lambda \|\phi_+\|_{\infty}$, $r_2 = \lambda \|\phi_-\|_{\infty}$ and $r_3 = -\lambda \|\phi_+ + \phi_-\|_{\infty}$ respectively. Here, ϕ_{\pm} is the positive or negative part of the vector. One can now show that the ICG C based on the K soft affiliations corresponding to the

leading K/3 eigenvectors approximates \mathbf{A} in cut metric with error $O(K^{-1/2})$. Note that computing the leading eigenvectors is efficient with any variant of the power iteration for sparse matrices, like any variant of Lanczos algorithm, which takes $\mathcal{O}(E)$ operations per iteration, and requires just a few iteration due to its fast super-exponential convergence [42]. We moreover initialize the community signal optimally by $\mathbf{F} = \mathbf{Q}^{\dagger} \mathbf{S}$.

4.3. Subgraph SGD for fitting ICGs to large graphs

In many situations, we need to process large graphs for which E is too high to read to the GPU memory, but NK is not. These are the situation where processing graph-signals using ICGs is beneficial. However, to obtain the ICG we first need to optimize the loss (7) using a message-passing type algorithm that requires reading E edges to memory. To allow such processing, we next show that one can read the E edges to shared RAM (or storage), and at each SGD step read to the GPU memory only a random subgraph with M nodes.

At each interation, we sample $M \ll N$ random nodes $\mathbf{n} := (n_m)_{m=1}^M$ uniformly and independently from [N] (with repetition). We construct the sub-graph $\mathbf{A}^{(n)} \in \mathbb{R}^{M \times M}$ with entries $a_{i,j}^{(n)} = a_{n_i,n_j}$, and the sub-signal $\mathbf{S}^{(n)} \in \mathbb{R}^{M \times K}$ with entries $\mathbf{s}_i^{(n)} = \mathbf{s}_{n_i}$. We similarly define the sub-community affiliation matrix $\mathbf{Q}^{(n)} \in [0,1]^{M \times K}$ with entries $q_{i,j}^{(n)} = q_{n_i,j}$. We consider the loss

$$L^{(n)}(\boldsymbol{Q^{(n)}}, \boldsymbol{r}, \boldsymbol{F}) = \left\| \boldsymbol{A^{(n)}} - \boldsymbol{Q^{(n)}} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q^{(n)}}^{\top} \right\|_{F}^{2} + \lambda \left\| \boldsymbol{S^{(n)}} - \boldsymbol{Q^{(n)}} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{F} \right\|_{F}^{2}$$
(9)

which depends on all entries of F and r and on the n entries of Q. Each SGD updates all of the entries of F and F, and the F0 entries of F1 by incrementing them with the respective gradients of $E^{(n)}(Q^n, r, F)$. Hence, $\nabla_Q E^{(n)}(Q^{(n)}, r, F)$ may only be nonzero for entries F0 with F1. Proposition E.1 in Appendix E shows that the gradients of F1 approximate the gradients of F2. More concretely, F3 and F4 and F5 approximate the stochastic gradients with respect to F6 approximate a scaled version of the full gradients.

5. Learning with ICG

Given a graph-signal (A, S) and its approximating ICG (C, P), the corresponding soft affiliations $Q = (q_k)_{k=1}^K$ represent intersecting communities that can describe the adjacency structure A and can account for the variability of S. In a deep network architecture, one computes many latent signals, and these signals typically correspond in some sense to the structure of the data (A, S). It is hence reasonable to put a special emphasis on latent signals that can be described as linear combinations of $(q_k)_{k=1}^K$. Next, we develop a signal processing framework for such signals.

Graph signal processing with ICG. We develop a signal processing approach with O(NK) complexity for each elemental operation. Let $Q \in \mathbb{R}^{N \times K}$ be a fixed community

matrix. We call $\mathbb{R}^{N \times D}$ the node space and $\mathbb{R}^{K \times D}$ the community space. We process signals via the following operations:

- Synthesis is the mapping $F \mapsto QF$ from the community space to the node space, in O(NKD).
- Analysis is the mapping $S \mapsto Q^{\dagger}S$ from the node space to the community space, in O(NKD).
- Community processing refers to any operation that manipulates the community feature vector \mathbf{F} (e.g., an MLP or Transformer) in $O(K^2D^2)$ operations.
- Node processing is any function Θ that operates in the node space on nodes independently via $\Theta(\mathbf{S}) := (\theta(\mathbf{s}_n))_{n=1}^N$, where $\theta : \mathbb{R}^D \to \mathbb{R}^{D'}$ (e.g., an MLP) takes O(DD') operations. Node processing has time complexity of O(NDD').

Analysis and synthesis satisfy the reconstruction formula $Q^{\dagger}QF = F$. Moreover, $QQ^{\dagger}S$ is the projection of S upon the space of linear combinations of communities $\{QF \mid F \in \mathbb{R}^{K \times D}\}$.

Deep ICG Neural Networks. In the following, we propose deep architectures based on the elements of signal processing with an ICG, which takes $O(D(NK + K^2D + ND))$ operations at each layer. Note that message passing networks take $O(ED^2)$ operations. Hence, ICG neural networks are more efficient than MPNNs if K = O(Dd), where d is the average node degree.

We denote by $D^{(\ell)}$ the dimension of the node features at layer ℓ and define the initial node representations $\boldsymbol{H}^{(0)} = \boldsymbol{S}$ and the initial community features $\boldsymbol{F}^{(0)} = \boldsymbol{Q}^{\dagger} \boldsymbol{S}$. The node features at layers $0 \leq \ell \leq L - 1$ are defined by

$$\begin{split} \boldsymbol{H}^{(\ell+1)} &= \sigma \left(\boldsymbol{H}^{(\ell)} \boldsymbol{W}_1^{(\ell)} + \boldsymbol{Q} \boldsymbol{\Theta} \left(\boldsymbol{F}^{(\ell)} \right) \boldsymbol{W}_2^{(\ell)} \right), \\ \boldsymbol{F}^{(\ell+1)} &= \boldsymbol{Q}^{\dagger} \boldsymbol{H}^{(\ell)}, \end{split}$$

where Θ is a neural network (i.e. multilayer perceptron or Multi-Head Attention), $\boldsymbol{W}_{1}^{(\ell)}, \boldsymbol{W}_{2}^{(\ell)} \in \mathbb{R}^{D^{(\ell)} \times D^{(\ell+1)}}$ are learnable matrices acting on signals in the node space, and σ is a non-linearity. We call this method ICG neural network (ICG-NN). The final representations $\boldsymbol{H}^{(L)}$ can be used for predicting node-level properties.

We propose another deep ICG method, where $\mathbf{F}^{(\ell)} \in \mathbb{R}^{K \times D^{(\ell)}}$ are taken directly as trainable parameters. Namely,

$$oldsymbol{H}^{(\ell+1)} = \sigma \left(oldsymbol{H}^{(\ell)} oldsymbol{W}_s^{(\ell)} + oldsymbol{Q} oldsymbol{F}^{(\ell)} oldsymbol{W}^{(\ell)}
ight).$$

We call this method ICG_u -NN for the *unconstrained* community features. The motivation is that $QF^{(\ell)}$ exhausts the space of all signals that are linear combinations of the communities. If the number of communities is not high, then this is a low dimensional space that does not lead to overfitting in typical machine learning problems. Therefore, there is no need to reduce the complexity of $F^{(\ell)}$ by constraining it to be the output of a neural network Θ on latent representations. The term $QF^{(\ell)}$ can hence be interpreted as a type of positional encoding that captures the community structure.

ICG-NNs for spatio-temporal graphs. For a fixed graphs with varying node features, the ICG is fitted to the graph once⁶. Given that there are T training signals, each learning step with ICG-NN takes $\mathcal{O}(TN(K+D))$ rather than $\mathcal{O}(TED^2)$ for MPNNs. Note that T does not scale the preprocessing time. Hence, the time dimension amplifies the difference in efficiency between ICG-NNs and MPNNs.

6. Experiments

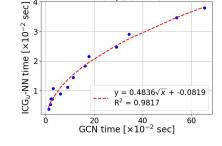

We empirically validate our method on the following experiments:

- Runtime analysis (Section 6.1): We report the forward pass runtimes of ICG_u-NN and GCN [26], empirically validating the theoretical advantage of the former.
- Node classification (Appendix F.1): We evaluate our method on real-world node classification datasets [38, 40, 31], observing that the model performance is competitive with standard approaches.
- Node classification using Subgraph SGD (Section 6.2): We evaluate our subgraph SGD method (Section 4.3) to identify the effect of sampling on the model performance on tolokers dataset [38]: we find the model performance to be very robust even when dropping %99 of the nodes.
- Spatio-temporal tasks (Section 6.3): We evaluate ICG_u-NN on real-world spatio-temporal tasks [30] and obtain competitive performance to domain-specific baselines.

All our experiments are run on a single NVidia L40 GPU 7 .

6.1. How does the runtime compare to standard GNNs?

Setup. We compare the forward pass runtimes of our signal processing pipeline (ICG_u-NN) and GCN [26]. We sample graphs with up to 7k nodes from the $Erd\~os$ -R'enyi distribution ER(n,p(n)=0.5). Node features are independently drawn from U[0,1] and the initial feature dimension is 128. ICG_u-NN and GCN use a hidden dimension of 128, 3 layers and an output dimension of 5.

Results. Figure 2 reveals a strong square root relationship between the runtime of ICG_u -NN and the runtime of GCN. This aligns with our expectations, as the time complexity of GCN is $\mathcal{O}(E)$, while

Figure 2: Runtime of K-ICG_u-NN (for K=100) as a function of GCN forward pass duration on graphs $G \sim \text{ER}(n, p(n) = 0.5)$.

⁶We either ignore the signal in the loss, or concatenate random training signals and reduce their dimension to obtain one signal with low dimension D. This signal is used as the target for the ICG.

⁷We made our codebase available online: https://github.com/benfinkelshtein/ICGNN.

the time complexity of ICG-NNs is $\mathcal{O}(N)$, highlighting the computational advantage of using ICGs. We complement this analysis with experiments using sparse $Erd\tilde{o}s$ - $R\acute{e}nyi$ graphs in Appendix F.4.

