Abstract—Cyclic arbitrage chances exist abundantly among decentralized exchanges (DEXs), like Uniswap V2. For an arbitrage cycle (loop), researchers or practitioners usually choose a specific token, such as Ether (the cryptocurrency from Ethereum) as input, and optimize their input amount to get the net maximal amount of the specific token as arbitrage profit without considering the tokens' market price from the centralized markets (CEXs). By considering the tokens' prices from CEXs in this paper, the new arbitrage profit will be quantified as the product of the net number of a specific token we got from the arbitrage loop and its corresponding price in CEXs. The new arbitrage profit will be called monetized arbitrage profit in this paper. Based on this concept, we put forward three different strategies to maximize the monetized arbitrage profit for each arbitrage loop. The first strategy is called the MaxPrice strategy. Under this strategy, arbitrageurs start arbitrage only from the token with the highest CEX price. The second strategy is called the MaxMax strategy. Under this strategy, we calculate the monetized arbitrage profit for each token as input in turn in the arbitrage loop. Then, we pick up the most maximal monetized arbitrage profit among them as the monetized arbitrage profit of the MaxMax strategy. It is easy to prove that this strategy can bring more profit than the MaxPrice strategy. The third one is called the Convex Optimization strategy. In this strategy, we mapped the MaxMax strategy to a convex optimization problem and proved that the Convex Optimization strategy could get more profit in theory than the MaxMax strategy, which is proved again in a given example. We also proved that if no arbitrage profit exists according to the MaxMax strategy, then the Convex Optimization strategy can not detect any arbitrage profit, either. However, the empirical data analysis denotes that the profitability of the Convex Optimization strategy is almost equal to that of the MaxMax strategy, and the MaxPrice strategy is not reliable in getting the maximal monetized arbitrage profit compared to the MaxMax strategy.

*Index Terms*—Uniswap V2, cyclic arbitrage, arbitrage profit, arbitrage strategy, convex optimization

## I. INTRODUCTION

Decentralized finance (DeFi) has emerged as a promising field within the cryptocurrency ecosystem, leveraging blockchain technology to create financial applications that are open, transparent, and accessible to anyone. One key part of DeFi is decentralized exchanges (DEXs), which facilitate peerto-peer trading of tokens without the need for intermediaries [1]. Traders engage in transactions either amongst themselves or against a token liquidity pool, exchanging one token for another within the decentralized exchanges (DEXs). Among various DEXs, Uniswap is the largest DEX in terms of Total Value Locked (TVL) running on the Ethereum blockchain. Uniswap adopts the Automated Market Maker (AMM) mechanism [2], which facilitates tokens' trading using a liquidity pool without an intermediary market maker. Anyone can participate in the transaction activity on the Uniswap platform without approval from a centralized authority. There are two main kinds of participants on this platform, liquidity providers and liquidity takers. Liquidity providers are those who build a new liquidity pool or inject liquidity into an already existing liquidity pool. Liquidity takers, also called traders in this paper, are those who apply the liquidity pool to exchange tokens.

Under the AMM model, if a pair of tokens form a liquidity pool, then this pair of tokens can be exchanged with each other and the relative price (exchange rate) of this pair of tokens equals the ratio of their reservation balance in the same pool. The Uniswap V2 uses the constant product market maker (CPMM) for cryptocurrency exchange, which leads to price slippage that limits the arbitrage profit that traders can get.

As of October 2023, there have been more than ten thousand tokens and one hundred thousand liquidity pools by checking the on-chain data. Similar to the foreign exchange market (Forex) where triangular arbitrage [3] exploits exchange rate differences between different currency pairs, extensive research has shown that Uniswap provides abundant arbitrage opportunities due to the price discrepancies of tokens across various liquidity pools [1], [4]. For example, [4] found that the revenue of the most exploitable arbitrage opportunity is higher than 1 Ether for each block from May 2020 to April 2021, and almost three hundred thousand loop transactions within eleven months. [5] also used the Bellman-Ford-Moore algorithm to detect the arbitrage loops.

After an arbitrage loop is found, researchers usually only target a specific token, like Ether, to calculate the corresponding arbitrage profit. We call this strategy the traditional strategy in this paper. For example, [4], [5] took this strategy to calculate the arbitrage profit starting and backing to Ether for all arbitrage loops.

By considering each token's price from centralized exchanges (CEXs), we introduced the concept of monetized arbitrage profit which is quantified as the product of the net number of a specific token we got from the arbitrage loop as profit and its corresponding price in CEXs. For example, for an arbitrage loop starting from token A and back to A again  $(A \rightarrow B \cdots \rightarrow A)$ , if we get  $\pi_A$  unit of token A as profit at most by input token A in the arbitrage loop and its price in CEXs is  $P_A$ , then the monetized arbitrage profit of starting from token A is  $\pi_A P_A$ . If we start arbitrage from different tokens, then the monetized arbitrage profits are also different (e.g.  $\pi_B P_B$ ). So, after arbitrage loops were found, a question is whether they got maximal monetized arbitrage profits.

