## ABSTRACT

Using a large sample of fast radio bursts (FRBs) from the first CHIME/FRB catalog, we apply the Lynden-Bell's  $c^-$  method to study their energy function and formation rate evolutions with redshift. It is found with the non-parametric Kendall's  $\tau$  statistics that the FRB energy strongly evolves with the cosmological redshift as  $E(z) \propto (1+z)^{5.23}$ . After removing the redshift dependence, the local energy distribution can be described by a broken power-law form of  $\Psi(E_0) \propto E_0^{-0.38}$  for the low-energy segment and  $\Psi(E_0) \propto E_0^{-2.01}$  for the high-energy segment with a dividing line of  $\sim 2.1 \times 10^{40}$  erg. Interestingly, we find that the formation rate of CHIME FRBs also evolves with redshift as  $\rho(z) \propto (1+z)^{-4.73 \pm 0.08}$ . The local formation rate  $\rho(0)$  of the CHIME FRBs is constrained to be about  $1.25 \times 10^4$  Gpc $^{-3}$  yr $^{-1}$  that is comparable with some previous estimations. In addition, we notice the formation rate not only exceeds the star formation rate at the lower redshifts but also always declines with the increase of redshift, which does not match the star formation history at all. Consequently, we suggest that most FRBs could originate from the older stellar populations.

## 1. INTRODUCTION

Over the past decade, Fast radio bursts (FRBs) have motivated more and more people's research interests in seeking for their physical origins. Unfortunately, the progenitors and central engines of FRBs are still unclear in nature. Many authors proposed that they may associate with star formation regions inside galaxies and can be explained by different progenitors such as black holes (BHs), magnetars, supernovae (SNe), neutron stars (NSs), etc.(e.g. [Platts et al. 2019](#); [Zhang 2020](#); [Xiao et al. 2021](#); [Petroff et al. 2022](#))<sup>1</sup>. Accurate localization of FRBs in their host galaxies can offer good clue to their origins. The host galaxies of roughly two dozen FRBs have been successfully identified<sup>2</sup> ([Heintz et al. 2020](#), reference therein). For instance, the detection of a bright FRB 20200428 originating from the galactic magnetar SGR 1935+2154 provides an important link between FRBs and magnetars ([CHIME/FRB Collaboration et al. 2020](#); [Bochenek et al. 2020](#); [Lin et al. 2020](#); [Mereghetti et al. 2020](#); [Li et al. 2021a](#); [Ridnaia et al. 2021](#); [Tavani et al. 2021](#); [Wada & Ioka 2023](#)). Thus, the magnetar model is one of the most likely explanations for FRBs as the magnetar-based models can reproduce multiple FRB characteristics ([Zhang 2020](#)). Importantly, magnetars can be formed in both young (via core-collapse SNe) and old (namely white dwarf (WD) -NS coalescence, accretion induced collapse (AIC) and other compact binary coalescences) star populations.

Good localization can also help identify FRB progenitors according to distinct galactic environments ([Kremer et al. 2021](#); [Popov S. & Pshirkov M. 2023](#)). It was found that most well-localized FRBs such as FRB 20121102A ([Tendulkar et al. 2017](#)), FRB 20190520B ([Niu et al. 2022](#)) and FRB 20190303A ([Michilli et al. 2023](#)) are generally generated from active or quasi star-forming galaxies (eg., [Tendulkar et al. 2017](#); [Bannister et al. 2019](#); [Prochaska et al. 2019](#); [Marcote et al. 2020](#); [Fong et al. 2021](#); [Ravi et al. 2022](#); [Niu et al. 2022](#); [Bhandari et al. 2023](#); [Law et al. 2023](#); [Gordon et al. 2023](#)). In this situation, it will be expected that young star populations should be favored as the origin of FRBs. However, there are some well-localized FRBs whose host galaxies are quiescent instead of star-forming. For example, the optical observations reveal that FRB 20201124A was situated in an inter-arm region of a barred-spiral galaxy, in which the galactic environment does not comply with the young star populations ([Xu et al. 2021](#)). In addition, FRB 20220509G is recorded to localize in a quiescent galaxy ([Law et al. 2023](#)). Furthermore, the host galaxy location of FRB 20180916B was found to deviate from the star-forming region ([Tendulkar et al. 2021](#)). Therefore, the explanation of this phenomenon is that at least some FRBs are associated with old star populations, namely NSs and BHs (see, e.g., [Mottez & Zarka 2014](#); [Zhang 2017](#); [Deng et al. 2018](#); [Zhang & Zhang 2022](#)). In particular, FRB 20200120E is identified to be within an old globular cluster with an age of 9 Gyr in the extragalaxy M81 ([Bhardwaj et al. 2021](#); [Kirsten et al. 2022](#)). As a whole, FRB host galaxies have two kinds of environments, that is the star formation region (eg., [Tendulkar et al. 2017](#); [Bassa et al. 2017](#); [Bannister et al. 2019](#);

<sup>2</sup> See <https://github.com/FRBs/FRBhostpage>

Tendulkar et al. 2021; Niu et al. 2022) and the star quiescent region (eg., Bhardwaj et al. 2021; Kirsten et al. 2022). It shows that FRBs might originate from multiple galactic environment channels. However, a very limited number of well-localized FRBs is inadequate to reveal the FRB origins.