6.2. Node classification using Subgraph SGD

Setup. We evaluate ICG_u -NN on the non-sparse graphs tolokers [38], following the 10 data splits of [38]. We report the mean ROC AUC and standard deviation as a function of the ratio of nodes that are removed from the graph. We compare to the baseline of MLP on the full graph.

Results. Figure 3 shows a slight degradation of 2.8% when a small number of nodes is removed from the graph. However, the key insight is that when more than 10% of the graph is removed, the performance stops degrading.

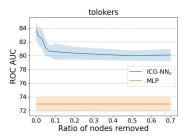

Figure 3: ROC AUC of ICG_u -NN and an MLP as a function of the % nodes removed from the graph.

These results further support our Proposition E.1 in Appendix E about the error between subgraph gradients and full-graph gradients of the Frobenius loss, and establish ICG-NNs as a viable option for learning on large graphs.

6.3. Spatio-temporal graphs

Setup & baselines. We evaluate ICG-NN and ICG_u-NN on real-world traffic networks, METR-LA and PEMS-BAY [30] following the methodology described by [15]. We segment the datasets into windows of 12 time steps and train the models to predict the subsequent 12 observations. For all datasets, these windows are divided sequentially into 70% for training, 10% for validation, and 20% for testing. We report the mean absolute error (MAE) and standard deviation averaged over the forecastings. The baselines DCRNN [30], GraphWaveNet [52], AGCRN [8], T&S-IMP, TTS-IMP, T&S-AMP, and TTS-AMP

Table 1: Results on dense temporal graphs. Top three models are colored by First, Second, Third.

	METR-LA	PEMS-BAY
DCRNN	3.22 ± 0.01	1.64 ± 0.00
GraphWaveNet	$\frac{3.05}{2} \pm 0.03$	1.56 ± 0.01
AGCRN	3.16 ± 0.01	1.61 ± 0.00
T&S-IMP	3.35 ± 0.01	1.70 ± 0.01
TTS-IMP	3.34 ± 0.01	1.72 ± 0.00
T&S-AMP	3.22 ± 0.02	1.65 ± 0.00
TTS-AMP	3.24 ± 0.01	1.66 ± 0.00
ICG-NN	3.42 ± 0.03	1.76 ± 0.00
ICG _u -NN	3.12 ± 0.01	1.56 ± 0.00

[15], are adopted from [15]. We incorporate a GRU to embed the data before inputting it into our ICG-NN models, we symmetrize the graph to enable our method to operate on it, and we disregard the features in the ICG approximation (setting $\lambda = 0$ in (7)). Additionally, we use the Adam optimizer and detail all hyperparameters in Appendix H.

Results. Table 1 shows that ICG-NNs achieve competitive performance when compared to methods that are specially tailored for spatio-temporal data such as DCRNN, GraphWaveNet and AGCRN. Despite the small graph size (207 and 325 nodes) and the

low ratio of edges (graph densities of $3.54 \cdot 10^{-2}$ and $2.24 \cdot 10^{-2}$), ICG-NNs perform well, corroborating the discussion in Section 3.3.

7. Related work

We provide the main related work in this Section. In Appendix I we give an additional review.

Intersecting communities and stochastic block models. We express graphs as intersections of cliques, or communities, similarly to classical works in statistics and computer science [1, 54]. Our approach can be interpreted as fitting a stochastic-block-model (SBM) to a graph. As opposed to standard SBM approaches, our method is interpreted as data fitting with norm minimization rather than statistical inference. Similarly to the intersecting community approach of BigCLAM [54], our algorithm takes O(E) operations. Unlike BigCLAM, however, we can approximate any graph, as guaranteed by the regularity lemma. This is possible since ICGs are allowed to have negative coefficients, while BigCLAM only uses positive coefficients due to its probabilistic interpretation. To the best of our knowledge, we are the first to propose a SBM fitting algorithm based on the weak regularity lemma. For a survey on SBMs we refer the reader to [27].

The Weak Regularity Lemma. The Regularity Lemma is a central result in graph theory with many variants and many proof techniques. One version is called the Weak Regularity Lemma (for graphs [19], graphons [33], or graph-signals and graphon-signals [28]), and has the following interpretation: every graph can be approximated in the cut metric by an ICG, where the error rate ϵ is uniformly $\mathcal{O}(K^{-1/2})^8$. While [19, Theorem 2] proposes an algorithm for finding the approximating ICG, the algorithm takes $2^{\mathcal{O}(N^2K)}$ time to find this minimizer⁹. This time complexity is too high to be practical in real-world problems. Alternatively, since the cut metric is defined via a maximization process, finding a minimizing ICG by directly optimizing cut metric via a GD approach involves a min-max problem, which appears numerically problematic in practice. Moreover, computing cut norm is NP-hard [4, 39]. Instead, we introduce a way to bypass the need to explicitly compute the cut norm, finding a K community ICG with error $\mathcal{O}(K^{-1/2})$ in the cut metric by minimizing the Frobenius norm. We note that for the Szemerédi (non-weak) regularity lemma [43], it was shown by [3] that a regular partition with error $<\epsilon$ into non-intersecting communities (the analogue to ICG in the Szemerédi regularity lemma) can be found in polynomial time with respect to N, provided that N is very large $(N \sim 2^{\epsilon^{-20}})$. For more details on the Weak Regularity Lemma, see Appendix A.

⁸In the above papers the lemma is formulated for non-intersecting blocks $\sum_{i,j} r_{i,j} \mathbb{1}_{\mathcal{U}_i} \mathbb{1}_{\mathcal{U}_j}$, where $\cup \{\mathcal{U}_j\} = [N]$, with error $\epsilon = \mathcal{O}((\log(K))^{-1/2})$. The intersecting community case is an intermediate step of the proof.

⁹One needs to convert the scaling of the Frobenius and cut norms used in [19] to our scaling to see this.

Subgraph methods. Learning on large graphs requires sophisticated subgraph sampling techniques for deployment on contemporary processors [22, 12, 13, 7, 57]. After the preprocessing step on the ICG, our approach allows processing very large networks more accurately, avoiding subsampling schemes that can alter the properties of the graph in unintended ways.

8. Summary

We introduced an new approach for learning on large non-sparse graphs, using ICGs. We proved a new constructive variant of the weak regularity lemma, which shows that minimizing the Frobenius error between the ICG and the graph leads to a uniformly small error in cut metric. We moreover showed how to optimize the Frobenius error efficiently. We then developed a signal processing setting, operating on the ICG and on the node representations in $\mathcal{O}(N)$ complexity. The overall pipeline involves precomputing the ICG approximation of the graph in $\mathcal{O}(E)$ operations per iteration, and then solving the task on the graph in $\mathcal{O}(N)$ operations per iteration. Both fitting an ICG to a large graph, and training a standard subgraph GNNs, require an online subsampling method, reading from slow memory during optimization. However, fitting the ICG is only done once, and does not require an extensive hyperparameter optimization. Then, learning to solve the task on the graph with ICG-NNs is efficient, and can be done directly on the GPU memory. Since the second learning phase is the most demanding part, involving an extensive hyperparameter optimization and architecture tuning, ICG-NN offer a potentially significant advantage over standard subgraph GNNs. This gap between ICG-NNs and MPNNs is further amplified for time series on graphs.

The main limitation of our method is that the ICG-NN is fitted to a specific ICG, and cannot be naïvely transferred between different ICGs approximating different graphs. Another limitation is the fact that the current ICG construction is limited to undirected graphs, while many graphs, especially spatiotemporal, are directed. One potential avenue for future work is thus to extend the ICG construction to directed graphs. Additional future work will study the expressive power of ICGs.

A. The weak regularity lemma

Let $G = \{\mathcal{N}, \mathcal{E}\}$ be a graph and $\mathcal{P} = \{\mathcal{N}_1, \dots, \mathcal{N}_k\}$ be a partition of \mathcal{N} . The partition is called *equipartition* if $||\mathcal{N}_i| - |\mathcal{N}_j|| \le 1$ for every $1 \le i, j \le k$. For any two subsets $\mathcal{U}, \mathcal{S} \subset \mathcal{N}$, the number of edges from \mathcal{U} to \mathcal{S} are denoted by $e_G(\mathcal{U}, \mathcal{S})$. Given two node set $\mathcal{U}, \mathcal{S} \subset \mathcal{N}$, if the edges between \mathcal{N}_i and \mathcal{N}_j were distributed randomly, then, the number of edges between \mathcal{U} and \mathcal{S} would have been close to the expected value

$$e_{\mathcal{P}(\mathcal{U},\mathcal{S})} := \sum_{i=1}^{k} \sum_{j=1}^{k} \frac{e_G(\mathcal{N}_i,\mathcal{N}_j)}{|\mathcal{N}_i| |\mathcal{N}_j|} |\mathcal{N}_i \cap \mathcal{U}| |\mathcal{N}_j \cap \mathcal{S}|.$$

Thus, the *irregularity*, which measure of how non-random like the edges between $\{\mathcal{N}_j\}$ are, is defined to be

$$irreg_{G}(\mathcal{P}) = \max_{\mathcal{U}, \mathcal{S} \subset \mathcal{N}} |e_{G}(\mathcal{U}, \mathcal{S}) - e_{\mathcal{P}}(\mathcal{U}, \mathcal{S})| / |\mathcal{N}|^{2}.$$
(10)

Theorem A.1 (Weak Regularity Lemma [19]). For every $\epsilon > 0$ and every graph $G = (\mathcal{N}, \mathcal{E})$, there is an equipartition $\mathcal{P} = \{\mathcal{N}_1, \dots, \mathcal{N}_k\}$ of \mathcal{N} into $k \leq 2^{c/\epsilon^2}$ classes such that $\operatorname{irreg}_G(\mathcal{P}) \leq \epsilon$. Here, c is a universal constant that does not depend on G and ϵ .

The weak regularity lemma states that any large graph G can be represented by the weighted graph G^{ϵ} with node set $\mathcal{N}^{\epsilon} = \{\mathcal{N}_1, \dots, \mathcal{N}_k\}$, where the edge weight between the nodes \mathcal{N}_i and \mathcal{N}_j is $\frac{e_G(\mathcal{N}_i, \mathcal{N}_j)}{|\mathcal{N}_i|, |\mathcal{N}_j|}$, which depicts a smaller, coarse-grained version of the large graph. The "large-scale" structure of G is given by G^{ϵ} , and the number of edges between any two subsets of nodes $\mathcal{U}_i \subset \mathcal{N}_i$ and $\mathcal{U}_j \subset \mathcal{N}_j$ is close to the "expected value" $e_{\mathcal{P}(\mathcal{U}_i,\mathcal{U}_j)}$. Hence, the deterministic graph G "behaves" as if it was randomly sampled from the "stochastic block model" G^{ϵ} .