Based on this consideration, we put forward several different strategies to maximize the monetized arbitrage profit for each arbitrage loop. Researchers or practitioners may also think that the maximal monetized arbitrage profit can be obtained if arbitrageurs always start arbitraging from the token with the highest CEX price in the arbitrage loop. We call this strategy the MaxPrice strategy which is just like the traditional arbitrage strategies in the implementation process and is our first strategy. We will show that the MaxPrice is not reliable in getting the maximal monetized arbitrage profit in an example and by empirical data from Uniswap V2. The second strategy is called the MaxMax strategy. Under this strategy, not only one specific token (like Ether or another token with the highest CEX price), but each token in the arbitrage loop will be taken as input in turn, and then we calculate their respective monetized arbitrage profit. At last, we pick up the most maximal monetized arbitrage profit among them as the monetized arbitrage profit of the MaxMax strategy  $(Max(\pi_A P_A, \pi_B P_B, \dots))$ . It is easy to prove that this strategy can bring more profit than the traditional strategy and the MaxPrice strategy because  $Max(\pi_A P_A, \pi_B P_B, ...) \geq$  $\pi_A P_A, Max(\pi_A P_A, \pi_B P_B, \dots) \geq \pi_B P_B, \dots$  The third one is called a ConvexOptimization strategy. In the later section, we will map the MaxMax strategy to a convex optimization problem and prove that the *Convex Optimization* strategy could get more profit in theory than the MaxMax strategy, which will be shown again in a given example. We will also prove that if no arbitrage profit exists according to the MaxMax strategy, then the Convex Optimization strategy can not detect any arbitrage profit, either.

The paper is organized as follows: Section 2 introduces related work about arbitrage on Uniswap; Section 3 introduces the AMM rules and the MaxMax strategy to get more monetized arbitrage profit along the arbitrage loops. Section 4 shows how to map the MaxMax strategy to the Convex Optimization strategy and prove that the monetized profit we get by the Convex Optimization strategy is larger than the MaxMax strategy. Section 5 gives an arbitrage example and shows that the MaxMax strategy can get more monetized profit than the traditional strategy, but the Convex Optimization strategy can get more monetized profit than the MaxMax strategy. We will also show that the MaxPrice strategy is not liable in calculating the maximal monetized arbitrage profit. In Section 6, we analyze some empirical loop arbitrage data on Uniswap V2 and compare the profitability of traditional strategies, the MaxMax strategy

to that of *Convex Optimization* strategy, the traditional strategies, and the *MaxPrice* strategy. Section 7 summarizes and discusses the relative advantages and disadvantages of the *MaxMax* strategy and the *Convex Optimization* strategy.

# II. RELATED WORK

The arbitrage on a DEX is similar to the Forex in the aspect that any exchangeable pair of tokens has a unique exchange rate, but also different from the arbitrage in the Forex, like in the exchange rate determination process.

After the appearance of the DEXs, like Uniswap V2, though still in its early stage, there have been some scientific papers that focus on analyzing the arbitrage opportunities of DEXs. Wang et al. [6] analyze the potential cyclic arbitrage chances and explored arbitrage profit by traversing all triangles with Ether (ETH), the native token of Ethereum, included on Uniswap V2. Robert et al. [7] used the trade event log to recognize historic arbitrage profit and applied Johnson's cycledetection algorithm to look for potential arbitrage chances. Zhou et al. [5] applied the Moore-Bellman-Ford algorithm to recognize arbitrage loops. Danos et al. [8] took the arbitrage problem as a convexity problem and applied the optimization operation to find arbitrage paths from a theoretical perspective. Berg et al. [9] applied the method in [8] on Uniswap V2 to research the efficiency of DEX by recognizing profitable arbitrages.

In this paper, we do not focus on the arbitrage loop detection on DEXs, but on how to maximize the monetized arbitrage profit in an arbitrage loop, which makes our research very different from those that usually only target a specific token without considering tokens' price in CEXs [5], [6]. [8] introduce the convex optimization method to detect the arbitrage path and calculate traders' optimal utility. Using the convex optimization method to detect the arbitrage paths, like [8], can be problematic because the arbitrage paths we get are always very complicated and are hard to implement in the real Uniswap platform. However, their work enlightens our research in using the Convex Optimization strategy to calculate the monetized arbitrage profit for an arbitrage loop. Our work focuses on the strategies to maximize the monetized arbitrage profit for any arbitrage loops, but not an arbitrage detection problem, which makes our research very different from that in [8]. There is still a lack of research systematically focusing on the maximization of monetized arbitrage profit in arbitrage loops on Uniswap.

