(Dated: June 21, 2024)

We derive selection rules in optical absorption and Raman scattering spectra, that can determine the parity of pairing order parameters under inversion symmetry in two classes of clean superconductors: (i) chiral superconductors with strong spin-orbit couplings, (ii) singlet superconductors with negligible spin-orbit couplings. Experimentally, the inversion parity of pair wave functions can be determined by comparing the “optical gap” Δ_{op} in Raman and optical spectroscopy and the “thermodynamic gap” 2Δ in specific heat measurements, and the selection rules apply when $\Delta_{\text{op}} > 2\Delta$. We demonstrate the selection rules in superconductivity in models of (i) doped Weyl semimetals and (ii) doped graphene. Our derivation is based on the relation between pairing symmetry and fermion projective symmetry group of a superconductor. We further derive similar selection rules for two-dimensional superconductors with 2-fold rotational symmetry, and discuss how they apply to the superconducting state in magic-angle twisted bilayer graphene.

I. INTRODUCTION

As a best known quantum phenomenon in the macroscopic scale, superconductivity has many important technological applications ranging from quantum sensing[1] and quantum computing[2] to improving energy efficiency[3]. Spontaneously breaking the $U(1)$ charge conservation symmetry in the material, superconductors (SCs) exhibit a Landau-type off-diagonal long range order, characterized by a pairing order parameter $\Delta(\mathbf{k})$ in the momentum space (labeled by crystal momentum \mathbf{k}), also known as the pair wave function[4–6]. Most metals and alloys are conventional superconductors, where superconductivity is induced by the electron-phonon coupling and well described by the BCS theory, with an isotropic s -wave spin-singlet pairing order parameter. On the other hand, other types of interactions can give rise to non- s -wave unconventional superconductivity[5] with many desirable properties, such as high temperature d -wave superconductivity in cuprates with strong Coulomb repulsions[7–10], and topological superconductivity in materials with strong spin-orbit interactions[11, 12]. Unique applications can arise from unconventional superconductivity, such as fault-tolerant topological qubits based on Majorana zero modes[13–16] (MZMs).

However, to identify an unconventional superconductor, the experimental determination of the pairing symmetry has been a challenging task for almost every candidate material[4–6, 17], for the following reason. To determine the symmetry of the complex pair wave function $\Delta(\mathbf{k})$, one needs information of both its magnitude $|\Delta(\mathbf{k})|$ and the phase $\arg[\Delta(\mathbf{k})]$. Most common experimental probes are believed to be only sensitive to the magnitude of the order parameter, such as penetration depth, specific heat, thermal transport, angle-resolved photoemission and NMR spectroscopy[6, 17, 18]. On the other hand, phase-sensitive measurements, able to probe the relative phase of the order parameter as a function of \vec{k} -space direction, require more complicated de-

vices and measurements, such as SQUID interferometry and tricrystal/tetracrystal magnetometry[6, 17], which are not easily accessible to many candidate materials. Therefore, new experimental probes that can sharply determine the symmetry representation of the pairing order parameter $\Delta(\mathbf{k})$ are highly desirable.

As one simplest manifestation of pairing symmetry, in the presence of inversion symmetry, the pairing order parameter can either be an even or an odd function of \vec{k} , corresponding to (conventional) even-parity and (unconventional) odd-parity superconductivity. Odd-parity superconductors are often associated with exotic physical properties, such as MZMs in the vortex core of chiral p -wave superconductors in two dimensions (2d)[19]. In this work, we derive a set of selection rules in optical absorption and in Raman spectroscopy, for the particle-hole continuum of Bogoliubov quasiparticle excitations in a superconductor, that allows us to sharply distinguish odd-parity from even-parity superconductors. These selection rules are derived using the correspondence between the pairing symmetry and fermion Projective Symmetry Group (PSG) in a SC, recently established in Ref.[20]. We demonstrate how to use the selection rules to detect the parity of pair wave functions in two systems: (i) chiral superconductors in doped Weyl semimetals, as an example of chiral superconductors with strong spin-orbit couplings (SOCs), (ii) singlet superconductors in doped graphene, as an example of singlet superconductors with $SU(2)$ spin rotational symmetries. For superconductors in 2d materials, we establish similar selection rules for the parity of pair wavefunction under a 2-fold rotational symmetry $C_{2,z}$, and discuss how they apply to superconductors in magic-angle twisted bilayer graphenes (MATBG)[21].

Symmetry actions on Bogoliubov quasiparticles In the optical absorption and Raman spectroscopies of a SC, the dominating electronic contribution comes from a pair of Bogoliubov quasiparticles with opposite momenta, known as the “particle-hole continuum” of a SC. To obtain their selection rules under a crystalline symmetry such as inversion, we need to understand how the Bo-

goliubov quasiparticles transform under crystalline symmetry operations. This is captured by the following Bogoliubov de Gennes (BdG) Hamiltonian for the SC phase:

$$\hat{H}_{\text{BdG}} = \hat{H}_0 + (\hat{H}_{\text{pair}} + h.c.), \quad (1)$$

$$\hat{H}_0 = \sum_{\alpha\beta;\mathbf{k}} \hat{c}_{\mathbf{k}\alpha}^\dagger h_{\alpha\beta}(\mathbf{k}) \hat{c}_{\mathbf{k}\beta} \quad (2)$$

$$\hat{H}_{\text{pair}} = \sum_{\alpha\beta;\mathbf{k}} \hat{c}_{\mathbf{k}\alpha}^\dagger \Delta_{\alpha\beta}(\mathbf{k}) \hat{c}_{-\mathbf{k}\beta}^\dagger \quad (3)$$

where \hat{H}_0 describes the normal-state band structure $h_{\alpha,\beta}(\mathbf{k})$ of electrons, and \hat{H}_{pair} describes the Cooper pairing of electrons. We use α, β to generally denote the spin, orbital and sublattice indices of electrons. Under a crystalline symmetry operation \hat{g} , the electron transforms as $\hat{g} c_{\mathbf{k}\alpha} \hat{g}^{-1} = [U_0^g(\mathbf{k})]_{\alpha\beta}^\dagger \hat{c}_{g\mathbf{k}\beta}$ where $U_0^g(\mathbf{k})$ is a unitary matrix. Although the normal-state band structure preserves the \hat{g} symmetry as $[\hat{g}, \hat{H}_0] = 0$, the pairing term \hat{H}_{pair} in an unconventional SC is generally NOT invariant under crystal symmetry \hat{g} [20, 22, 23].

In this paper we restrict ourselves to the SCs without spontaneous breaking of spin rotational symmetries, i.e. the normal state and SC shares the same global (spin rotation) symmetry group. In this case, due to the broken $U(1)$ charge symmetry, the pairing term \hat{H}_{pair} can acquire a phase $e^{i\Phi_g}$ under crystal symmetry \hat{g} [20, 22, 23]:

$$U_0^g(\mathbf{k})\Delta(\mathbf{k})[U_0^g(-\mathbf{k})]^T = e^{i\Phi_g} \Delta(\hat{g}\mathbf{k}) \quad (4)$$

The phase factors $\{e^{i\Phi_g} | \hat{g} \in X\}$ form a one-dimensional irreducible representation (irrep) of the crystal symmetry group X , satisfying $e^{i(\Phi_g + \Phi_h)} = e^{i\Phi_{gh}}$ for any $g, h \in X$.

For the order-2 inversion symmetry $\hat{\Gamma}$ of interests to this work, we have $e^{i\Phi_\Gamma} = \pm 1$ and hence

$$U_0^\Gamma(\mathbf{k})\Delta(\mathbf{k})[U_0^\Gamma(-\mathbf{k})]^T = \pm\Delta(-\mathbf{k}). \quad (5)$$

where \pm signs correspond to even- and odd-parity under inversion symmetry respectively. Note that due to nontrivial transformations of the pairing wavefunction $\Delta(\mathbf{k})$ shown above, the BdG Hamiltonian is not invariant under the normal-state symmetry \hat{g} anymore. Instead, \hat{H}_{BdG} preserves a combination \hat{g}' of normal state crystal symmetry $\hat{g} \in X$ and a $U(1)$ charge rotation $e^{-i\Phi_g \hat{F}/2}$ where \hat{F} is the total fermion number:

$$\begin{aligned} \hat{g}' \hat{H}_{\text{BdG}} (\hat{g}')^{-1} &= \hat{H}_{\text{BdG}}, \quad \hat{g}' = e^{-i\Phi_g \hat{F}/2} \hat{g}; \\ \hat{g}' c_{\mathbf{k},\alpha} (\hat{g}')^{-1} &= e^{-i\Phi_g/2} [U_0^g(\mathbf{k})]_{\alpha\beta}^\dagger \hat{c}_{\hat{g}\mathbf{k},\beta}. \end{aligned} \quad (6)$$

In the case of order-2 inversion symmetry Γ , we have

$$(\Gamma')^2 = e^{-i\Phi_\Gamma \hat{F}} = (\pm 1)^{\hat{F}} \quad (7)$$

In other words, inversion squares to ± 1 when acting on a fermion operator in a SC with an even/odd-parity under inversion symmetry. They correspond to two different fermion PSGs[20] with distinct physical properties. In particular, we consider Bogoliubov quasiparticles (BQPs) $\{\gamma_{\mathbf{k},a}\}$ of the BdG Hamiltonian (1):

$$\hat{H}_{\text{BdG}} = \sum_{\mathbf{k},a} E_a(\mathbf{k}) \gamma_{\mathbf{k},a}^\dagger \gamma_{\mathbf{k},a}, \quad E_a(\mathbf{k}) \geq 0. \quad (8)$$

where a generally labels the spin/band indices of BQPs.