It can be shown that irregularity coincides with error in cut metric between the graph and its coarsening SBM. Namely, to see how the cut-norm is related to irregularity (10), consider a graphon W_G induced by the graph $G = \{\mathcal{N}, \mathcal{E}\}$. Let $\mathcal{P} = \{\mathcal{N}_1, \dots, \mathcal{N}_k\}$ be an equipartition of \mathcal{N} . Consider the graph $G^{\mathcal{P}}$ defined by the adjacency matrix $A^{\mathcal{P}} = (a_{i,j}^{\mathcal{P}})_{i,j=1}^{|\mathcal{N}|}$ with

$$a_{i,j}^{\mathcal{P}} = \frac{e_G(\mathcal{N}_{q_i}, \mathcal{N}_{q_j})}{|\mathcal{N}_{q_i}|, |\mathcal{N}_{q_j}|},$$

where $\mathcal{N}_{q_i} \in \mathcal{P}$ is the class that contains node i. Now, it can be verified that

$$||W_G - W_{GP}||_{\square} = irreg_G(\mathcal{P}).$$

Hence, the weak regularity lemma can be formulated with cut norm instead of irregularity.

B. Graphon-Signal Intersecting Communities and the Constructive Regularity Lemma

In this section we prove a constructive weak regularity lemma for graphon-signals, where Theorem 3.1 is a special case. We start by defining graphon-signals in Subsection B.1.

We define graphon-signal cut norm and metric in Subsection B.2, and graphon-signal intersecting communities in B.3. In Subsections B.4 and B.5 we formulate and prove the constructive graphon-signal weak regularity lemma. Finally, in Subsection B.6 we prove the constructive graph-signal weak regularity lemma as a special case.

For $m, J \in \mathbb{N}$, the L_2 norm of a measurable function $f = (f_i)_{i=1}^j : [0,1]^m \to \mathbb{R}^J$, where $f_i : [0,1]^m \to \mathbb{R}$, is defined to be $||f||_2 = \sqrt{\sum_{j=1}^J \int_{[0,1]^m} |f_j(\boldsymbol{x})|^2 d\boldsymbol{x}}$.

B.1. Graphon-signals

A graphon [11, 32] can be seen as a weighted graph with a "continuous" node set [0, 1]. The space of graphons \mathcal{W} is defined to be the set of all measurable symmetric function $W:[0,1]^2 \to [0,1], \ W(x,y) = W(y,x)$. Each edge weight $W(x,y) \in [0,1]$ of a graphon $W \in \mathcal{W}$ can be seen as the probability of having an edge between nodes x and y. Graphs can be seen as special graphons. Let $\mathcal{I}_m = \{I_1, \ldots, I_m\}$ be an interval equipartition: a partition of [0,1] into disjoint intervals of equal length.

A graph with an adjacency matrix $\mathbf{A} = (a_{i,j})_{i,j=1}^N$ induces the graphon $W_{\mathbf{A}}$, defined by $W_{\mathbf{A}}(x,y) = a_{\lceil xm \rceil, \lceil ym \rceil}^{-10}$. Note that $W_{\mathbf{A}}$ is piecewise constant on the partition \mathcal{I}_m . We hence identify graphs with their induced graphons. A graphon can also be seen as a generative model of graphs. Given a graphon W, a corresponding random graph is generated by sampling i.i.d. nodes $\{u_n\}$ from the graphon domain [0,1], and connecting each pair u_n, u_m in probability $W(u_n, u_m)$ to obtain the edges of the graph.

The space of grahon-signals is the space of pairs of measurable functions (W,s) of the form $W:[0,1]^2 \to [0,1]$ and $s:[0,1] \to [0,1]^D$, where $D \in \mathbb{N}$ is the number of signal channels. Note that datasets with signals in value ranges other than [0,1] can always be transformed (by translating and scaling in the value axis of each channel) to be $[0,1]^D$ -valued. Given a discrete signal $S:[N] \to [0,1]^D$, we define the induced signal S:[0,1] over [0,1] by S:[0,1] we define the Frobenius distance between two graphon-signals S:[0,1] and S:[0,1] where S:[0,1] is imply as their S:[0,1] distance, namely,

$$\|(W,s) - (W',s')\|_{F} := \sqrt{a \|W - W'\|_{2}^{2} + b \sum_{j=1}^{D} \|s_{j} - s'_{j}\|_{2}^{2}}$$
(11)

for some a, b > 0.

B.2. Cut-distance

The *cut metric* is a natural notion of graph similarity, based on the *cut norm*. The graphon-signal cut norm was defined in [28], extending the standard definition to a graphon with node features.

Definition B.1. The graphon cut norm of $W \in L^2[0,1]^2$ is defined to be

$$||W||_{\square} = \sup_{S,T \subset [0,1]} \left| \int_{S} \int_{T} W(x,y) dx dy \right|. \tag{12}$$

¹⁰In the definition of $W_{\mathbf{A}}$, the convention is that $\lceil 0 \rceil = 1$.

The signal cut norm of $s = (s_1, \ldots, s_D) \in (L^2[0,1])^D$ is defined to be

$$||s||_{\square} = \frac{1}{D} \sum_{j=1}^{D} \sup_{U \subset [0,1]} \left| \int_{U} s_j(x) dx \right|.$$
 (13)

The graphon-signal cut norm of $(W,s) \in L^2[0,1]^2 \times (L^2[0,1])^D$, with weights $\alpha > 0$ and $\beta > 0$, is defined to be

$$\|(W,s)\|_{\square} = \alpha \|W\|_{\square} + \beta \|s\|_{\square}. \tag{14}$$

Given two graphons W, W', their distance in *cut metric* is the *cut norm* of their difference, namely

$$\|W - W'\|_{\square} = \sup_{S,T \subset [0,1]} \left| \int_{S} \int_{T} (W(x,y) - W'(x,y)) dx dy \right|.$$
 (15)

The right-hand-side of (15) is interpreted as the similarity between the adjacencies W and W' on the block on which they are the most dissimilar. The graphon-signal cut metric is similarly defined to be $\|(W,s)-(W',s')\|_{\square}$. The cut metric between two graph-signals is defined to be the cut metric between their induced graphon-signals.

In Subsection B.6 we show that the graph-signal cut norm of Definition 2.1 are a special case of graphon-signal cut norm for induced graph-signals.

B.3. Intersecting community graphons

Here, we define ICGs for graphons. Denote by χ the set of all indicator function of measurable subset of [0,1]

$$\chi = \{\mathbb{1}_u \mid u \subset [0,1] \text{ measurable}\}.$$

Definition B.2. A set Q of bounded measurable functions $q:[0,1] \to \mathbb{R}$ that contains χ is called a soft affiliation model.

Definition B.3. Let $D \in \mathbb{N}$. Given a soft affiliation model \mathcal{Q} , the subset $[\mathcal{Q}]$ of $L^2[0,1]^2 \times (L^2[0,1])^D$ of all elements of the form (rq(x)q(y),bq(z)), with $q \in \mathcal{Q}$, $r \in \mathbb{R}$ and $b \in \mathbb{R}^D$, is called the soft rank-1 intersecting community graphon (ICG) model corresponding to \mathcal{Q} . Given $K \in \mathbb{N}$, the subset $[\mathcal{Q}]_K$ of $L^2[0,1]^2 \times (L^2[0,1])^D$ of all linear combinations of K elements of $[\mathcal{Q}]$ is called the soft rank-K ICG model corresponding to \mathcal{Q} . Namely, $(C,p) \in [\mathcal{Q}]_K$ if and only if it has the form

$$C(x,y) = \sum_{k=1}^{K} r_k q_k(x) q_k(y)$$
 and $p(z) = \sum_{k=1}^{K} b_k q_k(z)$

for $(q_k)_{k=1}^K \in \mathcal{Q}^K$ called the community affiliation functions, $(r_k)_{k=1}^K \in \mathbb{R}^K$ called the community affiliation magnitudes, and $(b_k)_{k=1}^K \in \mathbb{R}^{K \times D}$ called the community features.

B.4. A constructive graphon-signal weak regularity lemma

The following theorem is the semi-constructive version of the weak regularity lemma for intersecting communities of graphons. Recall that α and β denote the weights of the graphon-signal cut norm (14).

Theorem B.1. Let $D \in \mathbb{N}$. Let (W, s) be a D-channel graphon-signal, $K \in \mathbb{N}$, $\delta > 0$, and let Q be a soft indicators model. Let m be sampled uniformly from [K], and let $R \geq 1$ such that $K/R \in \mathbb{N}$. Consider the graphon-signal Frobenius norm with weights $\sqrt{\alpha \|W\|_F^2 + \beta \sum_{j=1}^D \|s_j\|_F^2}$.

Then, in probability $1 - \frac{1}{R}$ (with respect to the choice of m), for every $(C^*, p^*) \in [\mathcal{Q}]_m$,

if
$$\|(W,s) - (C^*, p^*)\|_F \le (1+\delta) \min_{(C,p) \in [Q]_n} \|(W,s) - (C,p)\|_F$$

then
$$||(W,s)-(C^*,p^*)||_{\square} \le$$

$$\left(\frac{3}{2}\sqrt{\alpha^{2}\|W\|_{\mathrm{F}}^{2}+\alpha\beta\left\|s\right\|_{\mathrm{F}}}+\sqrt{\alpha\beta\|W\|_{\mathrm{F}}^{2}+\beta^{2}\left\|s\right\|_{\mathrm{F}}}\right)\sqrt{\frac{R}{K}+\delta}.$$

B.5. Proof of the soft constructive weak regularity lemma

In this subsection we prove the constructive weak graphon-signal regularity lemma.

B.5.1. Constructive regularity lemma in Hilbert spaces

The classical proof of the weak regularity lemma for graphons is given in [33]. The lemma is a corollary of a regularity lemma in Hilbert spaces. Our goal is to extend this lemma to be constructive. For comparison, let us first write the classical result, from [33, Lemma 4], even though we do not use this result directly.