# III. AMM EXCHANGE RULES IN DEXS AND THE MaxMax Strategy

Firstly, we define the relative price between two tokens in the same liquidity pool. We use  $p_{ij}$  to denote the price of token *i* in the unit of token *j* which is the ratio between the reserve of the token *i* and *j* in the same pool. So,  $p_{ij} = (1 - \lambda) \frac{r_j}{r_i}$ , where  $r_i$  and  $r_j$  is the reserve of token *i* and *j*, and  $\lambda$  is the imposed tax rate by the liquidity pool. Correspondingly,  $p_{ji}$  is the price of token *j* in the unit of token *i* and  $p_{ji} = (1 - \lambda) \frac{r_i}{r_j}$ . A token loop is called an arbitrage loop when the product of all relative prices along the token loop is larger than 1. For example, in the case of three tokens in the same loop, when  $p_{ij} \cdot p_{jk} \cdot p_{ki} > 1$ , or  $log(p_{ij}) + log(p_{jk}) + log(p_{ki}) > 0$ , this loop is an arbitrage loop, where *i*, *j*, *k* are three different tokens. This condition is applicable in the case of more tokens in an arbitrage loop.

After we find an arbitrage loop, the next question is how much we should invest to maximize our profit. Now, we explain it as follows.

The constant AMM equation in any liquidity pool of Uniswap V2 is in the form of

$$[x + (1 - \lambda)\Delta x](y - \Delta y) = xy = k$$

where x and y are constant and denote the reserve of token X and Y before trading in the liquidity pool, respectively. k equals the product of x and y,  $\lambda$  is the transaction tax rate.  $\Delta x$  and  $\Delta y$  denote the input number of token X and the output number of token Y in trading, which are variables that we will focus on. So, the above equation quantifies the number of token Y we can get  $(\Delta y)$  by inputting a specific number of token X  $(\Delta x)$  in trading. By simple derivation, we can get the function  $\Delta y = F(\Delta x | \theta)$  between  $\Delta y$  and  $\Delta x$ :

$$F(\Delta x|\theta) = y - \frac{x \cdot y}{x + (1 - \lambda) \cdot \Delta x}$$

where  $\theta = (x, y, \lambda)$  denotes a parameter tuple including x, yand  $\lambda$ . From the above equation, we know that  $\Delta y = F(\Delta x | \theta)$ is a convex and monotone-increasing function with  $\Delta x$ . When an arbitrage path includes more tokens, the number of inputs of the starting token is still a convex and monotonically increasing function of the number of target tokens taken out.

Now, we assume there exists a cyclic arbitrage opportunity by exchanging token X to token Y, then from token Y to token Z, and finally from token Z to token X again, namely  $X \to Y \to Z \to X$ .

In the first liquidity pool between token X and token Y, the function between  $\Delta y$  and  $\Delta x$  is:

$$\Delta y = F(\Delta x | \theta_1) = y_1 - \frac{x_1 \cdot y_1}{x_1 + (1 - \lambda) \cdot \Delta x} \tag{1}$$

where  $\theta_1 = (x_1, y_1, \lambda)$  denotes the parameters in the first liquidity pool,  $x_1$  and  $y_1$  is corresponding reserve of token X and Y in the first liquidity pool, respectively.

In the second liquidity pool between token Y and token Z, the function between  $\Delta z$  and  $\Delta y$  is:

$$\Delta z = F(\Delta y | \theta_2) = z_2 - \frac{y_2 \cdot z_2}{y_2 + (1 - \lambda) \cdot \Delta y}$$
(2)

where  $\theta_2 = (y_2, z_2, \lambda)$  denotes the parameters in the second liquidity pool,  $y_2$  and  $z_2$  is corresponding reserve of token Y and Z, respectively.

In the third liquidity pool between token Z and token X, the function between  $\Delta x$  and  $\Delta z$  is:

$$\Delta x = F(\Delta z | \theta_3) = x_3 - \frac{z_3 \cdot x_3}{x_3 + (1 - \lambda) \cdot \Delta z}$$
(3)

where  $\theta_3 = (z_3, x_3, \lambda)$  denotes the parameters in the third liquidity pool,  $z_3$  and  $x_3$  is corresponding reserve of token