In optical absorption and Raman spectroscopy experiments, the dominant electronic contribution comes from a pair of BQPs with opposite momenta. Considering inversion symmetry Γ' in (7) of the SC phase, we can always choose a gauge so that

$$\Gamma' \begin{pmatrix} \gamma_{\mathbf{k},a}^\dagger \\ \gamma_{-\mathbf{k},a}^\dagger \end{pmatrix} (\Gamma')^{-1} = \begin{pmatrix} \gamma_{-\mathbf{k},a}^\dagger \\ \pm \gamma_{\mathbf{k},a}^\dagger \end{pmatrix} \quad (9)$$

This relation and fermi statistics together lead to a gauge-invariant inversion eigenvalue for a pair of BQPs with opposite momenta:

$$\Gamma'(\gamma_{\mathbf{k},a}^\dagger \gamma_{-\mathbf{k},a}^\dagger) (\Gamma')^{-1} = \mp (\gamma_{\mathbf{k},a}^\dagger \gamma_{-\mathbf{k},a}^\dagger) \quad (10)$$

In a chiral SC with strong spin-orbit couplings (SOCs), there is no Kramers degeneracy for BQPs at a generic momentum, and therefore the BQP pair with the lowest energy comes from the same Bogoliubov band $a = 0$. Therefore inversion quantum number (10) directly applies to the low frequency spectroscopy of a chiral SC. On the other hand, in a singlet SC with $SU(2)$ spin rotational symmetries, each Bogoliubov band has a 2-fold spin degeneracy $\alpha, \beta = \uparrow, \downarrow$ at every momentum. In this case, the spin-singlet BQP pair with the lowest energy has the following gauge-invariant inversion eigenvalue:

$$\Gamma'(\epsilon^{\alpha\beta} \gamma_{\mathbf{k},0,\alpha}^\dagger \gamma_{-\mathbf{k},0,\beta}^\dagger) (\Gamma')^{-1} = \pm (\epsilon^{\alpha\beta} \gamma_{\mathbf{k},0,\alpha}^\dagger \gamma_{-\mathbf{k},0,\beta}^\dagger) \quad (11)$$

Here, band index 0 in the subscript means the lowest BdG band with a non-negative energy. Below we show how the gauge-invariant inversion eigenvalues in (10)-(11) lead to selection rules in optical absorption and Raman spectroscopy, which can be used to detect the inversion parity of pairing order parameters.

II. OPTICAL ABSORPTION SPECTROSCOPY

It was believed that optical spectroscopy via inelastic light scattering is sensitive only to the magnitude of the pairing order parameter[6, 24]. Although Higgs modes have been proposed to characterize and differentiate different pairing symmetries in unconventional superconductors[25], they have proven difficult to be observed in superconductors due to the nonlinear light-Higgs coupling[26]. On the other hand, the particle-hole continuum above the 2Δ threshold, created by breaking a Cooper pair and exciting two Bogoliubov quasiparticles, is the most important electronic responses to inelastic optical probes in a superconductor[24]. Below we demonstrate that the aforementioned symmetry transformations on BQPs lead to distinct optical selection rules for the particle-hole continuum in SCs.

The dominant component of light-matter interaction is the coupling of vector potential \mathbf{A} of light with the particle current operator $\hat{\mathbf{j}}$ of the system:

$$\hat{H}_{\text{int}} = -e\mathbf{A}(t) \cdot \hat{\mathbf{j}} \quad (12)$$

The optical absorption rate is given by the transition rate in time-dependent perturbation theory, where the 1st-order perturbation theory leads to

$$\begin{aligned} \sum_f w_{i \rightarrow f} &= \frac{2\pi}{\hbar} \sum_f |\langle f | \hat{H}_{\text{int}} | i \rangle|^2 \delta(E_f - E_i - \omega) \\ &= \frac{\pi e^2}{\epsilon_0 \omega} \sum_f |\langle i | \mathbf{e} \cdot \hat{\mathbf{j}} | f \rangle|^2 \delta(\omega + E_i - E_f) \end{aligned} \quad (13)$$

$$= \frac{\hbar}{\epsilon_0} \omega \cdot \text{Im}\chi(\omega) = \frac{\hbar}{\epsilon_0} \text{Re}\sigma(\omega) \quad (14)$$

where \mathbf{e} is the polarization vector of the light, $\chi(\omega) = \chi' + i\chi''$ and $\sigma(\omega)$ are the electric susceptibility and optical conductivity in linear response theory. At zero temperature, the initial state $|i\rangle$ is the SC ground state $|0\rangle$, and the final state $|f\rangle$ is obtained by creating a zero-momentum BQP pair on the ground state so that

$$\begin{aligned} \frac{\hbar}{\epsilon_0} \omega \text{Im}\chi(T=0, \omega) &= \frac{\pi e^2}{2\epsilon_0 \omega} \sum_{\mathbf{k}, a, b} |\langle 0 | \mathbf{e} \cdot \hat{\mathbf{j}} (\gamma_{\mathbf{k}, a}^\dagger \gamma_{-\mathbf{k}, b}^\dagger) | 0 \rangle|^2 \\ &\cdot \delta(\omega - E_a(\mathbf{k}) - E_b(-\mathbf{k})) + \dots \end{aligned} \quad (15)$$

where \dots stands for other contributions from e.g. Higgs modes or 4 Bogoliubov quasiparticles. If we label the bottom of the lowest and 2nd lowest BQP bands as Δ and Δ' respectively with $\Delta < \Delta'$, for the following frequency

Parity of $\Delta(\mathbf{k})$	$(\hat{\Gamma}')^2$	Parity of $\gamma_{\mathbf{k}, a}^\dagger \gamma_{-\mathbf{k}, a}^\dagger$	$\text{Im}\chi(2\Delta < \omega < \Delta + \Delta')$	$I_{\text{Raman}}(2\Delta < \omega < \Delta + \Delta')$

TABLE III. Selection rules for the parity of pairing wavefunctions under rotational symmetry $\hat{C}'_{2,z}$ in 2d chiral SCs with strong SOCs, in optical absorption spectroscopy and Raman spectroscopy.

Below we demonstrate the absorption selection rules in two examples. First we study superconductivity in doped magnetic Weyl semimetals[28, 29] as an example of chiral SCs with strong SOC. Specifically we consider two different pairing symmetries[30] of zero-momentum Cooper pairs, one with even parity under inversion and another with odd parity, in the 2-band model of an inversion-symmetric Weyl semimetal that breaks time re-

range

$$\omega < \Delta + \Delta' \quad (16)$$

only a pair of BQPs from the lowest Bogoliubov band $a = b = 0$ contributes, which corresponds to

$$|f\rangle = \gamma_{\mathbf{k}, 0}^\dagger \gamma_{-\mathbf{k}, 0}^\dagger |0\rangle \quad (17)$$

in a chiral SC with a strong SOC, or

$$|f\rangle = \epsilon^{\alpha\beta} \gamma_{\mathbf{k}, 0, \alpha}^\dagger \gamma_{-\mathbf{k}, 0, \beta}^\dagger |0\rangle \quad (18)$$

in a singlet SC with $SU(2)$ symmetry. Since the current operator $\hat{\mathbf{j}}$ is odd under inversion symmetry

$$\Gamma' \hat{\mathbf{j}} (\Gamma')^{-1} = -\hat{\mathbf{j}} \quad (19)$$

Eqs. (10)-(11) immediately lead to optical absorption selection rules summarized in Table I and II, for chiral SCs with SOC and singlet SCs without SOC respectively. It is worth mentioning that the above absorption selection rules recover one well-known conclusion in the single-band ($\Delta' \rightarrow \infty$) limit: there is no optical absorption for $\omega > 2\Delta$ in single-band clean s -wave SCs[27].