Lemma B.2 ([33]). Let $K_1, K_2, ...$ be arbitrary nonempty subsets (not necessarily subspaces) of a real Hilbert space \mathcal{H} . Then, for every $\epsilon > 0$ and $g \in \mathcal{H}$ there is $m \leq \lceil 1/\epsilon^2 \rceil$ and $(f_i \in K_i)_{i=1}^m$ and $(\gamma_i \in \mathbb{R})_{i=1}^m$, such that for every $w \in K_{m+1}$

$$\left| \left\langle w, g - \left(\sum_{i=1}^{m} \gamma_i f_i \right) \right\rangle \right| \le \epsilon \|w\| \|g\|. \tag{16}$$

Next, we show how to modify the result to be written explicitly with an approximate minimizer of a Hilbert space norm minimization problem. The proof follows the step of [33] with some modifications required for explicitly constructing an approximate optimizer.

Lemma B.3. Let $\{K_j\}_{j\in\mathbb{N}}$ be a sequence of nonemply subsets of a real Hilbert space \mathcal{H} and let $\delta \geq 0$. Let K > 0, let $R \geq 1$ such that $K/R \in \mathbb{N}$, and let $g \in \mathcal{H}$. Let m be randomly uniformly sampled from [K]. Then, in probability $1 - \frac{1}{R}$ (with respect to the choice of m), any vector of the form

$$g^* = \sum_{j=1}^m \gamma_j f_j$$
 such that $\boldsymbol{\gamma} = (\gamma_j)_{j=1}^m \in \mathbb{R}^m$ and $\mathbf{f} = (f_j)_{j=1}^m \in \mathcal{K}_1 \times \ldots \times \mathcal{K}_m$

that gives a close-to-best Hilbert space approximation of g in the sense that

$$\|g - g^*\| \le (1 + \delta) \inf_{\gamma, \mathbf{f}} \|g - \sum_{i=1}^m \gamma_i f_i\|,$$
 (17)

where the infimum is over $\gamma \in \mathbb{R}^m$ and $\mathbf{f} \in \mathcal{K}_1 \times \ldots \times \mathcal{K}_m$, also satisfies

$$\forall w \in \mathcal{K}_{m+1}, \quad |\langle w, g - g^* \rangle| \le ||w|| \, ||g|| \, \sqrt{\frac{R}{K} + \delta}.$$

Proof. Let K > 0. Let $R \ge 1$ such that $K/R \in \mathbb{N}$. For every k, let

$$\eta_k = (1+\delta) \inf_{\gamma, \mathbf{f}} \|g - \sum_{i=1}^k \gamma_i f_i\|^2$$

where the infimum is over $\gamma = \{\gamma_1, \dots, \gamma_k\} \in \mathbb{R}^k$ and $\mathbf{f} = \{f_1, \dots, f_k\} \in \mathcal{K}_1 \times \dots \times \mathcal{K}_k$. Note that $\|g\|^2 \ge \frac{\eta_1}{1+\delta} \ge \frac{\eta_2}{1+\delta} \ge \dots \ge 0$. Therefore, there is a subset of at least $(1-\frac{1}{R})K+1$ indices m in [K] such that $\eta_m \le \eta_{m+1} + \frac{R(1+\delta)}{K} \|g\|^2$. Otherwise, there are $\frac{K}{R}$ indices m in [K] such that $\eta_{m+1} < \eta_m - \frac{R(1+\delta)}{K} \|g\|^2$, which means that

$$\eta_K < \eta_1 - \frac{K}{R} \frac{R(1+\delta)}{K} \|g\|^2 \le (1+\delta) \|g\|^2 - (1+\delta) \|g\|^2 = 0,$$

which is a contradiction to the fact that $\eta_K \geq 0$.

Hence, there is a set $\mathcal{M} \subseteq [K]$ of $(1 - \frac{1}{R})K$ indices such that for every $m \in \mathcal{M}$, every

$$g^* = \sum_{j=1}^m \gamma_j f_j \tag{18}$$

that satisfies

$$\|g - g^*\|^2 \le \eta_m$$

also satisfies

$$\|g - g^*\|^2 \le \eta_{m+1} + \frac{(1+\delta)R}{K} \|g\|^2.$$
 (19)

Let $w \in \mathcal{K}_{m+1}$. By the definition of η_{m+1} , we have for every $t \in \mathbb{R}$,

$$||g - (g^* + tw)||^2 \ge \frac{\eta_{m+1}}{1+\delta} \ge \frac{||g - g^*||^2}{1+\delta} - \frac{R}{K} ||g||^2.$$

This can be written as

$$\forall t \in \mathbb{R}, \quad \|w\|^2 t^2 - 2 \langle w, g - g^* \rangle t + \frac{R}{K} \|g\|^2 + \left(1 - \frac{1}{1+\delta}\right) \|g - g^*\|^2 \ge 0. \tag{20}$$

The discriminant of this quadratic polynomial is

$$4 \langle w, g - g^* \rangle^2 - 4 \|w\|^2 \left(\frac{R}{K} \|g\|^2 + \left(1 - \frac{1}{1+\delta}\right) \|g - g^*\|^2 \right)$$

and it must be non-positive to satisfy the inequality (20), namely

$$4 \langle w, g - g^* \rangle^2 \le 4 \|w\|^2 \left(\frac{R}{K} \|g\|^2 + \left(1 - \frac{1}{1+\delta} \right) \|g - g^*\|^2 \right)$$

$$\le 4 \|w\|^2 \left(\frac{R}{K} \|g\|^2 + \left(1 - \frac{1}{1+\delta} \right) \eta_m \right)$$

$$\le 4 \|w\|^2 \left(\frac{R}{K} \|g\|^2 + \left(1 - \frac{1}{1+\delta} \right) (1+\delta) \|g\|^2 \right)$$

which proves

$$\langle w, g - g^* \rangle \le ||w|| \, ||g|| \, \sqrt{\frac{R}{K} + \delta}.$$

This is also true for -w, which concludes the proof.

B.5.2. Proof of the Soft Constructive Weak Regularity Lemma for Graphon-Signals

For two functions $f, g: [0,1] \to \mathbb{R}$, we denote by $f \otimes g: [0,1]^2 \to \mathbb{R}$ the function

$$f \otimes g(x,y) = f(x)g(y).$$

We recall here Theorem B.1 for the convenience of the reader.

Theorem B.1. Let (W, s) be a graphon-signal, $K \in \mathbb{N}$, $\delta > 0$, and let \mathcal{Q} be a soft indicators model. Let m be sampled uniformly from [K], and let $R \ge 1$ such that $K/R \in \mathbb{N}$. Consider the graphon-signal Frobenius norm with weights $\sqrt{\alpha \|W\|_F^2 + \beta \sum_{j=1}^D \|s_j\|_F^2}$. Then, in probability $1 - \frac{1}{R}$ (with respect to the choice of m), for every $(C^*, p^*) \in [\mathcal{Q}]_m$,

$$\begin{split} if & & \|(W,s) - (C^*,p^*)\|_F \leq (1+\delta) \min_{(C,p) \in [\mathcal{Q}]_n} \|(W,s) - (C,p)\|_{\mathcal{F}} \\ then & & \|(W,s) - (C^*,p^*)\|_{\square} \leq \\ & & \Big(\frac{3}{2}\sqrt{\alpha^2\|W\|_{\mathcal{F}}^2 + \alpha\beta\,\|s\|_{\mathcal{F}}} + \sqrt{\alpha\beta\|W\|_{\mathcal{F}}^2 + \beta^2\,\|s\|_{\mathcal{F}}}\Big)\sqrt{\frac{R}{K} + \delta}. \end{split}$$

The proof follows the techniques of a part of the proof of the weak graphon regularity lemma from [33], while tracking the approximate minimizer in our formulation of Lemma B.3. This requires a probabilistic setting, and extending to soft indicators models. We note that the weak regularity lemma in [33] is formulated for non-intersecting blocks, but the intersecting community version is an intermediate step in its proof.

Proof. Let us use Lemma B.3, with $\mathcal{H}=L^2[0,1]^2\times (L^2[0,1])^D$ with the weighted inner product

$$\langle (W,s), (W',s') \rangle = \alpha \iint_{[0,1]^2} W(x,y)W'(x,y)dxdy + \beta \sum_{j=1}^D \int_{[0,1]} s_j(x)s'_j(x)dx,$$

and corresponding norm $\sqrt{\alpha \|W\|_F^2 + \beta \sum_{j=1}^D \|s_j\|_F^2}$ and corresponding weighted inner product, and $\mathcal{K}_j = [\mathcal{Q}]$. Note that the Hilbert space norm is the Frobenius norm in this case. In the setting of the lemma, we take g = (W, s), and $g^* \in [\mathcal{Q}]_m$. By the lemma, in the event of probability 1 - 1/R, any approximate Frobenius minimizer (C^*, p^*) , namely, that satisfies $\|(W, s) - (C^*, p^*)\|_F \leq (1 + \delta) \min_{(C, p) \in [\mathcal{Q}]_m} \|(W, s) - (C, p)\|_F$, also satisfies

$$\langle (T,y), (W,s) - (C^*,p^*) \rangle \le ||(T,y)||_{\mathcal{F}} ||(W,s)||_{\mathcal{F}} \sqrt{\frac{R}{K} + \delta}$$

for every $(T, y) \in [\mathcal{Q}]$. Hence, for every choice of measurable subsets $\mathcal{S}, \mathcal{T} \subset [0, 1]$, we have