Z and X, respectively. To differentiate the input amount of token X in equation 1 from the output amount of token X in equation 3, we use  $\Delta x_{in}$  and  $\Delta x_{out}$  to denote the input amount in equation 1 and output amount in equation 3, respectively. The problem of maximizing profit in this arbitrage loop is

$$Max(\Delta x_{out} - \Delta x_{in}). \tag{4}$$

By equation 1, 2 and 3,  $\Delta x_{out} = F(F(F(\Delta x_{in}|\theta_1)|\theta_2)|\theta_3)$ fact that  $F(\cdot)$  is convex and increases and the monotone, the maximization problem will be а straightforward one-variable maximization problem, namely,  $Max[F(F(\Delta x_{in}|\theta_1)|\theta_2)|\theta_3) - \Delta x_{in}]$  Similarly, by equation 1, 2 and 3, the objective function to maximize from token Y and Z are  $\Delta y_{out} = F(F(F(\Delta y_{in}|\theta_2)|\theta_3)|\theta_1)$ and  $\Delta z_{out} = F(F(F(\Delta z_{in}|\theta_3)|\theta_1)|\theta_2)$ , respectively. These definitions of  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  are the same as that in equations 1, 2 and 3. The only difference among  $\Delta x_{out}$ ,  $\Delta y_{out}$  and  $\Delta z_{out}$  is the different orders of  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  in the functions.

If we input a small amount of token X ( $\Delta x_{in}^{*}$ ) based on equation 4, then the reserves of tokens in the liquidity pool along the loop will change, which means that these parameters in functions  $\Delta y_{out}$  and  $\Delta z_{out}$  will change. The question is how the change of these parameters affects the functions of  $\Delta y_{out}$  and  $\Delta z_{out}$ . After we input a small amount of token Xand get some arbitrage profit in the arbitrage loop  $X \to Y \to$  $Z \to X$ , the total potential arbitrage profit in the same loop will decrease, which means that the arbitrage profit in the loop  $Y \to Z \to X \to Y$  by inputting token Y and  $Z \to X \to$  $Y \to Z$  by inputting token Z will decrease, too. This denotes that the input in token X will lead to the smaller  $\Delta y_{out}$  and  $\Delta z_{out}$  for each value of  $y_{in}$  and  $z_{in}$ , respectively.

When we increase the input amount of token X until the margin input of  $\Delta x_{in}$  equals the margin output of  $\Delta x_{out}$  in the amount equals, namely  $\frac{d\Delta x_{out}}{d\Delta x_{in}} = 1$ , the profit is maximal.

Fig. 1. The arbitrage profit is maximal when  $\frac{d\Delta x_{out}}{d\Delta x_{in}} = 1$ .

Because of the convexity and monotonically-increasing property of this function, it is easy to use the bisection method to calculate the optimal input of  $\Delta x_{in}$  or get the solution by solving the equation  $\frac{d\Delta x_{out}}{d\Delta x_{in}} = 1$ . We assume that  $\Delta x_{in}^*$  is the optimal amount of input, then

We assume that  $\Delta x_{in}^*$  is the optimal amount of input, then we have  $\frac{d\Delta x_{out}}{d\Delta x_{in}}|_{\Delta x_{in}=\Delta x_{in}^*} = 1$  and  $log(p_{ij}^*) + log(p_{jk}^*) + log(p_{ki}^*) = 0$ , and there is no arbitrage anymore starting from token X. Because of  $log(p_{ij}^*) + log(p_{jk}^*) + log(p_{ki}^*) = 0$ , there are also no arbitrage chances starting from other tokens in the loop, which means that  $\frac{d\Delta y_{out}}{d\Delta y_{in}}|_{\Delta y_{in}=0} = 1$  and  $\frac{d\Delta z_{out}}{d\Delta z_{in}}|_{\Delta z_{in}=0} = 1$  with new parameters  $\theta_1^*$ ,  $\theta_2^*$  and  $\theta_3^*$ .

By considering tokens' prices from CEXs, equation (4) has the same solution as equation (5).

$$Max[P_x(\Delta x_{out} - \Delta x_{in})] \tag{5}$$

where  $P_x$ ,  $P_y$  and  $P_z$  are tokens X, Y and Z's price from CEXs, respectively.

The MaxMax strategy to get the maximal monetized arbitrage profit by taking each token as input in turn can be expressed as

$$Max[Max[P_x(\Delta x_{out} - \Delta x_{in})], \\ Max[P_y(\Delta y_{out} - \Delta y_{in})], Max[P_z(\Delta z_{out} - \Delta z_{in})]].$$
(6)

# IV. MAPPING MaxMax Strategy to Convex Optimization Strategy

Now, the monetized arbitrage profit is measured in the same unit of fiat currency, which facilitates accumulating the monetized arbitrage profit from different tokens. By summing up the monetized arbitrage profits from different tokens, the object function in equation (5) can be converted to a convex optimization problem with constraints  $\Delta y_{out}^1 = \Delta y_{in}^2$  and  $\Delta z_{out}^2 = \Delta z_{in}^3$  which is as follows:

$$\max \quad P_x(\Delta x_{out}^3 - \Delta x_{in}^1) + P_y(\Delta y_{out}^1 - \Delta y_{in}^2) + P_z(\Delta z_{out}^2 - s.t. \quad (x_1 + \gamma \Delta x_{in}^1) \cdot (y_1 - \Delta y_{out}^1) \ge x_1 \cdot y_1 \\ (y_2 + \gamma \Delta y_{in}^2) \cdot (z_2 - \Delta z_{out}^2) \ge y_2 \cdot z_2 \\ (z_3 + \gamma \Delta z_{in}^3) \cdot (x_3 - \Delta x_{out}^3) \ge z_3 \cdot x_3 \\ \Delta x_{out}^3 \ge \Delta x_{in}^1 \\ \Delta y_{out}^1 = \Delta y_{in}^2 \\ \Delta z_{out}^2 = \Delta z_{in}^3 \\ \Delta x, \Delta y, \Delta z \ge 0,$$

$$(7)$$

where  $\gamma = 1 - \lambda$ ,  $x_1$ ,  $y_1$ ,  $x_2$ ,  $y_2$ ,  $y_3$ , and  $z_3$  are liquidity reserves in each pool and are constant parameters of the above equation.

Equation (7) is a convex optimization problem with only one optimal solution. Conditions  $\Delta y_{out}^1 = \Delta y_{in}^2$  and  $\Delta z_{out}^2 = \Delta z_{in}^3$  make it reduce to an initial problem, namely, adjusting the  $\Delta x_{in}$  to maximize the profit  $\Delta x_{out} - \Delta x_{in}$ . Equation (7) also implicitly indicates the transaction order of token  $X \rightarrow Y \rightarrow Z \rightarrow X$ .

If we change conditions  $\Delta y_{out}^1 = \Delta y_{in}^2$  and  $\Delta z_{out}^2 = \Delta z_{in}^3$ to  $\Delta y_{out}^1 \ge \Delta y_{in}^2$  and  $\Delta z_{out}^2 \ge \Delta z_{in}^3$ , the problem will become:

$$\max P_x(\Delta x_{out}^3 - \Delta x_{in}^1) + P_y(\Delta y_{out}^1 - \Delta y_{in}^2) + P_z(\Delta z_{out}^2 - \Delta z_{in}^3)$$
s.t.  $(x_1 + \gamma \Delta x_{in}^1) \cdot (y_1 - \Delta y_{out}^1) \ge x_1 \cdot y_1$   
 $(y_2 + \gamma \Delta y_{in}^2) \cdot (z_2 - \Delta z_{out}^2) \ge y_2 \cdot z_2$   
 $(z_3 + \gamma \Delta z_{in}^3) \cdot (x_3 - \Delta x_{out}^3) \ge z_3 \cdot x_3$   
 $\Delta x_{out}^3 \ge \Delta x_{in}^1$   
 $\Delta y_{out}^1 \ge \Delta y_{in}^2$   
 $\Delta z_{out}^2 \ge \Delta z_{in}^3$   
 $\Delta x, \Delta y, \Delta z \ge 0,$ 
(8)

The problem in equation (8) is still a convex optimization problem because all constraint functions are still convex. However, the search space in the problem of equation (8) is larger than that in the problem of equation (7), so, we can get more profit in the problem of equation (8). In the search space of the problem of equation (8), we have constraints  $\Delta x_{out}^3 \geq \Delta x_{in}^1, \ \Delta y_{out}^1 \geq \Delta y_{in}^2$  and  $\Delta z_{out}^2 \geq \Delta z_{in}^3$ , so, this arbitrage is also risky-free.

Now, if we delete the constraint conditions  $\Delta x_{out}^3 \ge \Delta x_{in}^1$ ,  $\Delta y_{out}^1 \ge \Delta y_{in}^2$  and  $\Delta z_{out}^2 \ge \Delta z_{in}^3$  in equation (8), the search space in the new problem will be larger than

the search space in the new problem will be larger than that in the problem of equation (8), but both problems have the same object function, so, the maximal monetized arbitrage profit in the new problem will be larger or equal to that in the problem of equation (8). Removing constraint conditions  $\Delta x_{out}^3 \ge \Delta x_{in}^1$ ,  $\Delta y_{out}^1 \ge \Delta y_{in}^2$  and  $\Delta z_{out}^2 \ge \Delta z_{in}^3$  further may lead to borrowing or shorting of some tokens, which may be very risky to investors, and we will not consider this corresponding convex optimization problem but only consider the problem of equation (8) in our research.

The same logic also applies to  $Max[P_y(\Delta y_{out} - \Delta y_{in})]$  and  $Max[P_z(\Delta z_{out} - \Delta z_{in})]$ , so, we can prove that the maximal  $-\frac{1}{M\delta n}$  dized arbitrage profit MaxMax strategy in equation (6) is equal to or less than that from the *Convex Optimization* strategy in equation (8).