With the increase of FRB numbers, a statistical study of luminosity/energy distributions is an alternative solution to disclose their progenitors. In other words, the luminosity/energy evolution with redshift or the formation rate (or co-moving density) evolution, is found to be an effective way to constrain the FRB origin models (e.g., Locatelli et al. 2019; Hashimoto et al. 2020a; Arcus et al. 2021; James et al. 2022; Zhang & Zhang 2022). Although the underlying physics of the FRBs still remains uncertain, the total energy output should be linked to the FRB progenitors. On the other hand, the progenitors of some FRBs are found to connect with the star-forming activity, which motivates us explore the FRB origins by describing how the luminosity/energy function and formation rate evolve with redshift. By contrast, the isotropic energy is reliably measured and the luminosity is usually uncertain since the intrinsic pulse width of most FRBs is unknown (Macquart & Ekers 2018; Ravi 2019; Pleunis et al. 2021a). Consequently, we analyze the energies instead of luminosities of FRBs in this work. The FRB energy function and their redshift evolution may provide an even more representative clue to constrain the possible FRB progenitors. Recently, Hashimoto et al. (2022) found that if FRBs are resulted from younger star populations tracking the cosmic star formation history, the FRB formation rate should increase with increasing redshift up to  $z \sim 2$ . They also speculated that the FRB formation rate may decrease towards higher redshifts if the origin of FRBs is related to old populations. This will help us constrain the progenitor models, plan the most adequate follow-up observations, and provide further clues to elucidate the origin of FRBs.

To estimate the formation rate of FRBs, several statistical methods such as the parametric methods including the direct fitting technique, the bayesian statistics (eg., Luo et al. 2018, 2020; Tang et al. 2023), the likelihood estimation (Marshall et al. 1983) and the non-parametric methods such as the  $V_{max}$  method (Hashimoto et al. 2020a,b, 2022), the  $V/V_{max}$  method (Locatelli et al. 2019) and the popular Lynden-Bell's  $c^-$  method, (e.g., Efron & Petrosian 1998; Petrosian et al. 2015; Yu et al. 2015; Deng et al. 2019; Dong et al. 2022) have been applied in the past (see also Dong et al. (2023) for a short review). For the purpose, the isotropic energy  $E$  or luminosity  $L$  is usually used to plot against the redshift  $z$ , where  $E$  or  $L$  shows an evolution with  $z$  for FRBs (Locatelli et al. 2019; Hashimoto et al. 2020a; James et al. 2022). However, this may be caused by the effect of instrument threshold truncation (see however Dong et al. 2022). Thus, as suggested by Deng et al. (2019) and Zhang & Zhang (2022), any attempt to measure the  $E - z$  or  $L - z$  correlation should carefully account for instrumental effect in advance. To mitigate instrumental selection effects between different telescopes, it is a typical practice to use a large and homogeneous sample collected by a single telescope. We here use the Kendall's  $\tau$  statistics proposed by Efron & Petrosian (1992, 1998) to examine the correlation between energy and redshift. Then, we apply the Lynden-Bell's  $c^-$  methods to obtain the distributions of energy de-evolved with redshift and the formation rate history.

This paper is organized as follows. Section 2 describes the data reduction process. Section 3 presents the Lynden-Bell's  $c^-$  method and the non-parametric Kendall's  $\tau$  statistics. In Section we derive the FRB energy function in Section 4 . The redshift distribution and formation rate are shown in Section 5. In Section 6, we gives the local event rate of the sample

of CHIME FRBs. Finally, we end with conclusion and discussions in Section 7. Throughout the paper, a flat  $\Lambda$ CDM universe with  $H_0 = 67.74 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_\Lambda = 0.6911$  and  $\Omega_m = 0.3089$  (Planck Collaboration et al. 2016) is assumed.