versal symmetry[28]. As shown in Fig. 1, while the electronic contribution to light absorption remains finite at all frequency $\omega > 2\Delta = 0$ for an even-parity SC, it vanishes at a low frequency ($\omega < \Delta + \Delta'$ in Fig. 1) for an odd-parity SC. Here, for the even-parity SC, the energy gaps are $\Delta = 0.5t, \Delta' = 3.5t$. Here, t is the hopping integral defined in the appendix, which is the characteristic energy scale of our models. The odd-parity SC

FIG. 1. $T = 0$ absorption spectra of two chiral SCs with opposite pairing parity under inversion symmetry, in a 2-band model of doped Weyl semimetals[28, 29] that breaks time reversal symmetry. (Left) $\Delta = 0.5t$, $\Delta' = 3.5t$; (Right) $\Delta = 0$, $\Delta' = 0.5t$.

state is gapless ($\Delta = 0$), due to the nontrivial topological charge of the Weyl points[31]. The energy gaps are $\Delta = 0, \Delta' = 0.5t$. Remarkably in the odd-parity SC, independent of the direction of light polarization \mathbf{e} [30], there is no optical absorption even above the thermodynamic gap 2Δ , and the associated "optical gap" is lower bounded by $\Delta_{\text{op}} \geq \Delta + \Delta'$, consistent with selection rules in Table I.

Next we study spin-singlet superconductivity in doped graphene, as an example of singlet SCs with $SU(2)$ spin rotational symmetry. Specifically we consider two different pairing symmetries[30] of zero center-of-mass momentum, in the honeycomb lattice model of graphene with a finite chemical potential. Energy gaps for even-parity case are $\Delta = 0.22t, \Delta' = 0.75t$, and for odd-parity case are $\Delta = 1.1t, \Delta' = 4.2t$. The absorption rate as a function of light frequency ω is shown in Fig. 2. The odd-parity SC is gapless, and its absorption rate is nonzero for all frequency. In contrast, the absorption rate of the even-parity SC is identically zero above the bulk thermodynamic gap $2\Delta \approx 0.4t$, until the light frequency reaches an "optical gap" of $\Delta_{\text{op}} \approx 1.2t > \Delta + \Delta'$. This demonstrates the selection rules for even-parity singlet SCs.

The selection rules for optical absorption (and conductivity) in Table I and II have been previously discussed by Ref.[23] in the context of Altland-Zirnbauer classes[32] of quadratic BdG Hamiltonians. Compared to Ref.[23] which is based on particle-hole symmetry of the quadratic BdG Hamiltonian, in the current work we derived the selection rules using the relation between fermion PSGs and SC pairing symmetry[20, 22], which generally applies to interacting fermions. In an interacting fermion system, since the Altland-Zirnbauer symmetry classes does not directly apply to a many-body interacting Hamiltonian, the symmetry group characterized by the fermion PSGs is required to properly describe the full symmetry of the superconducting phase. For example, in the case of global symmetries, class D corresponds to chiral superconductors w/o spin rotational symmetries (e.g. due to a strong spin-orbit coupling), class C corresponds to chiral singlet superconductors with $SU(2)$ spin rotational symmetries, while class CI corresponds to singlet supercon-

ductors with time reversal symmetry. As we have shown above, the parity of the pairing order parameter of these 3 symmetry types can be detected by selection rules, in the presence of inversion symmetry. Therefore our formulation enables a generalization of the single-particle results of Ref.[23] to correlated systems with well-defined Bogoliubov quasiparticles $\gamma_{\mathbf{k},a}$, in a way similar to how a fermi liquid generalizes a non-interacting fermi gas. Moreover, compared to Ref.[23], our results point to a clear protocol to detect the SC pairing symmetry through a comparison of the optical gap and the thermodynamic gap 2Δ , which can be obtained by e.g. measuring the specific heat. Based on the above relation between fermion PSG and the SC pairing symmetry, below we further derive new selection rules in Raman spectroscopy.

FIG. 2. $T = 0$ absorption spectra of two singlet SCs with opposite pairing parity under inversion symmetry, in the honeycomb lattice model of doped graphene. (Left) $\Delta = 0.22t$, $\Delta' = 0.75t$; (Right) $\Delta = 1.1t$, $\Delta' = 4.2t$.

III. RAMAN SPECTROSCOPY

The Raman differential scattering cross section is given by the Fermi's golden rule[24, 33, 34]:

$$\frac{\partial^2 \sigma}{\partial \Omega \partial \omega_s} = \frac{e^4 \omega_s}{\hbar \omega_i} \sum_f |\langle f | e_i^\alpha e_s^\beta M^{\alpha\beta} | i \rangle|^2 \delta(\omega + E_i - E_f) \quad (20)$$

where e_i and e_s are the polarization vectors of incident and scattered light. ω_i, ω_s are the frequencies of the incident and of the scattered light respectively, and $\omega = \omega_i - \omega_s$. \hat{M} is Raman scattering operator given by

$$\begin{aligned} \langle f | e_i^\alpha e_s^\beta M^{\alpha\beta} | i \rangle &= e_i^\alpha e_s^\beta \langle f | \sum_{\mathbf{k}, \alpha, \beta} c_{\mathbf{k}, \alpha}^\dagger \frac{\partial^2 h_{\alpha, \beta}(\mathbf{k})}{\partial k^\alpha \partial k^\beta} c_{\mathbf{k}, \beta} | i \rangle \\ &+ \sum_v \left[\frac{\langle f | (\vec{j} \cdot \hat{\mathbf{e}}_f) | v \rangle \langle v | (\vec{j} \cdot \hat{\mathbf{e}}_i) | i \rangle}{E_v - E_i - \omega_i} + \frac{\langle f | (\vec{j} \cdot \hat{\mathbf{e}}_i) | v \rangle \langle v | (\vec{j} \cdot \hat{\mathbf{e}}_f) | i \rangle}{E_v - E_i + \omega_s} \right]. \end{aligned} \quad (21)$$

where E_v labels the energy of eigenstate $|v\rangle$. Clearly \hat{M} operator is even under inversion symmetry.

As a result, following the same logic as in the discussions of absorption spectroscopy, we can obtain the selection rules for Raman intensity $I_{\text{Raman}}(\omega)$ shown in the last column of Table I-II. Note that the inversion symmetry selection rules for Raman spectra is opposite to those for absorption spectra. In particular, for chiral SCs with

strong SOCs, the Raman intensity vanishes even above the thermodynamic gap 2Δ for an even-parity pairing wavefunction.

FIG. 3. $T = 0$ Raman spectra of two chiral SCs with opposite pairing parity under inversion symmetry, in a 2-band model of doped Weyl semimetals. (Left) $\Delta = 0.5t$, $\Delta' = 3.5t$; (Right) $\Delta = 0$, $\Delta' = 0.5t$.

FIG. 4. $T = 0$ Raman spectra of two singlet SCs with opposite pairing parity under inversion symmetry, in the honeycomb lattice model of doped graphene. (Left) $\Delta = 0.22t$, $\Delta' = 0.75t$; (Right) $\Delta = 1.1t$, $\Delta' = 4.2t$.

We also calculate Raman spectra for both our models. For the model of Weyl semimetals without $SU(2)$, we show results in Fig. 3. For even-parity case, the selection rule requires the scattering to be zero below $\Delta + \Delta'$. For odd-parity case, there is no selection rule, and the spectrum is not zero at any frequency because the band is gapless ($\Delta = 0$).

The Raman spectra for SC on honeycomb lattice with $SU(2)$ symmetry is shown in Fig. 4. For even-parity case, the spectrum is not zero above energy gap $2\Delta = 0.44t$ because there is no selection rule. For the odd-parity case, the spectrum is zero between energy gap $2\Delta = 2.2t$ and $\Delta + \Delta' = 5.3t$, as requested by selection rule.

IV. $C_{2,z}$ SYMMETRY IN 2D SUPERCONDUCTORS

For a quasi-two-dimensional (2d) SC, the previous derivation of selection rules for inversion symmetry Γ naturally generalizes to 2-fold rotation $C_{2,z}$ whose rotation axis is perpendicular to the 2d plane. There is one subtlety though, from nontrivial $C_{2,z}$ symmetry actions

on electrons in the normal state: $\hat{C}_{2,z}^2 = 1$ for $SU(2)$ -symmetric 2d systems with a weak SOC, or $\hat{C}_{2,z}^2 = (-1)^{\hat{F}}$ for 2d systems with a strong SOC. In a 2d singlet SC with $SU(2)$ spin rotational symmetry, the 2-fold rotation $C_{2,z}$ simply reverses both x and y coordinates in the 2d space, in the same way as the inversion symmetry. This leads to the same set of selection rules in Table II for 2d singlet SCs with $C_{2,z}$ symmetry. On the other hand, for 2d chiral SCs with a strong SOC, due to the nontrivial $\hat{C}_{2,z}^2 = (-1)^{\hat{F}}$ action in the normal state, the $C_{2,z}$ selection rules are opposite to those of inversion symmetry, as summarized in Table III.