In this section, we take the loop with three tokens as an example, but the strategy of MaxMax and Convex Optimization can be applied to the loops with any length. In certain cases, arbitrageurs may only care more about how many specific tokens they can get. For example, if the objective function is  $Max(\Delta x_{out}^3 - \Delta x_{in}^1)$ , then the convexity of the AMM constraint conditions will ensure that the conditions  $\Delta y_{out}^1 = \Delta y_{in}^2$  and  $\Delta z_{out}^2 = \Delta z_{in}^3$  in equation (8) are satisfied, then the problem in this case will reduce to equation (4).

Another significant question is whether we can get any riskfree arbitrage profit if no risk-free arbitrage profit can be found by traditional strategy or the MaxMax strategy, namely when  $\frac{d\Delta x_{out}}{d\Delta x_{in}}|_{\Delta x_{in}=0} = 1$  or  $log(p_{ij}^*) + log(p_{jk}^*) + log(p_{ki}^*) = 0$ , where the definitions of these variables are the same as that in Section III. Now, we reason the answer to this question, here. Because of  $\frac{d\Delta x_{out}}{d\Delta x_{in}}|_{\Delta x_{in}=0} = 1$ , we can get one unit of token X if we input one unit of token X into the arbitrage loop theoretically. Keeping any number of the other two tokens (Y or Z) in hands as profit will lead to getting less number of token X, namely  $\Delta x_{out} < \Delta x_{in}$ , which is not consistent with the constraint condition  $\Delta x_{out}^3 \ge \Delta x_{in}^1$  in equation 8. So, we will have to keep  $\Delta y_{out}^1 = \Delta y_{in}^2$  and  $\Delta z_{out}^2 = \Delta z_{in}^3$  to ensure the condition  $\Delta x_{out} \ge \Delta x_{in}$  is satisfied. Combining the condition  $\frac{d\Delta x_{out}}{d\Delta x_{in}}|_{\Delta x_{in}=0} = 1$  or  $log(p_{ij}^*) + log(p_{jk}^*) + log(p_{ki}^*) = 0$ , it means that no more arbitrage profit can be gotten even if the *Convex Optimization* strategy is applied. Overall, if the traditional strategies don't detect any arbitrage chances in a token loop, then the arbitrage optimization method can not either, namely the optimal solution by the convex optimization to the  $(\Delta x_{out}^3, \Delta x_{in}^1, \Delta y_{out}^1, \Delta y_{in}^2, \Delta z_{out}^2, \Delta z_{in}^3) = (0, 0, 0, 0, 0, 0).$ 

# V. AN EXAMPLE OF COMPARE THE PROFITABILITY OF MaxMax Strategy, MaxPrice Strategy and Convex Optimization Strategy

This section gives an example of comparing the profitability of different strategies. Assuming the arbitrage loop  $X \rightarrow Y \rightarrow Z \rightarrow X$  is profitable and X, Y and Z denote three different tokens. The liquidity pools are (x, y) = (100, 200), (y, z) = (300, 200), (z, x) = (200, 400), respectively. x, y, zdenote the reserves of tokens X, Y, and Z. The letter tuple denotes the reserve variables of tokens in the liquidity pool and the number tuple denotes the corresponding reserve of corresponding tokens in the pool.

Based on the token reserves in the above example, we can know that  $\frac{PD_x}{PD_y}|_{(x,y)} = 2$ ,  $\frac{PD_y}{PD_z}|_{(y,z)} = \frac{2}{3}$ ,  $\frac{PD_z}{PD_x}|_{(z,x)} = 2$ . PD means the token's price from DEXs which is determined by the tokens' reserves in liquidity pools. The letter tuple (x, y) in each formula denotes the liquidity pool that includes both tokens X and Y, and other token letter tuples have a similar meaning.  $\frac{PD_x}{PD_y}|_{(x,y)} = 2$  denotes the ratio of the price of X and Y in liquidity pool (x, y) is 2, and the other two formulas have the similar interpretations.

have the similar interpretations. Because of  $\frac{PD_x}{PD_y}|_{(x,y)} \cdot \frac{PD_y}{PD_z}|_{(y,z)} \cdot \frac{PD_z}{PD_x}|_{(z,x)} = \frac{8}{3} \ (> 1)$ , we can get arbitrage profit in the loop  $X \to Y \to Z \to X$ . Practitioners can also get arbitrage profit by inputting token Y or token Z and then getting more Y or Z, respectively.

We assume the price of each token in a CEX is given, namely,  $P_x = 2$ ,  $P_y = 10.2$ ,  $P_z = 20$  and token Z has the highest price when compared to token X and Y.

We assume traders only concentrate on the arbitrage starting from token X and backing to token X again  $(X \rightarrow Y \rightarrow Z \rightarrow X)$ , but ignore the other two ways of arbitrage, such as  $Y \rightarrow Z \rightarrow X \rightarrow Y$  and  $Z \rightarrow X \rightarrow Y \rightarrow Z$ , which may lead to getting less monetized arbitrage profit than the maximal monetized arbitrage profit they can get from this arbitrage loop in theory, which will be shown below.