## 2. SAMPLE SELECTION

Until March 2022, more than 700 FRBs had been observed <sup>3</sup> (Spanakis-Misirlis 2021). Notably, the CHIME/FRB Collaboration published their first catalog of 482 FRBs of which 474 non-repeaters and 18 repeaters were involved. To weaken the selection bias effect, we select the FRB data detected by the CHIME telescope only<sup>4</sup> as listed in Table A.1 (refer to CHIME/FRB Collaboration et al. 2021), where the selection criteria are (1) FRBs with  $\text{bonsai\_snr} < 10$  are rejected, (2) FRBs with fluence detected directly after a system restarts are chosen, (3) three FRBs (FRB20190210D, FRB20190125B, FRB20190202B) detected in far side-lobes were excluded, (4) FRBs detected during pre-commissioning, periods of low sensitivity or on days of software upgrades are excluded, (5) the first burst is taken if a FRB is repeating. Thus a sample of 396 CHIME FRBs have been chosen for this study. Phenomenologically, FRBs can be classified into repeaters and apparent non-repeaters. However, there are some FRBs classified as "one-off FRBs" that are actually repeating ones (eg., Kumar et al. 2019; Chen et al. 2022). Interestingly, Li et al. (2021b) proposed that FRBs are better to be classified into long and short groups on basis of the time durations. It is still unknown whether different kinds of FRBs have the same origin (eg., Caleb et al. 2019; Geng et al. 2021; Kirsten et al. 2023; Gordon et al. 2023). Unfortunately, there is a repeating FRB 20151125 exhibiting wider radio pulses detected by the Big Scanning Array of the Lebedev Physical Institute (BSA/LPI) (Fedorova, V. A., & Rodin, A. E. 2019b, ARep, 63, 877). Categorizing FRBs into repeaters and non-repeaters may be not intrinsic but surferical owing to the sensitivity limits or the observational time coverage (Ai et al. 2021), which motivates us to combine the repeating and non-repeating CHIME FRBs into a large sample uniformly.

Following Zhang (2018), we estimate the redshift of a FRB by its **extrogalactic dispersion measure** ( $DM_E$ ) as  $z \sim DM_E/[855 \text{ pc cm}^3]$  and then calculate the isotropic energy at a central frequency of  $\nu_c$ . Owing to the effects of frequency drift and cosmological time dialation, the obseved FRB spectra should be corrected to the rest-frame in order to infer the detection rate accurately. The isotropic energy of a FRB is determined by

$$E = 4\pi D_L^2(z) F_{\text{obs}} \nu_c k(z)/(1+z), \quad (1)$$

where  $D_L = c(1+z) \int_0^z 1/\{H_0[(1+z)^3 \Omega_m + \Omega_\Lambda]^{1/2}\} dz$  is the luminosity distance,  $\nu_c = 600 \text{ MHz}$  (Bandura et al. 2014; CHIME/FRB Collaboration et al. 2018, 2021) and  $k(z)$  denote the central frequency and the K-correction factor, repectively. Assuming a power-law spectrum of  $F \propto \nu^{-\beta}$  within a narrow radio band, we have calculated the parameter  $k(z)$  defined by Lorimer et al. (2013); Cao et al. (2017); Zhang & Wang (2019); Bhattacharya & Kumar (2020) as

$$k(z) = \frac{\nu_{\text{max}}^{1-\beta} - \nu_{\text{min}}^{1-\beta}}{[(1+z)\nu_2]^{1-\beta} - [(1+z)\nu_1]^{1-\beta}}, \quad (2)$$

<sup>3</sup> For a complete list of known FRBs, see <https://www.herta-experiment.org/frbstats> or the Transient Name Server (TNS, Petroff & Yaron 2020)

<sup>4</sup> <https://www.chime-frb.ca/catalog>

where  $\nu_{\min}$  and  $\nu_{\max}$  are respectively the minimum and maximum frequencies of all FRBs in the rest frame. Here  $\nu_{\min} = 100$  MHz and  $\nu_{\max} = 8$  GHz have been assumed similar to some previous groups (Gajjar et al. 2018; Pastor-Marazuela et al. 2021; Pleunis et al. 2021b).  $\beta$  is the spectral index in radio band.  $\nu_1$  and  $\nu_2$  denote the observed frequency bands of CHIME, say,  $\nu_1 = 400$  MHz and  $\nu_2 = 800$  MHz for a spectral index of  $\beta = 1.4$  (CHIME/FRB Collaboration et al. 2021). The energy limit at redshift  $z$  is given as  $E_{\text{limit}} = 4\pi D_L^2(z)F_{\min}\nu_c k/(1+z)$  with a fluence sensitivity of  $F_{\min} = 0.41$  Jy ms.

### 3. Methods

The Lynden-Bell's  $c^-$  method adopted in this paper has been widely used to analyze the luminosity distribution, isotropic energy distribution and redshift distribution of quasars (Lynden-Bell 1971; Efron & Petrosian 1992), Gamma-Ray Bursts (GRBs) (see, e.g., Yu et al. 2015; Petrosian et al. 2015; Liu et al. 2021; Dong et al. 2022) and FRBs (see, e.g., Deng et al. 2019). This method can break the degeneracy between the energy function and the formation rate, as long as the sample is large enough. If the energy function does not evolve with redshift, one can write  $\Phi(E, z)$  as  $\Phi(E, z) = \Psi(E)\rho(z)$ , where  $\Psi(E)$  is the isotropic energy function,  $\rho(z)$  is the FRB formation rate at  $z$ . However, the energy function  $\Psi(E(z))$  usually evolves with redshift  $z$  as  $\Phi(E, z) = \Psi(E(z))\rho(z)$  instead of  $\Phi(E, z) = \Psi(E)\rho(z)$ , and this degeneracy can be eliminated by  $g(z) = (1+z)^k$ , so  $\Phi(E, z) = \rho(z)\Psi(E(z)/g(z)) = \rho(z)\Psi(E_0)$ , where  $\Psi(E_0)$  is independent of redshift and represents the local energy function at  $z = 0$ . Then, the isotropic energy at redshift  $z = 0$  is  $E_0 = E(z)/g(z)$ , with  $E_0$  being independent of  $z$ . Observationally, the energy and the redshift of the CHIME FRBs are correlated as displayed in Figure 1. This may result from the instrumental effects and is not an intrinsic dependence. Thus, we need to reduce the observational bias and obtain the intrinsic correlation between  $E$  and  $z$  in advance.