$$\begin{split} \left| \int_{\mathcal{S}} \int_{\mathcal{T}} (W(x,y) - C^*(x,y)) dx dy \right| \\ &= \frac{1}{2} \left| \int_{\mathcal{S}} \int_{\mathcal{T}} (W(x,y) - C^*(x,y)) dx dy + \int_{\mathcal{T}} \int_{\mathcal{S}} (W(x,y) - C^*(x,y)) dx dy \right| \\ &= \frac{1}{2} \left| \int_{\mathcal{S} \cup \mathcal{T}} \int_{\mathcal{S} \cup \mathcal{T}} (W(x,y) - C^*(x,y)) dx dy - \int_{\mathcal{S}} \int_{\mathcal{S}} (W(x,y) - C^*(x,y)) dx dy \right| \\ &- \int_{\mathcal{T}} \int_{\mathcal{T}} (W(x,y) - C^*(x,y)) dx dy \right| \\ &\leq \left| \frac{1}{2\alpha} \left\langle (\mathbbm{1}_{\mathcal{S} \cup \mathcal{T}} \otimes \mathbbm{1}_{\mathcal{S} \cup \mathcal{T}}, 0), (W,s) - (C^*,p^*) \right\rangle \right| + \left| \frac{1}{2\alpha} \left\langle (\mathbbm{1}_{\mathcal{S}} \otimes \mathbbm{1}_{\mathcal{S}}, 0), (W,s) - (C^*,p^*) \right\rangle \right| \\ &+ \left| \frac{1}{2\alpha} \left\langle (\mathbbm{1}_{\mathcal{T}} \otimes \mathbbm{1}_{\mathcal{T}}, 0), (W,s) - (C^*,p^*) \right\rangle \right| \\ &\leq \frac{1}{2\alpha} \|(W,s)\|_{\mathcal{F}} \left(\|(\mathbbm{1}_{\mathcal{S} \cup \mathcal{T}} \otimes \mathbbm{1}_{\mathcal{S} \cup \mathcal{T}}, 0)\|_{\mathcal{F}} + \|(\mathbbm{1}_{\mathcal{S}} \otimes \mathbbm{1}_{\mathcal{S}}, 0)\|_{\mathcal{F}} + \|(\mathbbm{1}_{\mathcal{T}} \otimes \mathbbm{1}_{\mathcal{T}}, 0)\|_{\mathcal{F}} \right) \sqrt{\frac{R}{K}} + \delta \\ &\leq \frac{3}{2\alpha} \sqrt{\alpha} \|W\|_{\mathcal{F}}^2 + \beta \|s\|_{\mathcal{F}} \sqrt{\alpha} \sqrt{\frac{R}{K}} + \delta \end{split}$$

Hence, taking the supremum over $\mathcal{S}, \mathcal{T} \subset [0, 1]$, we also have

$$\|\alpha\|W - C^*\|_{\square} \le \frac{3}{2} \sqrt{\alpha^2 \|W\|_{F}^2 + \alpha\beta \|s\|_{F}} \sqrt{\frac{R}{K} + \delta}.$$

Similarly, for every measurable $\mathcal{T} \subset [0,1]$ and every standard basis element $\boldsymbol{b} = (\delta_{j,i})_{i=1}^D$ for any $j \in [D]$,

$$\left| \int_{\mathcal{T}} (s_{j}(x) - p_{j}^{*}(x)) dx \right|$$

$$= \left| \frac{1}{\beta} \left\langle (0, \boldsymbol{b} \mathbb{1}_{\mathcal{T}}), (W, s) - (C^{*}, p^{*}) \right\rangle \right|$$

$$\leq \frac{1}{\beta} \|(W, s)\|_{F} \|(0, \boldsymbol{b} \mathbb{1}_{\mathcal{T}})\|_{F} \sqrt{\frac{R}{K}} + \delta$$

$$\leq \frac{1}{\beta} \sqrt{\alpha \|W\|_{F}^{2} + \beta \|s\|_{F}} \sqrt{\beta} \sqrt{\frac{R}{K}} + \delta,$$

so, taking the supremum over $\mathcal{T} \subset [0,1]$ independently for every $j \in [D]$, and averaging over $j \in [D]$, we get

$$\beta \|s - p^*\|_{\square} \le \sqrt{\alpha\beta \|W\|_{\mathrm{F}}^2 + \beta^2 \|s\|_{\mathrm{F}}} \sqrt{\frac{R}{K} + \delta}.$$

Overall, we get

$$\|(W,s) - (C^*,p^*)\|_{\square} \le \left(\frac{3}{2}\sqrt{\alpha^2\|W\|_{\mathrm{F}}^2 + \alpha\beta\|s\|_{\mathrm{F}}} + \sqrt{\alpha\beta\|W\|_{\mathrm{F}}^2 + \beta^2\|s\|_{\mathrm{F}}}\right)\sqrt{\frac{R}{K} + \delta}.$$

B.6. Proof of the constructive weak regularity lemma for sparse graph-signals

We now show that Theorem 3.1 is a special case of Theorem B.1, restricted to graphon-signals induced by graph-signals, up to choice of the graphon-signal weights α and β . Namely, choose $\alpha = \alpha' N^2 / E$ and $\beta = \beta'$ with $\alpha' + \beta' = 1$ as the weights of the graphon-signal cut norm of Theorem B.1, with arbitrary $\alpha', \beta' \geq 0$ satisfying $\alpha' + \beta' = 1$. It is easy to see the following relation between the graphon-signal and graph-signal cut norms

$$\|(W_{A}, s_{S}) - (W_{C^{*}}, s_{P^{*}})\|_{\square} = \|(A, S) - (C^{*}, P^{*})\|_{\square, N, E},$$

where $\|(\boldsymbol{A}, \boldsymbol{S}) - (\boldsymbol{C}^*, \boldsymbol{P}^*)\|_{\square, N, E}$ is based on the weights α' and β' . Now, since $\deg(\boldsymbol{A})/N^2 = \|\boldsymbol{A}\|_{\mathrm{F}}^2 = \frac{E}{N^2}$, and by $\|\boldsymbol{S}\|_{\mathrm{F}} \leq 1$, the bound in Theorem B.1 becomes

$$\|(\boldsymbol{A},\boldsymbol{S}) - (\boldsymbol{C}^*,\boldsymbol{P}^*)\|_{\square,N,E} \leq \left(\frac{3}{2}\sqrt{\alpha'^2\frac{N^4}{E^2}\frac{E}{N^2} + \alpha'\beta'\frac{N^2}{E}} + \sqrt{\alpha'\beta'\frac{N^2}{E}\frac{E}{N^2} + \beta'^2}\right)\sqrt{\frac{R}{K} + \delta}$$

$$\leq C \frac{N}{\sqrt{E}} \sqrt{\frac{R}{K} + \delta}$$

where, since $\alpha' + \beta' = 1$, and by convexity of the square root,

$$C = \frac{3}{2}\sqrt{\alpha'} + \sqrt{\beta'} \le \frac{3}{2}\sqrt{\alpha'} + \frac{3}{2}\sqrt{\beta'} \le \frac{3}{2}\sqrt{\alpha' + \beta'} = \frac{3}{2}.$$

The only thing left to do is to change the notations $\alpha' \mapsto \alpha$ and $\beta' \mapsto \beta$.

C. Fitting ICGs to graphs efficiently

Here, we prove Proposition 4.1. For convenience, we recall the proposition.

Proposition 4.1. Let $\mathbf{A} = (a_{i,j})_{i,j=1}^N$ be an adjacency matrix of a weighted graph with E edges. The graph part of the Frobenius loss can be written as

$$\begin{split} \left\| \boldsymbol{A} - \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{\mathrm{F}}^{2} &= \frac{1}{N^{2}} \operatorname{Tr} \left((\boldsymbol{Q}^{\top} \boldsymbol{Q}) \operatorname{diag}(\boldsymbol{r}) (\boldsymbol{Q}^{\top} \boldsymbol{Q}) \operatorname{diag}(\boldsymbol{r}) \right) + \| \boldsymbol{A} \|_{\mathrm{F}}^{2} \\ &- \frac{2}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j}. \end{split}$$

Computing the right-hand-side and its gradients with respect to \mathbf{Q} and \mathbf{r} has a time complexity of $\mathcal{O}(K^2N + KE)$, and a space complexity of $\mathcal{O}(KN + E)$.

Proof. The loss can be expressed as

$$\begin{aligned} & \left\| \boldsymbol{A} - \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{F}^{2} = \frac{1}{N^{2}} \sum_{i,j=1}^{N} \left(a_{i,j} - \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} \\ &= \frac{1}{N^{2}} \sum_{i=1}^{N} \left(\sum_{j \in \mathcal{N}(i)} \left(a_{i,j} - \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} + \sum_{j \notin \mathcal{N}(i)} \left(-\boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} \right) \\ &= \frac{1}{N^{2}} \sum_{i=1}^{N} \left(\sum_{j \in \mathcal{N}(i)} \left(a_{i,j} - \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} + \right. \\ &+ \sum_{j=1}^{N} \left(\boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} - \sum_{j \in \mathcal{N}(i)} \left(\boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} \right) \end{aligned}$$

We expand the quadratic term $\left(a_{i,j} - \mathbf{Q}_{i,:} \operatorname{diag}(\mathbf{r}) \left(\mathbf{Q}^{\top}\right)_{:,j}\right)^2$, and get

$$\begin{split} & \left\| \boldsymbol{A} - \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{\mathrm{F}}^{2} \\ &= \frac{1}{N^{2}} \sum_{i,j=1}^{N} \left(\boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} \right)^{2} + \frac{1}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \left(a_{i,j}^{2} - 2 \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j} \right) \\ &= \left\| \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right\|_{\mathrm{F}}^{2} + \frac{1}{N^{2}} \sum_{i,j=1}^{N} a_{i,j}^{2} - \frac{2}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j} \\ &= \frac{1}{N^{2}} \operatorname{Tr} \left(\boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \right) + \frac{1}{N^{2}} \sum_{i,j=1}^{N} a_{i,j}^{2} \\ &- \frac{2}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j} \\ &= \frac{1}{N^{2}} \operatorname{Tr} \left(\boldsymbol{Q}^{\top} \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \right) + \frac{1}{N^{2}} \sum_{i,j=1}^{N} a_{i,j}^{2} \\ &- \frac{2}{N^{2}} \sum_{i=1}^{N} \sum_{j \in \mathcal{N}(i)} \boldsymbol{Q}_{i,:} \operatorname{diag}(\boldsymbol{r}) \left(\boldsymbol{Q}^{\top} \right)_{:,j} a_{i,j} \end{split}$$

The last equality follows the identity $\forall \boldsymbol{B}, \boldsymbol{D} \in \mathbb{R}^{N \times K}$: $\text{Tr}(\boldsymbol{B}\boldsymbol{D}^{\top}) = \text{Tr}(\boldsymbol{D}^{\top}\boldsymbol{B})$, with $\boldsymbol{B} = \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r}) \boldsymbol{Q}^{\top} \boldsymbol{Q} \operatorname{diag}(\boldsymbol{r})$ and $\boldsymbol{D} = \boldsymbol{Q}^{\top}$.