If we only consider the arbitrage path  $X \to Y \to Z \to X$ , the monetized arbitrage profit is only 33.7\$. However, the monetized arbitrage profit can be as high as 201.1\$ if we arbitrage by the order  $Y \to Z \to X \to Y$  and 205.6\$ if by the order  $Z \to X \to Y \to Z$ , which makes it necessary to use the MaxMax strategy in calculating the maximal monetized arbitrage profit. Fig. 2 shows that the MaxMax strategy is always the up-bound of the three ways of arbitrage when a token's price from CEX changes. Now, we analyze these different strategies in detail.

If the strategy starts from token X, then arbitrageurs can input 27.0 token X and the arbitrage profit is 16.8 token X. If the strategy starts from token Y, then arbitrageurs can input 31.5 token Y and the arbitrage profit is 19.7 token Y. If the strategy starts from token Z, then arbitrageurs can input 16.4 token Z and the arbitrage profit is 10.3 token Z.

Fig. 2. Monetized arbitrage profit by starting from different ways tokens and by the MaxMax strategy with token X's price from CEX  $(P_x)$  changing. The red dot line denotes the monetized arbitrage profit from the MaxMaxstrategy, and the other three lines (green, yellow, and blue) denote the monetized arbitrage profits from the three different ways of arbitrage. "Start with token X" denotes the way of arbitrage  $X \to Y \to Z \to X$  and the other two "Start with  $\cdots$ " have similar interpretation.

Fig. 2 also shows that the MaxPrice strategy (the yellow line) can not always get the most monetized arbitrage profit. For example, token Z's price in CEXs is  $P_z = 20$ \$, while when token X's price in CEXs ( $P_x$ ) is about 15\$, the monetized arbitrage profit from the way  $X \to Y \to Z \to X$ is far above the MaxPrice strategy  $Z \to X \to Y \to Z$ .

If we applied the *Convex Optimization* for arbitrage, the monetized arbitrage profit can be up to 206.1\$ which is higher than that from the *MaxMax* strategy. The *Convex Optimization* strategy is as follows: inputting 31.3 token X to get 47.6 token Y in (x, y) liquidity pool at first; then inputting 42.6 token Y to get 24.8 token Z in (y, z)liquidity pool; at last, we input 17.1 token Z to get 31.3 token X again. The profit includes 5 token Y and 7.7 token Z. The strategy can be implemented in any order. For example, we can input 42.6 token Y to get 24.8 token Z in (y, z) liquidity pool; then, we input 17.1 token Z to get 31.3 token X in (z, x)liquidity pool; at last, we input 31.3 token X to get 47.6 token Y in (x, y) liquidity pool. To avoid any other risk, it is better to implement these three exchanges in the same transaction by applying flash loan in reality.

We can also find that the *Convex Optimization* strategy needs to input more tokens compared to the *MaxMax* strategy and other different ways of arbitrage strategies.

When the price of token X changes from 0\$ to twenty dollars, it is easy to find that we can always get more or equal profit by *Convex Optimization* strategy than that by the *MaxMax* strategy in all cases, which is shown in Fig. 3.

Fig. 3. Monetized arbitrage profit by the *Convex Optimization* strategy and the *MaxMax* strategy with token X's price from CEX  $(P_x)$  changing. The blue dot line denotes the monetized arbitrage profit by the *Convex Optimization* strategy and the red dot line denotes the monetized arbitrage profit by the *MaxMax* strategy. Arbitrageurs can always get more or at least equal profits by taking the *Convex Optimization* strategy.

We also plot the arbitrage profit in the form of the net number of tokens X, Y, and Z we get when token X's price changes from 0 dollars to twenty dollars, as shown in Fig. 4. From Fig. 4, we can find that the optimal points mainly lie in six positions, which denotes that the optimization problem of our method is not linearly correlated to the price of tokens and is difficult to get a general analytical solution.

Fig. 4. The profit in the form of the number of tokens X, Y, and Z when token X's price changes from 0 to twenty dollars with an interval of 0.2 dollars. The larger the point is in size, the more monetized arbitrage profit we get by the *Convex Optimization* strategy.

# VI. PROFITABILITY COMPARING USING EMPIRICAL DATA ON UNISWAP V2

We applied the liquidity pool data on September 1st, 2023, on Uniswap V2 and constructed the token exchange graph using similar procedures as that in the paper 'Identifying Arbitrage Paths and Loops on Decentralized Exchanges' Yu Zhang et al. (2024). The information on the token graph includes each token's reserve in corresponding liquidity pools. We chose those liquidity pools that have more than thirty thousand dollars TVL and where the number of each token is larger than one hundred. In the token graph we constructed, the node denotes the token, and the edge denotes the liquidity pool that includes the two different tokens corresponding to the edge's two ends. A liquidity pool (edge) is connected to another if they have the same token (node).