Following some previous works (eg., Lynden-Bell 1971; Efron & Petrosian 1992; Deng et al. 2019; Liu et al. 2021; Zeng et al. 2021; Dong et al. 2022), we use the non-parametric method to derive the value of  $k$  (Efron & Petrosian 1992). For the  $i$ th data point  $(E_i, z_i)$  in the  $E - z$  plane of Figure 1 (b), we define the set  $J_i$  and  $J'_i$  as

$$J_i = \left\{ j \mid E_j > E_i, E_{j,\min}(z) < E_i (\text{or } z_j < z_{i,\max}) \right\} \quad (3)$$

and

$$J'_i = \left\{ j \mid z_j < z_i, z_{j,\max} > z_i (\text{or } E_j > E_{i,\min}) \right\},$$

where  $z_{i,\max}$  is the maximum redshift at which a FRB with the energy  $E_i$  can be detected by CHIME, the parameter  $E_{i,\min}$  is the minimum energy which can be detected at redshift  $z_i$ . The region  $J_i$  is shown in Figure 1 (b) as a black rectangle, and the number of FRBs contained in this region is  $N_i$ . Similarly, the number of FRBs in  $J'_i$  (see Figure 1 (b) red rectangle) is denoted as  $M_i$ . Independence between  $E_i$  and  $z_i$  would make the number of the sample

$$R_i = \text{number} \left\{ j \in J_i \mid z_j \leq z_i \right\} \quad (4)$$

uniformly distribute between 1 and  $N_i$  (Efron & Petrosian 1992). The expected mean and the variance are  $E_i = (N_i + 1)/2$  and  $V_i = (N_i - 1)^2/12$ , respectively.

The statistic  $\tau$  used to test the dependence between energy and redshift is defined as

$$\tau \equiv \sum_i \frac{(R_i - E_i)}{\sqrt{V_i}}. \quad (5)$$

If energy and redshift don't have any correlations, the  $\tau$  statistic gives  $\tau = 0$ , we can then make the transformation  $E(z) \rightarrow E_0 = E(z)/g(z)$  and vary  $k$  until  $\tau \rightarrow 0$ , as well as the error is reported in  $1\sigma$  confidence level (when  $\tau = \pm 1$ ). Figure 2 (a) shows the variation of the  $\tau$  value with  $k$  and returns  $k = 5.23^{+0.19}_{-0.20}$  for  $\tau = 0$  within  $1\sigma$  confidence band. Then we apply the energy evolution form of  $g(z) = (1+z)^{5.23}$  to remove the evolution effect, the de-evolved energy can be expressed as  $E_0 = E(z)/(1+z)^{5.23}$  and the distribution of  $E_0$  and  $z$  is shown in Figure 2 (b).

### 4. The energy function evolved or de-evolved with redshift

Through  $M_i$  and  $N_i$  depicted in Figure 1, we now derive the de-evolved energy function  $\Psi(E_0)$  and the cumulative redshift distribution  $\Phi(z)$  by the following nonparametric method (Lynden-Bell 1971; Efron & Petrosian 1992),

$$\Psi(E_{0,i}) = \prod_{j < i} \left( 1 + \frac{1}{N_j} \right), \quad (6)$$

and

$$\phi(z_i) = \prod_{j < i} \left( 1 + \frac{1}{M_j} \right), \quad (7)$$

where  $j < i$  means that the energy  $E_{0,j}$  is greater than  $E_{0,i}$  in Eq. (6) and the FRB has a redshift  $z_j$  less than  $z_i$  in Eq. (7).