The middle term in the last line is constant and can thus be omitted in the optimization process. The leftmost term in the last line is calculated by performing matrix multiplication from right to left, or by first computing $\mathbf{Q}^{\top}\mathbf{Q}$ and then the rest of the product. Thus, the time complexity is $\mathcal{O}(K^2N)$ and the largest matrix held in memory is of size $\mathcal{O}(KN)$. The rightmost term is calculated by message-passing, which has time complexity of $\mathcal{O}(KE)$. Thus, Computing the right-hand-side and its gradients with respect to \mathbf{Q} and \mathbf{r} has a time complexity of $\mathcal{O}(K^2N+KE)$ and a space complexity of $\mathcal{O}(KN+E)$.

D. Initializing the optimization with eigenvectors

Next, we propose a good initialization for the GD minimization of (7). For that, we consider a corollary of the constructive soft weak regularity for grapohns, with the signal weight in the cut norm set to $\beta=0$, using all $L^2[0,1]$ functions as the soft affiliation model, and taking relative Frobenius error with $\delta=0$. In this case, the best rank-K approximation theorem (Eckart–Young–Mirsky Theorem [45, Theorem 5.9]), the minimizer of the Frobenius error is the projection of W upon its leading eigenvectors. This leads to the following corollary.

Corollary D.1. Let W be a graphon, $K \in \mathbb{N}$, let m be sampled uniformly from [K], and let $R \geq 1$ such that $K/R \in \mathbb{N}$. Let ϕ_1, \ldots, ϕ_m be the leading eigenvectors of W, with eigenvalues $\lambda_1, \ldots, \lambda_m$ of highest magnitudes $|\lambda_1| \geq |\lambda_2| \geq \ldots \geq |\lambda_m|$, and let $C^*(x,y) = \sum_{k=1}^m \lambda_k \phi_k(x) \phi_k(y)$. Then, in probability $1 - \frac{1}{R}$ (with respect to the choice of m),

$$||W - C^*||_{\square} < \frac{3}{2}\sqrt{\frac{R}{K}}.$$

The initialization is based on Corollary D.1 restricted to induced graphon-signals with cut norm normalized by N^2/E . We consider the leading K/3 eigenvectors, assuming K is divisible by 3, for reasons that will become clear shortly. Hence, for $C = \Phi_{K/3} \Lambda_{K/3} \Phi_{K/3}^{\rm T}$, where $\Phi_{K/3} \in \mathbb{R}^{N \times K/3}$ is the matrix consisting of the leading eigenvectors of A as columns, and $\Lambda_{K/3} \in \mathbb{R}^{K/3 \times K/3}$ the diagonal matrix of the leading eigenvalues, we have

$$\|\boldsymbol{A} - \boldsymbol{C}\|_{\square;N,E} < \frac{3N^2}{2E} \sqrt{\frac{3R}{K}}.$$
 (21)

To obtain soft affiliations with values in [0,1], we now initialize Q as described in (8).

E. Learning ICG with subgraph SGD

In this section we prove that the gradients of the subgraph SGD approximate the gradients of the full GD method.

Proposition E.1. Let 0 . Under the above setting, if we restrict all entries of <math>C, P, Q, r and F to be in [0,1], then in probability at least 1-p, for every $k \in [K]$, $d \in [D]$ and $m \in [M]$

$$\left| \nabla_{q_{n_{m},k}} L - \frac{M}{N} \nabla_{q_{n_{m},k}} L^{(n)} \right| \leq \frac{4}{N} \sqrt{\frac{2 \log(1/p_{3}) + 2 \log(N) + 2 \log(K) + 2 \log(2)}{M}},$$

$$\left| \nabla_{r_{k}} L - \nabla_{r_{k}} L^{(n)} \right| \leq 4 \sqrt{\frac{2 \log(1/p_{1}) + 2 \log(N) + 2 \log(K) + 2 \log(2)}{M}},$$

$$\left| \nabla_{f_{k,d}} L - \nabla_{f_{k,d}} L^{(n)} \right| \leq \frac{4\lambda}{D} \sqrt{\frac{2 \log(1/p_{2}) + 2 \log(K) + 2 \log(D) + 2 \log(2)}{M}}.$$

Proposition E.1 means that the gradient with respect to \mathbf{r} and \mathbf{F} computed at each SGD step approximate the full GD gradients. The gradients with respect to \mathbf{Q} approximate a scaled version of the full gradients, and only on the sampled nodes, where the unsampled nodes are not updated in the SGD step. This means that when optimizing the ICG with SGD, we need to scale the gradients with resect to \mathbf{Q} of the loss by $\frac{M}{N}$. To use the same entry-wise learning rate in SGD as in GD one must multiply the loss (9) by M/N. Hence, SGD needs in expectation N/M times the number of steps that GD requires. This means that in SGD we trade the memory complexity (reducing it by a factor M/N) by time complexity (increasing it by a factor N/M). Note that slower run-time, while not

desirable, can be tolerated, while higher memory requirement is often prohibitive due to hardware limitations.

From here until the end of this section we prove Proposition E.1. For that, we compute the gradients of the full loss L and the sampled loss $L^{(n)}$.

To avoid tensor notations, we treat by abuse of notation the gradient of a function as a linear operator. Recall that the differential $\mathcal{D}_{r}T = \mathcal{D}_{r}T(r')$ of the function $T : \mathbb{R}^{R} \to \mathbb{R}^{U}$ at the point $r' \in \mathbb{R}^{R}$ is the unique linear operator $\mathbb{R}^{R} \to \mathbb{R}^{U}$ that describes the linearization of T about r' via

$$T(r' + \epsilon r'') = T(r') + \epsilon \mathcal{D}_r T r'' + o(\epsilon)$$

where $\epsilon \in \mathbb{R}$. Given an inner product in \mathbb{R}^R , the gradient $\nabla_{\boldsymbol{r}} \boldsymbol{T} = \nabla_{\boldsymbol{r}} \boldsymbol{T}(\boldsymbol{r}') \in \mathbb{R}^{U \times R}$ of the function $\boldsymbol{T} : \mathbb{R}^R \to \mathbb{R}^U$ at the point $\boldsymbol{r}' \in \mathbb{R}^R$ is defined to be the vector (guaranteed to uniquely exist by the Riesz representation theorem) that satisfies

$$\mathcal{D}_{r}Tr'' = \langle r'', \nabla_{r}T \rangle$$

for every $r'' \in \mathbb{R}^R$. Here, the inner product if defined row-wise by

$$\langle \boldsymbol{r}'', \nabla_{\boldsymbol{r}} \boldsymbol{T} \rangle := (\langle \boldsymbol{r}'', \nabla_{\boldsymbol{r}} \boldsymbol{T}[u, :] \rangle)_{u=1}^{U},$$

where T[u,:] is the *u*-th row of $\nabla_r T$. In our analysis, by abuse of notation, we identify $\nabla_r T$ with $\mathcal{D}_r T$ for a fixed given inner product.

Define the inner product between matrices

$$\langle \boldsymbol{B}, \boldsymbol{D} \rangle_2 = \sum_{i,j} b_{i,j} d_{i,j}.$$

Denote

$$L(\boldsymbol{C}, \boldsymbol{P}) = \|\boldsymbol{A} - \boldsymbol{C}\|_{\mathrm{F}}^2 + \lambda \|\boldsymbol{S} - \boldsymbol{P}\|_{\mathrm{F}}^2.$$

First, the gradient of $\|\boldsymbol{A}-\boldsymbol{C}\|_{\mathrm{F}}^2$ with respect to \boldsymbol{C} is

$$\nabla_{\boldsymbol{C}} \|\boldsymbol{A} - \boldsymbol{C}\|_{\mathrm{F}}^2 = -\frac{2}{N^2} (\boldsymbol{A} - \boldsymbol{C}),$$

which is identified by abuse of notation by the linear functional $\mathbb{R}^{N^2} \to \mathbb{R}$

$$oldsymbol{D}\mapsto
abla_{oldsymbol{C}}\left\|oldsymbol{A}-oldsymbol{C}
ight\|_{\mathrm{F}}^{2}\left(oldsymbol{D}
ight)=\left\langleoldsymbol{D},-rac{2}{N^{2}}(oldsymbol{A}-oldsymbol{C})
ight
angle_{2}.$$

Similarly,

$$\nabla_{\boldsymbol{P}} \| \boldsymbol{S} - \boldsymbol{P} \|_{\mathrm{F}}^2 = -\frac{2}{ND} (\boldsymbol{S} - \boldsymbol{P}) : \mathbb{R}^{ND} \to \mathbb{R}.$$

Given any parameter $z \in \mathbb{R}^R$ on which the graph C = C(z) and the signal P = P(z) depend, we have

$$\nabla_{z}L(C, P) = \frac{2}{N^{2}}(C - A)\nabla_{z}C + \lambda \frac{2}{ND}(P - S)\nabla_{z}P,$$
(22)

where $\nabla_z \mathbf{C} : \mathbb{R}^R \to \mathbb{R}^{N^2}$ and $\nabla_z \mathbf{C} \in \mathbb{R}^R \to \mathbb{R}^{ND}$ are linear operators, and the products in (22) are operator composition, namely, in coordinates it is elementwise multiplication (not matrix multiplication).