Below we briefly discuss one example where such selection rules apply. By analyzing a collection of existing experimental data, Ref.[35] recently argued that the structure of SC pairing order parameters in magic-angle twisted bilayer graphene (MATBG) is almost uniquely determined except for its orbital parity under $C_{2,z}$ symmetry, which is either even (d -wave) or odd (p -wave). In the normal state of MATBG, $C_{2,z}^2 = (-1)^{\hat{F}}$ arises from spontaneously generated SOC due to spin-valley locking[35], and therefore the selection rules in Table III directly point to experimental signatures to determine the pairing symmetry of the chiral SC in MATBG[20].

Discussions and Outlook Using the correspondence between pairing symmetry and fermion PSG in SCs obtained recently[20, 22], we derived selection rules in optical absorption and Raman scattering spectroscopy for two classes of clean SCs: (i) chiral SCs with strong SOC and (ii) singlet SCs with weak SOC. In particular, the selection rules in case (i) can be applied to distinguish the inversion parity of pairing wavefunctions in many candidate materials of chiral superconductors[36], such as SrRuO₄[37, 38], UPt₃[39] and UTe₂[40]. We derive a similar set of selection rules for 2-fold rotational symmetry $C_{2,z}$ in 2d SCs, and discuss how they can be applied to distinguish the proposed d -wave from p -wave SCs in MATBG[35].

While this work focused on clean SCs, it is well known that optical absorption exists above the thermodynamic gap 2Δ in dirty SCs[41–43]. Since impurities break the crystalline inversion or rotation symmetry, the selection rules derived here for clean SCs do not apply in the dirty limit, giving rise to nonzero optical and Raman responses above 2Δ . In presence of impurities, one natural question is, how does the optical responses in absorption and Raman scattering depend on the frequency ω above the thermodynamic gap 2Δ ? For example, even- and odd-parity SCs may have different power-law dependence on $\omega - 2\Delta$ in optical absorption and in Raman intensity. Another future direction is to generalize the current work to selection rules of optical and Raman responses in topological orders, e.g. Z_2 spin liquids which are related to a SC by gauging the fermion parity symmetry Z_2^F . We leave these questions for future studies.

Appendix A: Chiral superconductivity in a 2-band model of doped Weyl semimetal

In this example, we demonstrate the phenomenon of selection rule by studying superconductivity in a doped Weyl semi-metal. In this example of a doped Weyl semimetal, time reversal symmetry is broken, while inversion and C_4 rotational symmetry along z axis are preserved. To be more specific, we consider nearest neighbour terms in a $3D$ cubic lattice model with 2 orbitals on each site, and the Hamiltonian[28, 29] in the momentum space is:

$$h_0(\mathbf{k}) = t \sin(k_x)\sigma^x + t \sin(k_y)\sigma^y + m(2 - \cos(k_x) - \cos(k_y))\sigma^z + t_z(\cos(k_z) - \cos(Q))\sigma^z + \mu\sigma^0 \quad (\text{A1})$$

Here, $t(k)$ means it is hopping part of the Hamiltonian, t, m, t_z, μ are real numbers. Two dimensions of matrix σ represents 2 orbitals. This Hamiltonian generally has Weyl nodes at $\mathbf{k} = (0, 0, \pm Q)$.

Inversion and C_4 rotational symmetries act on fermions in the following way:

$$\begin{aligned} I : c_{s,\mathbf{k}} &\rightarrow \sigma_{s,s'}^z c_{s',-\mathbf{k}} \\ C_4 : c_{s,(k_x,k_y,k_z)} &\rightarrow S_{s,s'} c_{s',(k_y,-k_x,k_z)} \end{aligned} \quad (\text{A2})$$

where σ^z and $S = \frac{1}{\sqrt{2}}(\sigma^0 + i\sigma^z)$ is action of C_4 on orbitals. Inversion and C_4 rotation act both on space (momentum is changed) and spin (matrix σ) degrees of freedoms. In the form of matrix, we can write

$$\begin{aligned} I : h_0(-\mathbf{k}) &\rightarrow \sigma^z h_0(\mathbf{k}) \sigma^z \\ C_4 : h_0(-k_y, k_x, k_z) &\rightarrow S^\dagger h_0(k_x, k_y, k_z) S \end{aligned} \quad (\text{A3})$$

To have superconductivity, we add pairing term $\Delta_{s_1,s_2}^\dagger(k) c_{s_1,-k} c_{s_2,k} + h.c.$. Inversion and rotational symmetry acting on the pairing terms in the following way:

$$\begin{aligned} I : \Delta(-\mathbf{k}) &\rightarrow \sigma^z \Delta(\mathbf{k}) \sigma^z \\ C_4 : \Delta(-k_y, k_x, k_z) &\rightarrow S^\dagger \Delta(k_x, k_y, k_z) S^* \end{aligned} \quad (\text{A4})$$

Under this transformation, different pairing terms have different quantum number and they are listed in Table IV.

$\Delta(\mathbf{k})$	I	C_4	I'^2	$C_4'^4$	$I' C_4' I'^{-1} C_4'^{-1}$
$\cos k_z i\sigma^y$	-1	1	-1	-1	1
$\sin k_z \sigma^x$	1	1	1	-1	1
$\sin k_z (\sigma^0 + \sigma^z)$	-1	-i	-1	1	1
$\sin k_z (\sigma^0 - \sigma^z)$	-1	i	-1	1	1
$(\cos k_x + \cos k_y) i\sigma^y$	-1	1	-1	-1	1
$(\cos k_x - \cos k_y) i\sigma^y$	-1	-1	-1	-1	1
$(\sin k_x + i \sin k_y) \sigma^x$	1	-i	1	1	1
$(\sin k_x - i \sin k_y) \sigma^x$	1	i	1	1	1
$(\sin k_x + i \sin k_y) (\sigma^0 + \sigma^z)$	-1	-1	-1	-1	1
$(\sin k_x - i \sin k_y) (\sigma^0 + \sigma^z)$	-1	1	-1	-1	1
$(\sin k_x + i \sin k_y) (\sigma^0 - \sigma^z)$	-1	1	-1	-1	1
$(\sin k_x - i \sin k_y) (\sigma^0 - \sigma^z)$	-1	-1	-1	-1	1

TABLE IV. For each pairing term, its quantum number under operators I and C_4 are listed. The true symmetry I', C_4' have different symmetry fractionalization classes, the corresponding quantum number $I'^2, C_4'^4, I' C_4' I'^{-1} C_4'^{-1}$ are listed.

In this table I and C_4 are the operators defined before. We show the quantum number of each term in the table. However, as discussed in the main text, symmetries of the BdG Hamiltonian are not I and C_4 , but different by a phase operator $\exp(i\Phi\hat{F})$. Here \hat{F} is fermion particle number operator. This phase operator transforms Δ as

$$\Delta(\mathbf{k}) \rightarrow \Delta(\mathbf{k}) \exp(i2\Phi) \quad (\text{A5})$$

Note that this phase operator does not influence hopping terms. When pairing terms are not invariant under I and C_4 , we redefine $I' = I \exp(i\Phi\hat{F})$ and $C'_4 = C_4 \exp(i\Phi\hat{F})$ so that I' and C'_4 are explicit symmetry of pairing terms. Then inversion symmetry I' and rotational symmetry C'_4 are still preserved for the system. Different choices of terms lead to different symmetries fractionalizations characterized by I'^2 , C'^4_4 and $I'C'_4I'^{-1}C'^{-1}_4$. We calculate these number for each pairing term and list them in Table IV.