Subsequently, the FRB formation rate  $\rho(z)$  can be determined by the following formula

$$\rho(z) = \frac{d\phi(z)}{dz} (1+z) \left( \frac{dV(z)}{dz} \right)^{-1}, \quad (8)$$

where the factor  $(1+z)$  denotes the correction for the effect of cosmic time dilation. The differential comoving volume  $dV(z)/dz$  is taken in the following form (Sun et al. 2015; Qiang et al. 2022)

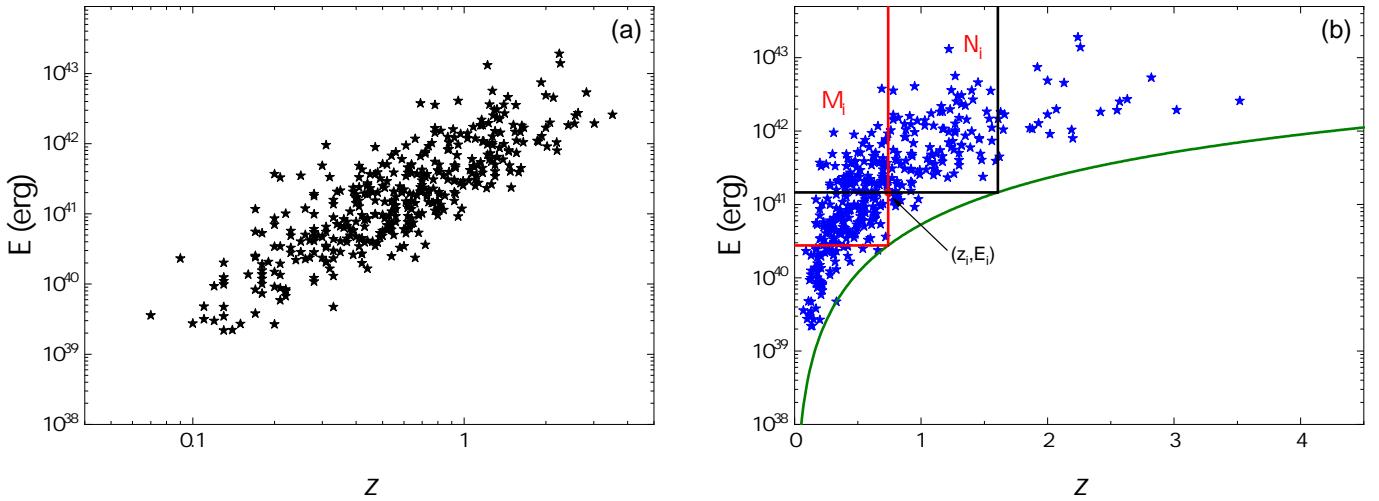

$$\frac{dV(z)}{dz} = \frac{c}{H_0} \frac{4\pi D_L^2}{(1+z)^2 \sqrt{\Omega_m(1+z)^3 + \Omega_\Lambda}}, \quad (9)$$

for a flat  $\Lambda$ CDM model.

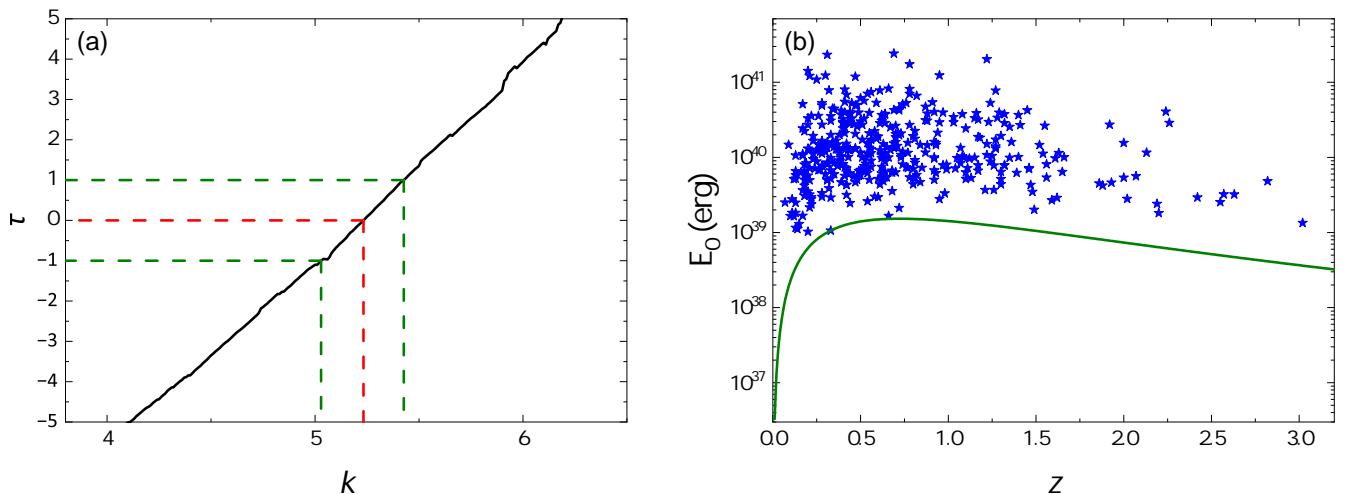

Using the new data set ( $N_j$ ), one can obtain the normalized cumulative energy function  $\Psi(E_0)$  in Figure 3, where the de-evolved energy function can be described by a broken power law as

$$\Psi(E_0) \propto \begin{cases} E_0^{-0.38 \pm 0.01}, & E_0 < E_b \\ E_0^{-2.01 \pm 0.12}, & E_0 \geq E_b \end{cases}, \quad (10)$$

where the broken energy is about  $E_b = 2.1 \times 10^{40}$  erg, which is roughly consistent with some previous results (e.g., Deng et al. 2019). It is worth noting that the energy function only represents the “local” form at  $z = 0$ . The energy function at a given redshift  $z$  should be  $\Psi(E_0)(1+z)^{5.23}$  in the observer frame and roughly break at  $E_b(1+z)^{5.23}$ .