Let us now compute the gradients of $C = Q \operatorname{diag}(r)Q^{\top}$ and P = QF with respect to Q, r and F in coordinates. We have

$$\nabla_{r_k} c_{i,j} = q_{i,k} q_{j,k}$$

and

$$\nabla_{q_{m,k}} c_{i,j} = r_k \delta_{i-m} q_{j,k} + r_k \delta_{j-m} q_{i,k},$$

where δ_l is 1 if l=1 and zero otherwise. Moreover,

$$\nabla_{f_{k,l}} p_{i,d} = q_{i,k} \delta_{l-d},$$

and

$$\nabla_{q_{m,k}} p_{i,d} = f_{k,d} \delta_{i-m}.$$

Hence,

$$\nabla_{r_k} L = \frac{2}{N^2} \sum_{i,i=1}^{N} (c_{i,j} - a_{i,j}) q_{i,k} q_{j,k},$$

$$\nabla_{q_{m,k}} L = \frac{2}{N^2} \sum_{i=1}^{N} (c_{m,j} - a_{m,j}) r_k q_{j,k} + \frac{2}{N^2} \sum_{i=1}^{N} (c_{i,m} - a_{i,m}) r_k q_{i,k} + \lambda \frac{2}{ND} \sum_{d=1}^{D} (p_{m,d} - s_{m,d}) f_{k,d},$$

and

$$\nabla_{f_{k,l}} L = \lambda \frac{2}{ND} \sum_{i=1}^{N} (p_{i,l} - s_{i,l}) q_{i,k}.$$

Similarly,

$$\nabla_{r_k} L^{(n)} = \frac{2}{M^2} \sum_{i,j=1}^{M} (c_{n_i,n_j} - a_{n_i,n_j}) q_{n_i,k} q_{n_j,k},$$

$$\nabla_{q_{n_m,k}} L^{(n)} = \frac{2}{M^2} \sum_{j=1}^{M} (c_{n_m,n_j} - a_{n_m,n_j}) c_k q_{n_j,k}$$

$$+ \frac{2}{M^2} \sum_{i=1}^{M} (c_{n_i,n_m} - a_{n_i,n_m}) c_k q_{n_i,k} + \lambda \frac{2}{MD} \sum_{d=1}^{D} (p_{n_m,d} - s_{n_m,d}) f_{k,d},$$

and

$$\nabla_{f_{k,l}} L^{(n)} = \lambda \frac{2}{MD} \sum_{i=1}^{M} (p_{n_i,l} - s_{n_i,l}) q_{n_i,k}.$$

We next derive the convergence analysis, based on Hoeffding's Inequality and two Monte-Carlo approximation lemmas.

Theorem E.2 (Hoeffding's Inequality). Let Y_1, \ldots, Y_M be independent random variables such that $a \leq Y_m \leq b$ almost surely. Then, for every k > 0,

$$\mathbb{P}\Big(\Big|\frac{1}{M}\sum_{m=1}^{M}(Y_m - \mathbb{E}[Y_m])\Big| \ge k\Big) \le 2\exp\Big(-\frac{2k^2M}{(b-a)^2}\Big).$$

The following is a standard Monte Carlo approximation error bound based on Hoeffding's inequality.

Lemma E.3. Let $\{i_m\}_{m=1}^M$ be uniform i.i.d in [N]. Let $\mathbf{v} \in \mathbb{R}^N$ be a vector with entries v_n in the set [-1,1]. Then, for every 0 , in probability at least <math>1-p

$$\left| \frac{1}{M} \sum_{m=1}^{M} v_{i_m} - \frac{1}{N} \sum_{n=1}^{N} v_n \right| \le \sqrt{\frac{2 \log(1/p) + 2 \log(2)}{M}}.$$

Proof. This is a direct result of Hoeffding's Inequality on the i.i.d. variables $\{v_{i_m}\}_{m=1}^M$.

The next lemma derives a Monte Carlo approximation error bound based on Hoeffding's inequality for 2D arrays, in case one samples only 1D independent sample points, and the 2D sample points are all pairs of the 1D points (which are hence no longer independent).

Lemma E.4. Let $\{i_m\}_{m=1}^M$ be uniform i.i.d in [N]. Let $\mathbf{A} \in \mathbb{R}^{N \times N}$ be symmetric with $a_{i,j} \in [-1,1]$. Then, for every 0 , in probability more than <math>1-p

$$\left| \frac{1}{N^2} \sum_{j=1}^N \sum_{n=1}^N a_{j,n} - \frac{1}{M^2} \sum_{m=1}^M \sum_{l=1}^M a_{i_m,i_l} \right| \le 2\sqrt{\frac{2\log(1/p) + 2\log(N) + 2\log(2)}{M}}.$$

Proof. Let $0 . For each fixed <math>n \in [N]$, consider the independent random variables $Y_m^n = a_{i_m,n}$, with

$$\mathbb{E}(Y_m^n) = \frac{1}{N} \sum_{j=1}^N a_{j,n},$$

and $-1 \le Y_m \le 1$. By Hoeffding's Inequality, for $k = \sqrt{\frac{2\log(1/p) + 2\log(N) + 2\log(2)}{M}}$, we have

$$\left| \frac{1}{N} \sum_{j=1}^{N} a_{j,n} - \frac{1}{M} \sum_{m=1}^{M} a_{i_m,n} \right| \le k$$

in an event \mathcal{E}_n of probability more than 1-p/N. Intersecting the events $\{\mathcal{E}_n\}_{n=1}^N$, we get

$$\forall n \in [N]: \quad \left| \frac{1}{N} \sum_{j=1}^{N} a_{j,n} - \frac{1}{M} \sum_{m=1}^{M} a_{i_m,n} \right| \le k$$

in the event $\mathcal{E} = \cap_n \mathcal{E}_n$ probability at least 1 - p. Hence, by the triangle inequality, we also have in the event \mathcal{E}

$$\left| \frac{1}{NM} \sum_{l=1}^{M} \sum_{j=1}^{N} a_{j,i_l} - \frac{1}{M^2} \sum_{l=1}^{M} \sum_{m=1}^{M} a_{i_m,i_l} \right| \le k,$$

and

$$\left| \frac{1}{N^2} \sum_{n=1}^{N} \sum_{j=1}^{N} a_{j,n} - \frac{1}{NM} \sum_{n=1}^{N} \sum_{m=1}^{M} a_{i_m,n} \right| \le k.$$

Hence, by the symmetry of A and by the triangle inequality,

$$\left| \frac{1}{N^2} \sum_{n=1}^{N} \sum_{j=1}^{N} a_{j,n} - \frac{1}{M^2} \sum_{l=1}^{M} \sum_{m=1}^{M} a_{i_m,i_l} \right| \le 2k.$$

Now, since all entries of A, S, C, P, Q, r and F are in [0,1], we may use Lemmas E.3 and E.4 to derive approximation errors for the gradients of L. Specifically, for any $0 < p_1 < 1$, for every $k \in [K]$ there is an event A_k of probability at least $1 - p_1$ such that

$$\left| \nabla_{r_k} L - \nabla_{r_k} L^{(n)} \right| \le 4\sqrt{\frac{2\log(1/p_1) + 2\log(N) + 2\log(2)}{M}}.$$

Moreover, for every $k \in [K]$ and $j \in [D]$, and every $0 < p_2 < 1$ there is an event $C_{k,j}$ of probability at least $1 - p_2$ such that

$$\left| \nabla_{f_{k,l}} L - \nabla_{f_{k,l}} L^{(\boldsymbol{n})} \right| \le \frac{4\lambda}{D} \sqrt{\frac{2 \log(1/p_2) + 2 \log(2)}{M}}.$$

For the approximation analysis of $\nabla_{q_{n_m,l}}L$, note that the index n_m is random, so we derive a uniform convergence analysis for all possible values of n_m . For that, for every $n \in [N]$ and $k \in [K]$, define the vector

$$\widetilde{\nabla_{q_{n,k}} L^{(n)}} = \frac{2}{M^2} \sum_{j=1}^{M} (c_{n,n_j} - a_{n,n_j}) c_k q_{n_j,k}
+ \frac{2}{M^2} \sum_{i=1}^{N} (c_{n_i,n} - a_{n_i,n}) c_k q_{n_i,k} + \lambda \frac{2}{MD} \sum_{d=1}^{D} (p_{n,d} - s_{n,d}) f_{k,d},$$

Note that $\nabla_{q_{n,k}} L^{(n)}$ is not a gradient of $L^{(n)}$ (since if n is not a sample from $\{n_m\}$ the gradient must be zero), but is denoted with ∇ for its structural similarity to $\nabla_{q_{n_m,k}} L^{(n)}$. Let $0 < p_3 < 1$. By Lemma E.3, for every $k \in [K]$ there is an event \mathcal{B}_k of probability at least $1 - p_3$ such that for every $n \in [N]$

$$\left|\nabla_{q_{n,k}}L - \frac{M}{N}\widetilde{\nabla_{q_{n,k}}L^{(n)}}\right| \leq \frac{4}{N}\sqrt{\frac{2\log(1/p_3) + 2\log(N) + 2\log(2)}{M}}.$$

This means that in the event \mathcal{B}_k , for every $m \in [M]$ we have

$$\left| \nabla_{q_{n_{m,k}}} L - \frac{M}{N} \nabla_{q_{n_{m,k}}} L^{(n)} \right| \le \frac{4}{N} \sqrt{\frac{2 \log(1/p_3) + 2 \log(N) + 2 \log(2)}{M}}.$$

Lastly, given $0 , choosing <math>p_1 = p_3 = p/3K$ and $p_2 = p/3KD$ and intersecting all events for all corrdinates gives and event \mathcal{E} of probability at least 1 - p such that

$$\left| \nabla_{r_k} L - \nabla_{r_k} L^{(n)} \right| \le 4\sqrt{\frac{2\log(1/p_1) + 2\log(N) + 2\log(K) + 2\log(2)}{M}},$$

$$\left| \nabla_{f_{k,l}} L - \nabla_{f_{k,l}} L^{(n)} \right| \le \frac{4\lambda}{D} \sqrt{\frac{2 \log(1/p_2) + 2 \log(K) + 2 \log(D) + 2 \log(2)}{M}},$$

and

$$\left| \nabla_{q_{n_m,k}} L - \frac{M}{N} \nabla_{q_{n_m,k}} L^{(n)} \right| \leq \frac{4}{N} \sqrt{\frac{2 \log(1/p_3) + 2 \log(N) + 2 \log(K) + 2 \log(2)}{M}}.$$

F. Additional experiments

F.1. Node classification

Setup. We evaluate ICG-NN and ICG_u-NN on the non-sparse graphs tolokers [38], squirrel [40] and twitch-gamers [31]. We follow the 10 data splits of [38] for tolokers, the 10 data splits of [37, 29] for squirrel and the 5 data splits of [31, 29] for twitch-gamers. We report the mean ROC AUC and standard deviation for tolokers and the accuracy and standard deviation for squirrel and twitch-gamers.

The baselines MLP, GCN [26], GAT [47], H₂GCN [58], GPR-GNN [14], LINKX [31], GloGNN [29] are taken from [38] for tolokers and from [29] for squirrel, twitch-gamers and penn94. We use the Adam optimizer and report all hyperparameters in Appendix H.

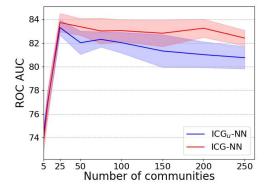

Results. All results are reported in Table 2. Observe that ICG-NNs achieve state-of-the-art results across the board, despite the low ratio of edge (graph densities of $2.41 \cdot 10^{-4}$ to $8.02 \cdot 10^{-3}$). ICG-NNs surpass the performance of more complex GNN models such as GT, LINKX and GloGNN, which solidify ICG-NNs as a strong method and a possible contender to message-passing neural networks.