The BdG Hamiltonian in the Nambu basis $\psi_{\mathbf{k}} = (c_{\mathbf{k},\uparrow}, c_{\mathbf{k},\downarrow}, c^\dagger_{-\mathbf{k},\uparrow}, c^\dagger_{-\mathbf{k},\downarrow})^T$ is written as

$$\hat{H}_{\text{BdG}} = \frac{1}{2} \sum_{\mathbf{k}} \psi_{\mathbf{k}}^\dagger H_{\mathbf{k}} \psi_{\mathbf{k}} \quad (\text{A6})$$

where

$$H_{\mathbf{k}} = \begin{bmatrix} h_0(\mathbf{k}) & \Delta(\mathbf{k}) \\ \Delta^\dagger(\mathbf{k}) & -h_0^T(-\mathbf{k}) \end{bmatrix} \quad (\text{A7})$$

We have suppressed the orbital index a in the fermion operator $c_{\mathbf{k},a,\uparrow/\downarrow}$. In other words, we use $c_{\mathbf{k},\uparrow}$ to denote a spinor $c_{\mathbf{k},\uparrow} = (c_{\mathbf{k},1,\uparrow}, \dots, c_{\mathbf{k},N,\uparrow})$ where N is the number of bands in the system.

Due to the particle-hole symmetry, the eigenvectors $u_{\mathbf{k},a}$ of above BdG Hamiltonian matrix $H_{\mathbf{k}}$ at momenta $\pm\mathbf{k}$ are related by:

$$u_{-\mathbf{k},a} = \tau_x u_{\mathbf{k},a}^* \quad (\text{A8})$$

$$H_{\mathbf{k}} u_{\mathbf{k},a} = E_a(\mathbf{k}) u_{\mathbf{k},a}, \quad H_{-\mathbf{k}} u_{-\mathbf{k},a} = -E_a(\mathbf{k}) u_{-\mathbf{k},a}. \quad (\text{A9})$$

where (τ_x, τ_y, τ_z) are Pauli matrices for the Nambu index. Therefore the eigenvectors of BdG Hamiltonian $H_{\mathbf{k}}$ include both ‘‘quasiparticles’’ $u_{\mathbf{k},a}$ with eigenvalue $E_a(\mathbf{k}) \geq 0$ and ‘‘quasiholes’’ $\tau_x u_{-\mathbf{k},b}^*$ with eigenvalue $-E_b(-\mathbf{k}) \leq 0$. Their associated eigenmode operators are

$$\gamma_{\mathbf{k},a}^\dagger = \sum_{\alpha} u_{\mathbf{k},a,\alpha} \psi_{\mathbf{k},\alpha}^\dagger; \quad \gamma_{-\mathbf{k},b} = \sum_{\alpha} u_{-\mathbf{k},b,\alpha}^* \psi_{-\mathbf{k},\alpha}. \quad (\text{A10})$$

and the BdG Hamiltonian is diagonalized in the following form:

$$\hat{H}_{\text{BdG}} = \frac{1}{2} \sum_{\mathbf{k},a} \left[E_a(\mathbf{k}) \gamma_{\mathbf{k},a}^\dagger \gamma_{\mathbf{k},a} - E_a(-\mathbf{k}) \gamma_{-\mathbf{k},a} \gamma_{-\mathbf{k},a}^\dagger \right] \quad (\text{A11})$$

Next, to study optical spectrum of this model, we need to first obtain the electric current operator. The particle current operator can be calculated as derivative of hopping part of Hamiltonian.

$$\hat{\mathbf{j}} = \sum_{\mathbf{k}} (c_{\mathbf{k},\uparrow}^\dagger, c_{\mathbf{k},\downarrow}^\dagger) \mathbf{j}(\mathbf{k}) (c_{\mathbf{k},\uparrow}, c_{\mathbf{k},\downarrow})^T \quad (\text{A12})$$

with

$$\mathbf{j}(\mathbf{k}) = \frac{\partial h_0(\mathbf{k})}{\partial \mathbf{k}} \quad (\text{A13})$$

Writing the current operator in the BdG basis $\psi_{\mathbf{k}} = (c_{\mathbf{k},\uparrow}, c_{\mathbf{k},\downarrow}, c^\dagger_{-\mathbf{k},\uparrow}, c^\dagger_{-\mathbf{k},\downarrow})^T$, we have

$$\mathbf{J}(\mathbf{k}) = \begin{bmatrix} \frac{\partial h_0}{\partial \mathbf{k}}(\mathbf{k}) & 0 \\ 0 & -\frac{\partial h_0^T}{\partial \mathbf{k}}(-\mathbf{k}) \end{bmatrix} \quad (\text{A14})$$

and the current operator is

$$\hat{\mathbf{j}} = \frac{1}{2} \sum_{\mathbf{k}} \psi_{\mathbf{k}}^\dagger \mathbf{J}(\mathbf{k}) \psi_{\mathbf{k}} \quad (\text{A15})$$

The electric current is odd under inversion. Current in z direction \hat{j}_z is invariant under C'_4 and $\hat{j}_x + i\hat{j}_y$ and $\hat{j}_x - i\hat{j}_y$ are two irreducible representation that carries phase $-i, i$ under C'_4 rotation. Specifically,

$$\begin{aligned}
I'(\hat{j}_x + i\hat{j}_y)I'^{-1} &= -(\hat{j}_x + i\hat{j}_y) \\
I'(\hat{j}_x - i\hat{j}_y)I'^{-1} &= -(\hat{j}_x - i\hat{j}_y) \\
I'\hat{j}_zI'^{-1} &= -\hat{j}_z \\
C'_4(\hat{j}_x + i\hat{j}_y)C'^{-1}_4 &= -i(\hat{j}_x + i\hat{j}_y) \\
C'_4(\hat{j}_x - i\hat{j}_y)C'^{-1}_4 &= i(\hat{j}_x - i\hat{j}_y) \\
C'_4\hat{j}_zC'^{-1}_4 &= -\hat{j}_z
\end{aligned} \tag{A16}$$

We calculate current operator from (A12) as follows:

$$\begin{aligned}
j_x(\mathbf{k}) &= t \cos k_x \sigma^x + m \sin k_x \sigma^z \\
j_y(\mathbf{k}) &= t \cos k_y \sigma^y + m \sin k_y \sigma^z \\
j_z(\mathbf{k}) &= -t_z \sin k_z \sigma^z
\end{aligned} \tag{A17}$$

We show two examples.

Case 1: $I'^2 = 1, C'^4_4 = -1$. In this case $I' = I, C'_4 = C_4$ are not changed. There is the only one pairing term invariant according to Table. IV:

$$\Delta(\mathbf{k}) = \Delta_1 \sin k_z \sigma^x \tag{A18}$$

Here Δ_1 is a complex number. Parameters are set as $Q = \pi/2, \mu = 3.5t, m = 0.5t, t_z = t, \Delta_1 = t$.

Case 2: $I'^2 = -1, C'^4_4 = -1$. And $I' = I \exp(i\pi\hat{F}/2), C'_4 = C_4$. In this case, all pairing terms with phase $-1, 1$ under transformation of I, C_4 are invariant under I' and C'_4 . According to Table. IV, pairing terms in the Hamiltonian are

$$\Delta(\mathbf{k}) = \Delta'_1 \cos k_z i\sigma^y + \Delta'_2 (\cos k_x + \cos k_y) i\sigma^y + \Delta'_3 (\sin k_x + i \sin k_y) (\sigma^0 - \sigma^z) + \Delta'_4 (\sin k_x - i \sin k_y) (\sigma^0 + \sigma^z) \tag{A19}$$

Parameters are set as $Q = \pi/2, \mu = 0.3t, m = t, t_z = t, \Delta'_i = 0.2t$.

FIG. 5. Energy band of electrons. Special points in Brillouin Zone are $\Gamma : (0, 0, 0), Z : (0, 0, \pi), R : (0, \pi, \pi), A : (\pi, \pi, \pi)$. Gapless point between Γ and Z is part of a sphere of gapless points. For odd-parity case, the energy gap of first band is $\Delta = 0.5t$ and the energy gap of the second band is $\Delta' = 3.5t$. For even-parity case, the energy gap of first band is 0 and the energy gap of the second band is $\Delta' = 0.5t$.

We show gapless electron bands in Fig. 5 and specific heat in Fig. 6. Specific heat is calculated by

$$C = \frac{1}{V} \sum_i \frac{\epsilon_i^2 \exp(\epsilon_i/T)}{T^2 (1 + \exp(\epsilon_i/T))^2} \tag{A20}$$

FIG. 6. Specific heat versus temperature T . Even-parity case is gapped with $\Delta = 0.5t$ and specific heat is exponential function of $1/T$ at low temperature. Odd-parity case has gapless momentum points and specific heat is proportional to T^3 at low temperature.

where ϵ_i sums over all positive eigenvalues of the BdG Hamiltonian, index i including momentum index \mathbf{k} and band index a . V is the number of unit cells. Even-parity case is gapped and heat capacity is close to exponential function $\exp(-\Delta/T)$ at low temperature. Odd-parity case has gapless points and heat capacity scales as T^3 at low temperature.