**Fig. 1.** The energy – redshift relations of 396 CHIME FRBs. The solid (green) curve shows the truncation boundary due to the instrumental fluence limit of 0.41 Jy ms. Panels (a) and (b) are different in the X-axis forms.

**Fig. 2.** (a): Variation of the  $\tau$  parameter with the power law index  $k$  of the energy evolution.  $\tau = 0$  means no correlation which gives the best value of  $k = 5.23_{-0.20}^{+0.19}$  for the assumed power law form with  $1\sigma$  confidence level. The red dashed line represents the best fit for  $\tau = 0$  and the green dashed lines stand for the  $1\sigma$  errors. (b):The distribution of the de-evolved energy  $E_0 = E(z)/(1+z)^{5.23}$  of 396 FRBs above the truncation line or fluence limit denoted by the solid line.

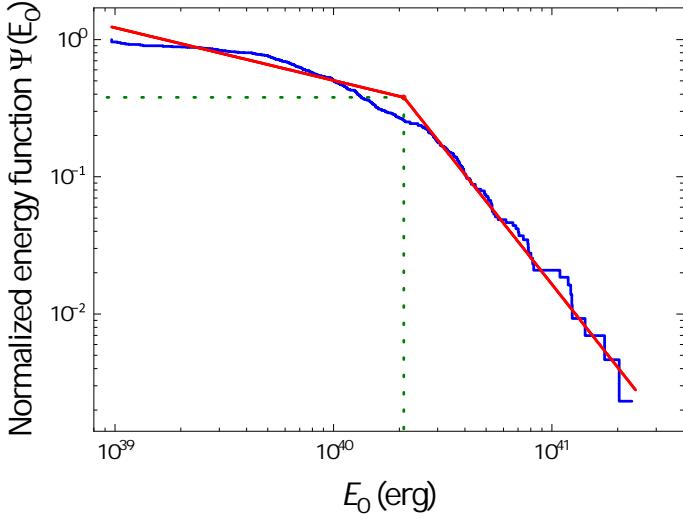

## 5. The redshift distribution and formation rate evolution

Figure 4 (a) shows the normalized cumulative redshift distribution. We also get the differential distribution  $d\phi(z)/dz$  of redshift in Figure 4 (b), where it is found that  $(1+z)d\phi(z)/dz$  increases quickly at low redshift of  $z \leq 0.5$ , and then quickly decreases with redshift at the region of  $z \geq 0.5$ . Now, we use Eq. (8) to estimate the FRB formation rate and plot its relation with redshift in Figure 5. It can be obviously found that the formation rate of FRBs does not match the SFR at all. In particular, it exceeds the SFR at the low redshift end, which is very similar to the situation of GRBs discovered in many previous works (e.g. Dong et al. 2022, 2023). Observationally, the formation rate can be simply fitted by a power-law form of

$$\rho(z) = 29.516_{-1.97}^{+2.11} \times (1+z)^{-4.73 \pm 0.08} \quad (\text{M}_\odot \text{ Mpc}^{-3} \text{ yr}^{-1}), \quad (11)$$

as shown in Figure 5, where we can obviously find that the detection rate of FRBs does not match the SFR completely. The higher event rate of FRBs at lower redshifts demonstrates that FRBs most probably originate from older stellar populations in the nearby universe.

However, there are some evidences that FRBs might follow the global SFR of the universe. For example, FRB 20180916B and FRB 20201124A are detected from the star-forming regions (Marcote et al. 2020; Piro et al. 2021). Simultaneously, there are more evidences showing that at least parts of FRBs originate from magnetars (Bochenek et al. 2020; CHIME/FRB Collaboration et al. 2020; Heintz et al. 2020; Li & Zhang 2020; Mereghetti et al. 2020; Bochenek et al. 2021), which means that the formation rate of such kind of FRBs would follow the cosmic SFR (CHIME/FRB Collaboration et al. 2021; Zhang et al. 2021; James et al. 2022), like the samples of Parkes and ASKAP FRBs (Deng et al. 2019; Zhang et al. 2021; James et al. 2022).

**Fig. 3.** The survival line (blue step line) of  $\Psi(E_0)$  normalized to unity at the lowest energy is fitted by a broken power-law function (red solid line) with  $\alpha_1 = -0.38 \pm 0.01$ ,  $\alpha_2 = -2.01 \pm 0.12$ ,  $E_b = 2.1 \times 10^{40}$  erg for a reduced Chi-square of  $\chi^2 = 1.70$ .