F.2. Ablation study over the number of communities

Setup. We evaluate ICG-NN and ICG_u-NN on non-sparse graphs tolokers [38] and squirrel [40]. We follow the 10 data splits of [38] for tolokers and [37, 29] for squirrel. We report the mean ROC AUC and standard deviation for tolokers and the accuracy and standard deviation for squirrel.

Table 2: Results on large g	graphs. Top three	models are colored	by First	, Second, '	Third.
-----------------------------	-------------------	--------------------	----------	-------------	--------

# nodes # edges avg. degree density	tolokers 11758 519000 88.28 $3.75 \cdot 10^{-3}$	squirrel 5201 217073 41.71 $8.02 \cdot 10^{-3}$	twitch-gamers 168114 6797557 40.43 $2.41 \cdot 10^{-4}$

ICG-NN ICG _u -NN	83.73 ± 0.78 83.31 ± 0.64	58.48 ± 1.77 62.10 ± 1.67	$65.73 \pm 0.36 \\ 66.10 \pm 0.42$

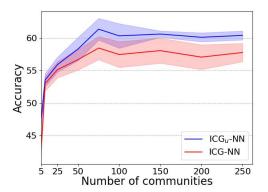

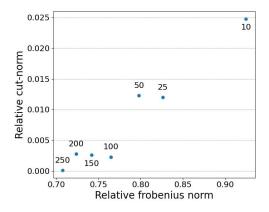

Figure 4: Test ROC AUC of tolokers (**left**) and test accuracy of squirrel (**right**) as a function of the number of communities.

Results. Figure 4 shows several key trends across both datasets. First, as anticipated, when a very small number of communities is used, the ICG fails to approximate the graph accurately, resulting in degraded performance. Second, the optimal performance is observed when using a relatively small number of communities, specifically 25 for tolokers and 75 for squirrel. Lastly, using a large number of communities does not appear to negatively impact performance.

F.3. The cut-norm and frobenius norm

In this experiment we aim to validate the bound presented in Theorem 3.1.

Setup. We evaluate our ICG approximation on non-sparse graphs tolokers [38] and squirrel [40]. We vary the number of communities used by the approximation and report the relative cut-norm (estimated by [4]) as a function of the relative frobenius norm.

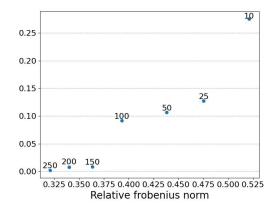

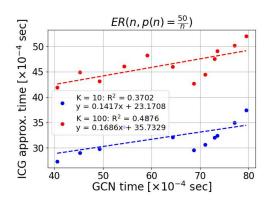

Figure 5: Cut-norm as a function of Frobenius norm on the tolokers (**left**) and squirrel (**right**) datasets. The number of communities used is indicated next to each point.

Results. As expected, both the cut-norm and frobenius norm are decreasing the more communities are used in Figure 5. Furthermore, the cut-norm is strictly smaller than the frobenius norm at each point, validating Theorem 3.1.

F.4. Run-time analysis

In this subsection, we compare the forward pass run times of our ICG approximation process, signal processing pipeline (ICG_u-NN) and the GCN [26] architecture. We sample graphs of sizes up to 7,000 from a dense and a sparse $Erd\~os-R\'enyi$ distribution ER(n,p(n)=0.5) and $ER(n,p(n)=\frac{50}{n})$, correspondingly. Node features are independently drawn from U[0,1] and the initial feature dimension is 128. ICG_u-NN and GCN use a hidden dimension of 128, 3 layers and an output dimension of 5.

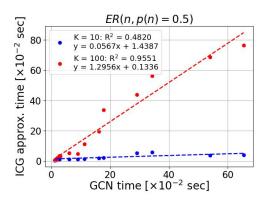

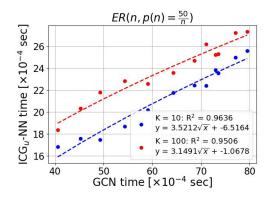

Figure 6: Empirical runtimes: K-ICG approximation process as a function of GCN forward pass duration on the dense (**left**) and sparse (**right**) $Erd\tilde{o}s$ - $R\acute{e}nyi$ distribution ER(n, p(n) = 0.5) and $ER(n, p(n) = \frac{50}{n})$ for K=10, 100.

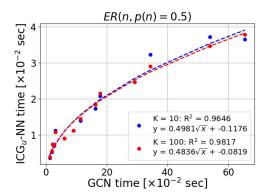

Figure 7: Empirical runtimes: K-ICG_u-NN as a function of GCN forward pass duration on the dense (**left**) and sparse (**right**) $Erd\tilde{o}s$ - $R\acute{e}nyi$ distribution ER(n, p(n) = 0.5) and $ER(n, p(n) = \frac{50}{n})$ for K=10, 100.

Results. Figure 6 demonstrates a strong linear relationship between the runtime of our ICG approximation and that of the message-passing neural network GCN for both sparse and dense graphs. Unlike GCN, our ICG approximation is versatile for multiple tasks and requires minimal hyperparameter tuning, which reduces its overall time complexity. Additionally, Appendix F.4 reveals a strong square root relationship between the runtime of ICG_u-NN and the runtime of GCN for both sparse and dense graphs. This aligns with our expectations, as the time complexity of GCN is $\mathcal{O}(E)$, while the time complexity of ICG-NNs is $\mathcal{O}(N)$, highlighting the computational advantage of using ICGs over message-passing neural networks.

G. Dataset statistics

The statistics of the real-world node-classification, and spatio-temporal benchmarks used can be found in Tables 3 and 4.

Table 3: Statistics of the node classification benchmarks.

	tolokers	squirrel	twitch-gamers
# nodes (N)	11758	5201	168114
# edges (E)	519000	217073	6797557
avg. degree $(\frac{E}{N})$	88.28	41.71	40.32
density $(\frac{E}{N^2})$	$3.75 \cdot 10^{-3}$	$8.02 \cdot 10^{-3}$	$2.41 \cdot 10^{-4}$
# node features	10	2089	7
# classes	2	5	2
metrics	AUC-ROC	ACC	ACC

Table 4: Statistics of the spatio-temporal benchmarks.

	METR-LA	PEMS-BAY
# nodes (N)	207	325
# edges (E)	1515	2369
avg. degree $(\frac{E}{N})$	7.32	7.29
density $\left(\frac{E}{N^2}\right)^{-1}$	$3.54\cdot10^{-2}$	$2.24\cdot10^{-2}$
# node features	34272	52128

H. Hyperparameters

In Table 5, we report the hyper-parameters used in our real-world node-classification and spatio-temporal benchmarks.

Table 5: Hyper-parameters used for the node classification benchmarks.

	tolokers	squirrel	twitch-gamers
# communities	25	75	500
Encoded dim	-	128	-
λ	1	1	1
Approx. lr	0.01, 0.05	0.01, 0.05	0.01, 0.05
Approx. epochs	10000	10000	10000
# layers	3,4,5	3,4,5	3,4,5,6
hidden dim	32, 64	64, 128	64, 128
dropout	0, 0.2	0, 0.2	0, 0.2
residual connection	-	\checkmark	\checkmark
Fit lr	0.001,0.003,0.005	0.001,0.003,0.005	0.001,0.003,0.005
Fit epochs	3000	3000	3000

For spatio-temporal dataset, we follow the methodology described in [15], where the time of the day and the one-hot encoding of the day of the week are used as additional features.

I. Additional related work

Latent graph GNNs. One way to interpret our ICG-NNs are as latent graph methods, where the ICG approximation of the given graph G is seen as a latent low complexity "clean version" of the observed graph G.

In latent graph methods, the graph on which the GNN is applied is inferred from the given data graph, or from some raw non-graph data. Two motivations for latent graph methods are (1) the given graph is noisy, and the latent graph is its denoised version, or (2) even if the given graph is "accurate", the inferred graph improves the efficiency of

Table 6: Hyper-parameters used for the spatio-temporal benchmarks.

	METR-LA	PEMS-BAY
# communities	50	100
Encoded dim	-	-
λ	0	0
Approx. lr	0.01, 0.05, 0.1	0.01, 0.05, 0.1
Approx. epochs	10000	10000
# layers	3,4,5	3,4,5, 6
hidden dim	32, 64, 128	32, 64, 128
Fit lr	0.001, 0.003	0.001, 0.003
Fit epochs	300	300

message passing. Our ICG GNN can be cast in category (2), since we use the latent ICG model to define an efficient "message passing" scheme, which has linear run-time with respect to the number of nodes.

Some examples of latent graph methods are papers like [24, 50, 16, 10, 17] which learn a latent graph from non-graph raw data. Papers like [34, 51, 23, 20] treat the given graph as noisy or partially observed, and learn the "clean" graph. Papers like [48, 44] modify the given graph to improve the efficiency of message passing (e.g., based on the notion of oversquashing [5]), and [36] modifies the weights of the given graph if the nodes were sampled non-uniformly from some latent geometric graph. Additionally, attention based GNN methods, which dynamically choose edge weights [47, 49, 46, 56], can be interpreted as latent graph approaches.

GNNs with local pooling. Local graph pooling methods, e.g., [55, 9], construct a sequence of coarsened versions of the given graph, each time collapsing small sets of neighboring nodes into a single "super-node." At each local pooling layer, the signal is projected from the finer graph to the coarser graph. This is related to our ICG-NN approach, where the signal is projected upon the communities. As opposed to local graph pooling methods, our communities intersect and have large-scale supports. Moreover, our method does not lose the granular/high-frequency content of the signal when projecting upon the communities, as we also have node-wise operations at the fine level.

Variational Graph Autoencoders. Our ICG construction is related to statistical network analysis with latent position graph models [6]. Indeed, the edge weight between any pair of nodes n, m in the ICG is the diagonal Bilinear product between their affiliation vectors, namely, $\sum_j r_j \mathbb{1}_{\mathcal{U}_j}(n) \mathbb{1}_{\mathcal{U}_j}(m)$, which is similar to the inner produce decoder in variational graph autoencoders [25, 6].