We can calculate absorption spectrum exactly using Eq. 13. For mean-field Hamiltonian, $|f\rangle$ can only be two particle states. At zero temperature, optical absorption rate is calculated by the following equations

$$\begin{aligned}
\omega \text{Im}\chi(T=0, \omega) &= \frac{\pi e^2}{2\hbar\omega} \sum_f |\langle 0 | \mathbf{e} \cdot \hat{\mathbf{j}} | f \rangle|^2 \delta(\omega - E_f + E_0) \\
&= \frac{\pi e^2}{2\hbar\omega} \sum_{\mathbf{k}, a, b} |\langle 0 | \mathbf{e} \cdot \hat{\mathbf{j}} \gamma_{\mathbf{k}, a}^\dagger \gamma_{-\mathbf{k}, b}^\dagger | 0 \rangle|^2 \delta(\omega - E_a(\mathbf{k}) - E_b(-\mathbf{k})) \\
&= \frac{\pi e^2}{2\hbar\omega} \sum_{\mathbf{k}, a, b, \alpha, \beta} |\mathbf{e} \cdot \mathbf{J}^{\alpha, \beta}(\mathbf{k}) \langle 0 | \psi_{\mathbf{k}, \alpha}^\dagger \psi_{\mathbf{k}, \beta} \gamma_{\mathbf{k}, a}^\dagger \gamma_{-\mathbf{k}, b}^\dagger | 0 \rangle|^2 \delta(\omega - E_a(\mathbf{k}) - E_b(-\mathbf{k})) \\
&= \frac{\pi e^2}{2\hbar\omega} \sum_{\mathbf{k}, a, b, \alpha, \beta} |\mathbf{e} \cdot \mathbf{J}^{\alpha, \beta}(\mathbf{k}) \langle 0 | \psi_{\mathbf{k}, \alpha}^\dagger \gamma_{-\mathbf{k}, b}^\dagger | 0 \rangle \langle 0 | \psi_{\mathbf{k}, \beta} \gamma_{\mathbf{k}, a}^\dagger | 0 \rangle|^2 \delta(\omega - E_a(\mathbf{k}) - E_b(-\mathbf{k}))
\end{aligned} \tag{A21}$$

Here, we apply the general formula on the first line onto BdG system. Since our current operators are only up to quadratic order of fermion operators, we only excite two quasi-particles at the same time. So, final state is specified as $\gamma_{\mathbf{k}, a}^\dagger \gamma_{-\mathbf{k}, b}^\dagger | 0 \rangle$ on the second line. a, b are the labels of bands of positive energy and α, β are the labels of basis of BdG Hamiltonian. In the last line, we use Wick's theorem and this is the only contraction consistent with quantum number momentum. Since we have obtained the eigenstates of the Hamiltonian by diagonalization as

$$\gamma_{\mathbf{k}, a}^\dagger = \sum_{\alpha} u_{\mathbf{k}, a, \alpha} \psi_{\mathbf{k}, \alpha}^\dagger \tag{A22}$$

where $u_{\mathbf{k}, a, \alpha}$ is the a -th eigenvector of BdG Hamiltonian (A7) at momentum \mathbf{k} , we can express the absorption rate more explicitly,

$$\omega \chi''(T=0, \omega) = \frac{\pi e^2}{2\hbar\omega} \sum_{a, b, \alpha, \beta} |u_{\mathbf{k}, b, \alpha} \mathbf{e} \cdot \mathbf{J}^{\alpha, \beta}(\mathbf{k}) u_{\mathbf{k}, a, \beta}^*|^2 \delta(\omega - E_a(\mathbf{k}) - E_b(-\mathbf{k})) \tag{A23}$$

Here, index a is summed over bands of positive energy $E_a(\mathbf{k})$, and index b is summed over bands of negative energy $E_b(\mathbf{k})$.

In Fig. 7, we show absorption spectrum of our model under a polarized beam of light. Figures on left and right represent two models and they reveal stark contrasts in the spectrum. Figures on the left ($I^2 = 1$) is normal, with

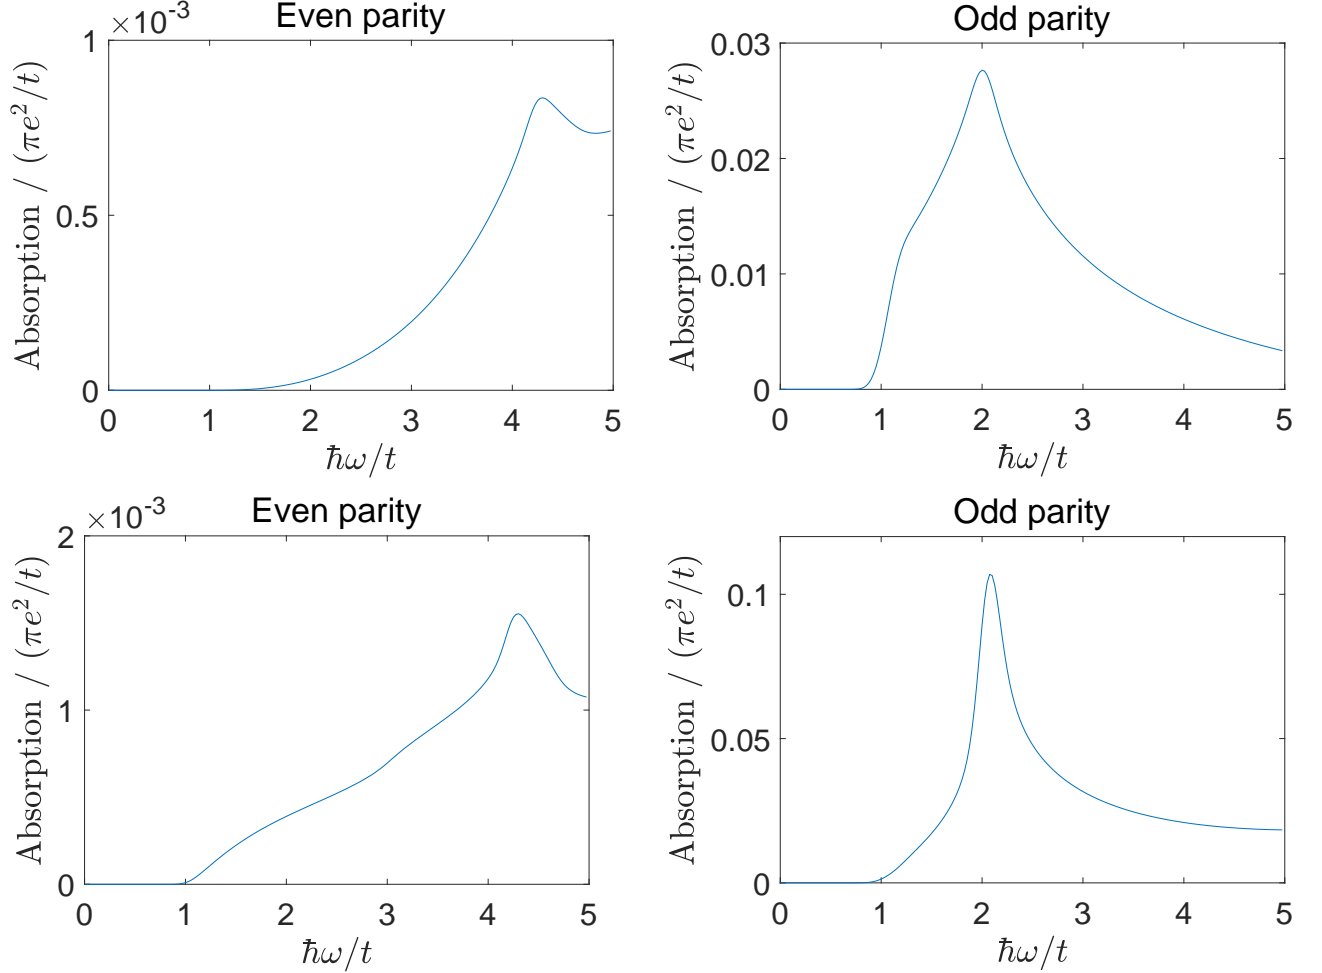

FIG. 7. Absorption spectrum are intensity I versus photon energy $\hbar\omega$. Spectrum is corresponding to models with $I^2 = 1$ and polarization in z direction (upper left) and x direction (bottom left). In comparison, we show the spectrum of model with $I^2 = -1$ and polarization in z direction (upper right) and x direction (bottom right).

non-zero amplitude above energy gap $2\Delta \approx t$. In contrast, spectrum on the right ($I^2 = -1$) is a flat line of zero at low energy above energy gap $2\Delta = 0$, only grow to finite above energy threshold $\Delta + \Delta' \approx 0.5t$, indicating selection rule of $I^2 = -1$. One detail is the spectrum is not zero even with ω a little bit higher than $0.5t$. That is because the band bottom of first and second band does not occur at the same momentum. This differences underscore the importance of inversion symmetry fractionalization on absorption spectrum of superconductors.