Noticeably, these previous results may be largely influenced by their limited FRB samples, causing the difference between our estimations of FRB rates especially in the low redshift range.

It is worth emphasizing that our sample is already large enough and the non-parametric method used in this work does not rely on any priori assumptions. Our conclusions support the recent finding that the CHIME FRB population does not track the SFR (Hashimoto et al. 2022; Qiang et al. 2022; Zhang & Zhang 2022). A significantly delayed FRB distribution tracking the star formation is also found to be reasonable (see, e.g., Cao et al. 2018a; Zhang et al. 2021; Qiang et al. 2022; Zevin et al. 2022; Panther et al. 2023; Gordon et al. 2023). This indicates that FRBs could be produced from multiple progenitor channels (e.g., Zhang & Zhang 2022; Gordon et al. 2023) or they might originate from distinct sub-populations (e.g., Good et al. 2023; Michilli et al. 2023; Nimmo et al. 2023; Zhang et al. 2023a), such as repeaters versus non-repeaters (Petroff et al. 2022), or long versus short FRBs (Li et al. 2021b). However, our recent investigations based on intensity function show that the repeating and non-repeating FRBs have similar event rates on the whole sky, hinting that both types of FRBs could share the same physical origin (Li et al. 2017; Zhang et al. 2022).

## 6. The local event rate of CHIME FRBs

According to Deng et al. (2019), the number of CHIME FRBs can be determined by

$$N = \frac{\Omega T}{4\pi} \int_{z_1}^{z_2} dz \int_{E_{min}}^{E_{max}} \frac{\Phi(E, z)}{1+z} \frac{dV}{dz} dE, \quad (12)$$

where  $z_1$  and  $z_2$  are the minimum and maximum redshifts respectively,  $E_{min}$  and  $E_{max}$  represent the lowest and highest energies of FRBs in the sample.  $\Phi(E, z)$  is the total energy function defined in Section 3. When the variables  $E$  and  $z$  are separated, we can utilize  $\Phi(E, z) = \Psi(E_0)\rho(z)$  and Equation (10) to rewrite the FRB number as

$$N = \frac{\Omega T}{4\pi} \int_{z_1}^{z_2} dz \int_{E_{0,min}}^{E_{0,max}} \frac{\Psi(E_0)\rho(z)}{1+z} \frac{dV}{dz} dE_0, \quad (13)$$