We also show Raman spectrum of both models in Fig. 8. We calculate Raman differential scattering cross section per volume from Eq. 20.

$$\frac{1}{V} \frac{\partial^2 \sigma}{\partial \Omega \partial \omega_s} = \frac{e^4}{\hbar V} \frac{\omega_s}{\omega_i} \sum_f |\langle f | e_i^\alpha e_s^\beta M^{\alpha\beta} | i \rangle|^2 \delta(\omega + E_i - E_f)$$

where V is the number of unit cells. This calculation is more complex, but can still be done accurately for mean-field theory. We make use of Eq. 21 and calculate expectation value for excitation of two particle states. This calculation is done by Wick's theorem similarly to the calculation of absorption spectrum. It is worth mentioning that four-particle states $|f\rangle$ has scattering amplitude M zero and do not contribute to raman scattering in mean-field calculation. Further details of this calculation refers to papers [24, 33, 34].

Raman spectrum has selection rule for even-parity case, which is opposite to the selection rule of absorption spectrum. In the even-parity case, Raman scattering is zero below $\Delta + \Delta' \approx 4t$, because of the selection rule. In the odd-parity case, Raman scattering is not zero at any frequency because the band is gapless.

FIG. 8. Differential scattering cross section of both incident and scattered light polarized in x direction. Figures are corresponding to $I^2 = 1$ (left) and $I^2 = -1$ (right).

Appendix B: Singlet superconductivity in doped graphene

Our second example is a 2D system on honeycomb lattice without spin orbital coupling, where $SU(2)$ spin rotational symmetry, space inversion and C_3 rotational symmetry are all preserved. With a beam of light, only a spin singlet pair of excitations at \mathbf{k} and $-\mathbf{k}$ are excited. Inversion symmetry can also have selection rules in this case. The spectrum is zero or not depends on whether inversion is $I'^2 = 1$ or -1 .

To be specific, if $I'^2 = 1$, we can choose a gauge such that under inversion I'

$$\begin{aligned} I' \gamma_{\mathbf{k},\uparrow} I'^{-1} &= \gamma_{-\mathbf{k},\uparrow} \\ I' \gamma_{\mathbf{k},\downarrow} I'^{-1} &= \gamma_{-\mathbf{k},\downarrow} \end{aligned} \quad (\text{B1})$$

This leads to the action of inversion on the excitation of singlet pair

$$I'(\gamma_{\mathbf{k},\uparrow}\gamma_{-\mathbf{k},\downarrow} - \gamma_{\mathbf{k},\downarrow}\gamma_{-\mathbf{k},\uparrow})I'^{-1} = \gamma_{-\mathbf{k},\uparrow}\gamma_{\mathbf{k},\downarrow} - \gamma_{-\mathbf{k},\downarrow}\gamma_{\mathbf{k},\uparrow} = \gamma_{\mathbf{k},\uparrow}\gamma_{-\mathbf{k},\downarrow} - \gamma_{\mathbf{k},\downarrow}\gamma_{-\mathbf{k},\uparrow}. \quad (\text{B2})$$

Therefore this excitation is even under inversion and there will be no absorption spectrum because current is odd $I' \hat{j} I'^{-1} = -\hat{j}$.

On the other hand, if $I'^2 = -1$, under a certain gauge, action of inversion on fermions are

$$\begin{aligned} I' \gamma_{\mathbf{k},\uparrow} I'^{-1} &= \gamma_{-\mathbf{k},\uparrow} \\ I' \gamma_{\mathbf{k},\downarrow} I'^{-1} &= -\gamma_{-\mathbf{k},\downarrow} \end{aligned} \quad (\text{B3})$$

we have one extra minus sign and excitation is odd under inversion. In this case, optical absorption is allowed.

With this general rule in mind, we write down a tight-binding model on honeycomb lattice explicitly. Total hamiltonian will still be in the form of Eq. A7 and A6. The only difference is operator $\Psi_{\mathbf{k}} = (c_{1,\mathbf{k},\uparrow}, c_{2,\mathbf{k},\uparrow}, c_{1,-\mathbf{k},\downarrow}^\dagger, c_{2,-\mathbf{k},\downarrow}^\dagger)^T$. Here label 1, 2 is sublattice number.

We consider only on-site and nearest neighbour terms. Due to the $SU(2)$ spin rotational symmetry, hopping terms between two sites can only be $t\hat{c}_{i,\uparrow}^\dagger\hat{c}_{j,\uparrow} + t\hat{c}_{i,\downarrow}^\dagger\hat{c}_{j,\downarrow} + h.c.$. It is even under link center inversion when t is real, and odd when t is imaginary. Pairing term can only be $\Delta\hat{c}_{i,\uparrow}\hat{c}_{j,\downarrow} - \Delta\hat{c}_{i,\downarrow}\hat{c}_{j,\uparrow} + h.c.$ and is even under permutation of i and j .

Hopping term of Hamiltonian is invariant under inversion and C_3 rotational symmetry:

$$\begin{aligned} I : h_0(-\mathbf{k}) &= \sigma^x h_0(\mathbf{k}) \sigma^x \\ C_3 : h_0((-k_2, k_1 - k_2)) &= S^\dagger h_0((k_1, k_2)) S \end{aligned} \quad (\text{B4})$$

where (k_1, k_2) are coordinates of the two reciprocal lattice vectors, meaning $\mathbf{k} = k_1\hat{k}_1 + k_2\hat{k}_2$. and S is matrix

$$S = \begin{bmatrix} 1 \\ e^{-ik_2} \end{bmatrix} \quad (\text{B5})$$

Symmetry allowed hopping terms are chemical potential and C_3 invariant real hopping between nearest neighbours. The general form of hopping term of Hamiltonian in momentum space is

$$h_0(\mathbf{k}) = \begin{bmatrix} \mu & t(1 + e^{ik_1} + e^{ik_2}) \\ t(1 + e^{-ik_1} + e^{-ik_2}) & \mu \end{bmatrix} \quad (\text{B6})$$

Here, t, μ are real numbers.

Next, current operator j^z is zero and $j^{x,y}$ are of the following form:

$$j_x(\mathbf{k}) = \begin{bmatrix} i\frac{t}{2}(e^{ik_1} - e^{ik_2}) \\ -i\frac{t}{2}(e^{-ik_1} - e^{-ik_2}) \end{bmatrix} \quad (\text{B7})$$

$$j_y(\mathbf{k}) = \begin{bmatrix} i\frac{\sqrt{3}t}{6}(-2 + e^{ik_1} + e^{ik_2}) \\ -i\frac{\sqrt{3}t}{6}(-2 + e^{-ik_1} + e^{-ik_2}) \end{bmatrix}$$

To write down pairing term of Hamiltonian explicitly, we need to fix inversion symmetry fractionalization. Below we consider two different kinds of pairing with $I^2 = \pm 1$.

Case 1: Inversion symmetry is $I' = I$, i.e. $I'^2 = 1$. Paring terms are invariant under symmetry I' and C_3 are onsite and nearest neighbour pairings of the same strength. Pairing terms in Hamiltonian are

$$\Delta(\mathbf{k}) = \begin{bmatrix} \Delta & \Delta_1(1 + e^{ik_1} + e^{ik_2}) \\ \Delta_1^*(1 + e^{-ik_1} + e^{-ik_2}) & \Delta \end{bmatrix} \quad (\text{B8})$$

Parameters are $\mu = 0.5t$, $\Delta = \Delta_1 = 0.5t$.

Case 2: Inversion symmetry is $I' = I \exp(i\pi\hat{F}/2)$, i.e. $I'^2 = -1$. Paring term in Hamiltonian is

$$\Delta(\mathbf{k}) = \Delta_2\sigma^z \quad (\text{B9})$$

Parameters are $\mu = t$, $\Delta_2 = 4t$.