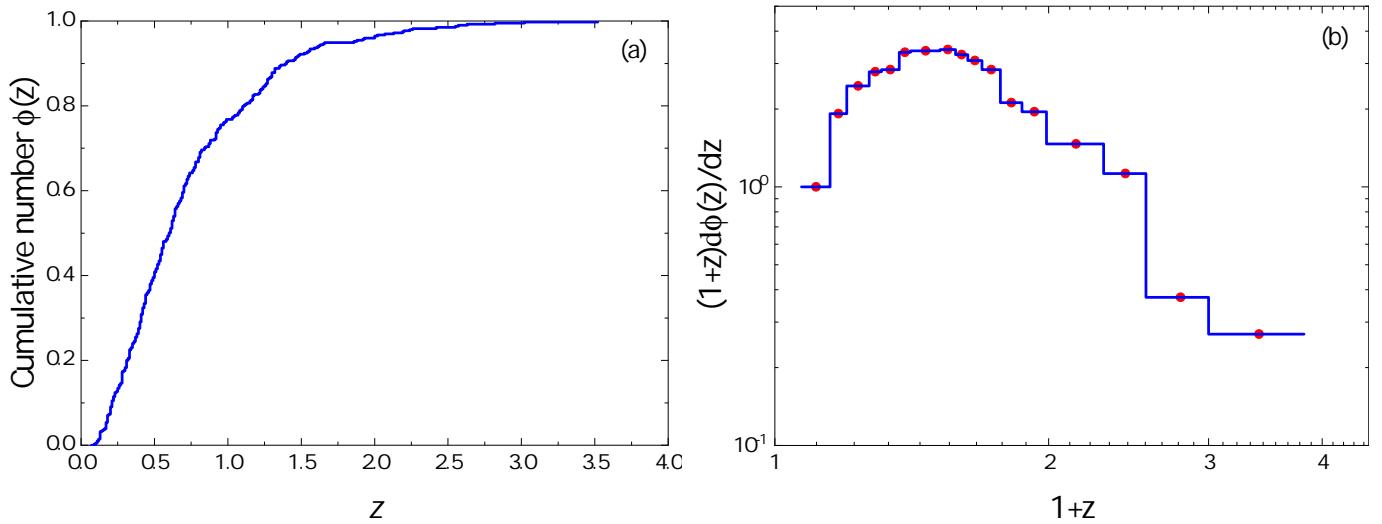

in which  $\rho(z)$  and  $dV/dz$  have been individually given in Equations (8) and (9). The event rate of FRBs at a given redshift  $z$  can be expressed by  $\rho(z) \propto \rho(0)(1+z)^{-4.73}$ , where  $\rho(0)$  denotes the local event rate of FRBs at redshift of  $z = 0$ . Here, we adopt the CHIME’s effective observation period of 214.8 days (CHIME/FRB Collaboration et al. 2021), the field-of-view (FOV) of  $200 \text{ deg}^2$  (CHIME/FRB Collaboration et al. 2018) and the total number of  $N = 396$  to estimate the local FRB rate to be  $\rho(0) \approx 1.25 \times 10^4 \text{ Gpc}^{-3}\text{yr}^{-1}$ , which is roughly consistent with the rates of Parkes FRBs (Cao et al. 2018b), but slightly larger than that of ASKAP FRBs (Deng et al. 2019). Surprisingly, our result is slightly smaller than the local event rate of high energy CHIME FRBs (Zhang et al. 2023b). These discrepancies could be caused by the instrumental biases and some potential sample selection effects. Interestingly, it was shown by simulations that the local rate of White Dwarf (WD) mergers can be a few  $10^4 \text{ Gpc}^{-3}\text{yr}^{-1}$  that is in good agreement with the observed SN Ia rate (Li et al. 2011). One can also convert the local CHIME FRB rate of our sample to a full sky rate as  $\rho(0) \approx 396/93 \times 1.25 \times 10^4 / 365 \approx 146 \text{ sky}^{-1}\text{day}^{-1}$  smaller than the official value of  $\sim 820 \text{ sky}^{-1}\text{day}^{-1}$  and other rates (see e.g. Zhang et al. 2022), which may be biased by the larger fraction of low redshift FRBs or the nonuniformity of CHIME FRB samples. Note that the FOV of  $200 \text{ deg}^2$  and 93 out of 396 FRBs within 1 Gpc have been utilized for the calculation.

## 7. CONCLUSIONS

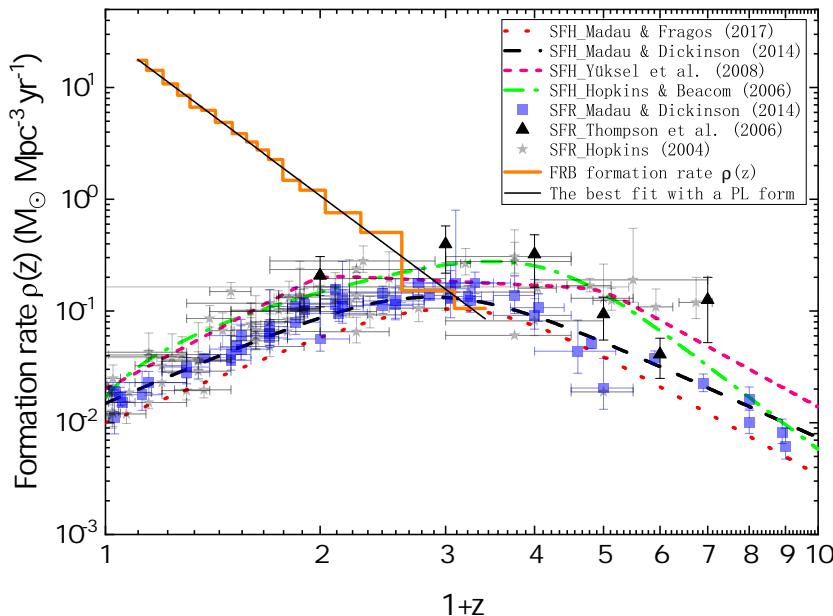

We have applied the non-parametric method to investigate the energy function and formation rate of a homogeneous sample of 396 CHIME FRBs. Our results are model-independent and not suffered from the instrumental difference. The following principle conclusions can be drawn:

- We build a tight correlation between the total energies and redshifts of CHIME FRBs to be  $E_0 \sim E(z)/(1+z)^{5.23}$  by using the Kendall’s  $\tau$  statistic method.
- After removing the evolution of energy with redshift, we derive the isotropic energy function that can be well fitted by a broken power-law form with two indices ( $-0.38 \pm 0.01$  and  $-2.01 \pm 0.12$ ) and a broken energy of  $E_b \approx 2.1 \times 10^{40}$  erg.
- The FRB formation rate is found to decrease quickly. The best fit is  $\rho(z) \propto (1+z)^{-4.71 \pm 0.12}$  for  $z < 0.77$  and  $\rho(z) \propto (1+z)^{-4.21 \pm 0.31}$  for  $z \geq 0.77$ , and also we have obtained the local FRB rate as  $\rho(0) \approx 1.25 \times 10^4 \text{ Gpc}^{-3}\text{yr}^{-1}$ , which is roughly consistent with some previous results.
- We find that the FRB formation rate does not match with the SFR and the former exceeds the latter at lower redshifts. It indicates that most FRBs are probably contributed by the older stellar populations in the universe.