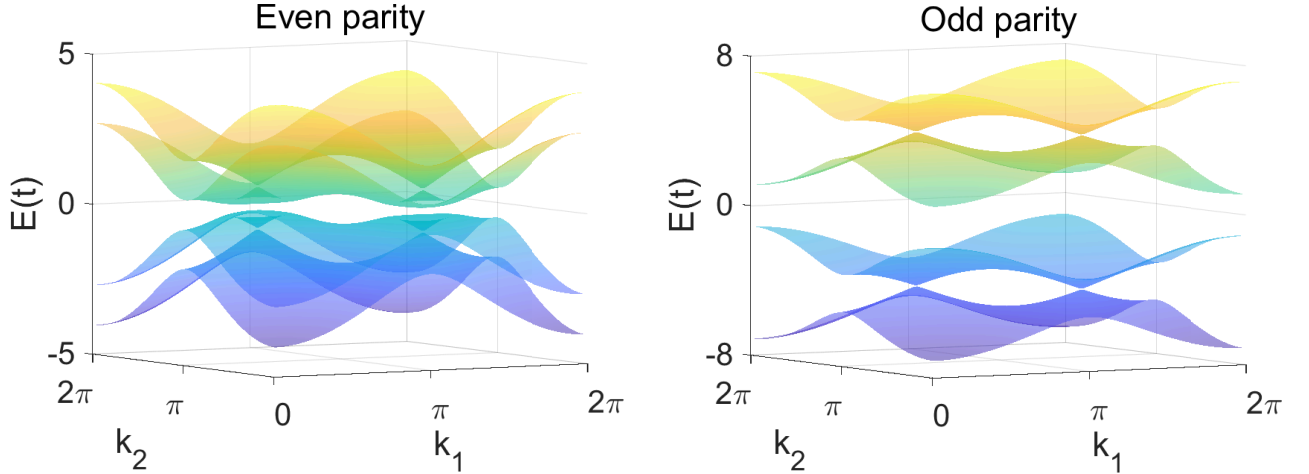

FIG. 9. Electron bands of two cases. Even parity case has a small gap. Energy gap of first band is $\Delta = 0.22t$ and second band gap is $\Delta' = 0.75t$. Odd parity case is gapless with first band gap $\Delta = 1.1t$ and gap of second band $\Delta' = 4.2t$.

Now we calculate observable quantities for this mode. The calculation is the same as the case without $SU(2)$ symmetry.

We show electron bands of two cases in Fig. 9 and specific heat in Fig.10. Both cases are gapped and specific heat shows $C \approx \exp(\Delta/T)$ at low temperature.

Absorption spectrum can be calculated based on Eq. A21. We use light polarized in x direction. Absorption spectrum of these two cases is shown in Fig. 11. On the left are models with $I'^2 = 1$, and on the right are $I'^2 = -1$.

FIG. 10. specific heat versus temperature T . Both the even-parity and odd-parity cases are gapped and specific heat are exponential function of $1/T$ at low temperature. Energy gap is $\Delta = 0.22t$ for even-parity case and $\Delta = 0.56t$ for odd-parity case.

FIG. 11. Absorption spectrum of models with $I^2 = 1$ and polarization in x direction (left). In comparison, we show the spectrum of model with $I^2 = -1$ and polarization in x direction (right).

It is clear the spectrum satisfies the selection rule for even-parity case. For even-parity case, spectrum is zero from energy gap $2\Delta = 0.44t$ to $\Delta + \Delta' = 0.97t$. For odd-parity case, the spectrum is not zero above energy gap $2\Delta = 2.2t$.

Raman spectrum is shown in Fig. 12. Odd-parity case shows selection rule. For even-parity case, scattering is not zero above energy gap 2Δ . But for odd-parity case, scattering is zero between energy gap 2Δ and $\Delta + \Delta'$.

Appendix C: Discussion of selection rules for general point group symmetries

In this section we systematically study possible selection rules in the case of a general point group. Our discussion includes the case of a unitary point group $G_{total} = G$ and the case of a magnetic point group that can be written as $G_{total} = G + AG$, where G is the unitary subgroup and AG is the coset corresponding to an anti-unitary symmetry A (including but not restricted to time-reversal symmetry).

In the same spirit as the case of inversion symmetry, we want to ask whether the strength of spectrum contributed by pair excitation from the lowest bands is constrained to vanish by symmetry. Specifically, we want to study for general momentum \mathbf{k} whether the following matrix element

$$\langle 0 | \hat{O} \gamma_{\mathbf{k},0}^\dagger \gamma_{-\mathbf{k},0}^\dagger | 0 \rangle \quad (C1)$$

FIG. 12. Differential scattering cross section of both incident and scattered light polarized in x direction. Figures are corresponding to $I^2 = 1$ (left) and $I^2 = -1$ (right).

is zero. Here \hat{O} represents current operator \hat{j} for absorption spectrum and Raman operator R for Raman spectrum. To study effect of symmetry on this, we study representation of pair excitation states

$$|f_{\mathbf{k}}\rangle = \gamma_{\mathbf{k},0}^\dagger \gamma_{-\mathbf{k},0}^\dagger |0\rangle \quad (\text{C2})$$

We decompose representation $\{|f_{g(\mathbf{k})}\rangle, g \in G_{total}\}$ into irreducible representations and check whether it can form a trivial representation after combining with operator \hat{O} . If it cannot, the matrix element transforms non-trivially under the symmetry group and is constrained to be zero-hence we have the selection rule. Otherwise, the spectrum does not vanish. In the special case of $\{|f_{\mathbf{k}}\rangle\}$ having all the representations of group G_{total} , there is no selection rule since the result does not depend on representations of operator \hat{O} .

Let's consider a general momentum \mathbf{k} . The only symmetries that does not change the $\mathbf{k}, -\mathbf{k}$ pair are inversion I , time-reversal symmetry T , and their product TI . In the following, we divide the problem into several situations and discuss in detail.

Case 1: Unitary point group G with inversion $I \notin G$. In this case, $\{|f_{\mathbf{k}}\rangle\}$ forms unitary representations of group G . Since inversion is not in G , all $g(\mathbf{k})$ are different and $\{|f_{\mathbf{k}}\rangle\}$ forms the $|G|$ dimensional fundamental representation of G . Since fundamental representation contains all irreducible representations, there is no selection rule in this case.

Case 2: Unitary point group G with inversion $I \in G$. In this case, every group element other than I will change momentum. So $\{|f_{\mathbf{k}}\rangle\}$ forms fundamental representation of G/Z_2^I (Z_2^I means Z_2 group of inversion). As representation of G , depending on $I = +1$ or $I = -1$, $\{|f_{\mathbf{k}}\rangle\}$ contains half of irreducible representations and misses the other half. This gives us the selection rule of inversion symmetry, as discussed before. There is no other selection rules.

Below we discuss the case of magnetic point groups with anti-unitary symmetries, where $\{|f_{\mathbf{k}}\rangle\}$ forms co-representation of the symmetry group [44]. One property we will use is the co-representations of $G + AG$ has a one to one correspondence with the representations of the unitary subgroup G . To see which co-representation is contained, we can simply forget about anti-unitary part and see which representation of G is contained.

Case 3: Magnetic point group $G_{total} = G + AG$ with inversion $I \notin G$. In this case, $\{|f_{\mathbf{k}}\rangle\}$ forms fundamental representation of G as in case 1. Therefore, it contains every co-representation of G_{total} and there is no selection rule.

Case 4: Magnetic point group $G_{total} = G + AG$ with inversion $I \in G$ and time-reversal $T \notin AG$. Following the same logic, this case is the same as case 2. $\{|f_{\mathbf{k}}\rangle\}$ contains half of irreducible co-representations of G_{total} depending on $I = +1$ or $I = -1$. This gives us selection rule of inversion symmetry.

Case 5: Magnetic point group $G_{total} = G + AG$ with inversion $I \in G$ and time-reversal $T \in AG$. This case is special because IT guarantees a two-fold band degeneracy. We have states

$$|f_{\mathbf{k},\alpha,\beta}\rangle = \gamma_{\mathbf{k},0,\alpha}^\dagger \gamma_{-\mathbf{k},0,\beta}^\dagger |0\rangle \quad (\text{C3})$$

where $\alpha, \beta = 1, 2$ is label of degenerate bands. We pick up states with $\alpha = 1, \beta = 2$ and realize $|f_{\mathbf{k},1,2}\rangle$ and $|f_{-\mathbf{k},1,2}\rangle$ are two different states. So, $\{|f_{\mathbf{k},1,2}\rangle\}$ forms fundamental representation of G . Since $\{|f_{\mathbf{k},1,2}\rangle\}$ already has all irreducible representations, the matrix element (C1) is non-zero and there is no selection rule in this case.

In conclusion, selection rules only arise for inversion symmetry (and $C_{2,z}$ symmetry in 2d, which acts like an inversion symmetry). No other crystal symmetries or magnetic crystal symmetries lead to nontrivial selection rules in optical and Raman spectroscopy.