The token graph we got had fifty-one nodes (tokens) and two hundred and eight edges (liquidity pools). The token's price from CEX (Binance) was downloaded on CoinGecko by API. To compare the profitability of different arbitrage strategies, we focus on only the loops with length 3 at first because the same analysis is easy to extend to arbitrage loops with any length.

We traversed all token loops with 3 tokens and selected those loops where arbitrage profit exists. For any loop, if the condition  $p_{ij} \cdot p_{jk} \cdot p_{ki} > 1$ , or  $log(p_{ij}) + log(p_{jk}) + log(p_{ki}) > 0$  is satisfied, then the loop is an arbitrage loop. In the above formula, *i*, *j*, *k* are three different tokens, and  $p_{ij}$  are the relative price between token *i* and *j* and is determined by their token reserve in the liquidity pool (x, y). Other parameters in the above formula are defined similarly. After this procedure, we got one hundred and twenty-three arbitrage loops with length 3.

In this experiment, we record the respective monetized arbitrage profits from the traditional arbitrage strategies, the *MaxMax* strategy, the *MaxPrice* strategy, and the *Convex Optimization* strategy. The monetized arbitrage profits from traditional strategies will correspond to several different values because the arbitrage may be implemented from any token in the arbitrage loop. For example, in a given arbitrage loop  $X \rightarrow Y \rightarrow Z \rightarrow X$ , the monetized arbitrage profits of traditional arbitrage strategies will include three different values which are the monetized arbitrage profit from the arbitrage order  $X \rightarrow Y \rightarrow Z \rightarrow X$ ,  $Y \rightarrow Z \rightarrow X \rightarrow Y$ , and  $Z \rightarrow X \rightarrow Y \rightarrow Z$ , respectively. Then, we compare the arbitrage profit from the *MaxMax* strategy and those from traditional strategies, which is shown in Fig. 5.

All points in Fig. 5 are under or on the  $45^{\circ}$  line, which means that the monetized arbitrage profits from the MaxMax strategy are the up-bound of all other three traditional arbitrage strategies. This is easy to understand because the monetized arbitrage profits from the MaxMax strategy equals the maximal monetized arbitrage profit from the traditional arbitrage strategies in definition.

We compare the profitability of the MaxMax strategy to the MaxPrice strategy which is shown in Fig. 6. From this figure, we can find that it is not always that the maximal monetized arbitrage profit can be obtained by starting arbitrage from the token with the highest price in CEXs, which makes the MaxPrice strategy unreliable in calculating maximal monetized arbitrage profit.

The MaxMax strategy can be mapped to the Convex Optimization strategy and we have proved

Fig. 5. Monetized arbitrage profit from the MaxMax strategy vs that from traditional arbitrage strategies. The x-axis of each scatter plot is the monetized arbitrage profit from the MaxMax strategy, and the y-axis of each scatter point denotes the monetized arbitrage profit from a traditional arbitrage strategy. An arbitrage loop with length 3 corresponds to three different points with different shapes (circle, diamond, triangle) and colors (yellow, red, green) but the same values in x-axis.

in theory that the *Convex Optimization* strategy can get more monetized arbitrage profit than the *MaxMax* strategy. So, here, we also compare the profitability of the *Convex Optimization* strategy and the *MaxMax* strategy, by plotting the scatter plot which is shown in Fig. 7. In Fig. 7, all points are almost on the  $45^{\circ}$  line, which means that the profit from the *Conevx Optimization* strategy is almost equal to that from the *MaxMax* strategy. This result may come partly from the reason that the monetized difference between the two arbitrage strategies is tiny. To find out whether these two strategies got the same results, we need to compare the arbitrage profits of these two arbitrage strategies from the perspective of the absolute net number of each token we get as profit. We find that the results are almost the same under the two strategies, which is shown in Fig. 8.

### VII. RESULT AND DISCUSSION

In this paper, we put forward the MaxMax strategy and the Conevx Optimization strategy by considering tokens' prices from CEXs. It is easy to prove that the MaxMax strategy can get more monetized arbitrage profit than the traditional arbitrage strategies and the MaxPrice strategy. Then we mapped the MaxMax strategy to the Convex Optimization strategy and proved in theory that more monetized arbitrage profit can be obtained by the Conevx Optimization strategy than the MaxMax strategy. We also prove that if no arbitrage profit can be found by the traditional arbitrage strategies or the MaxMax strategy, then no arbitrage profit can be detected by the Convex Optimization strategy, either. These are some main theoretical contributions of this paper.

By the example and empirical data analysis, both the traditional strategies and the MaxPrice strategy are not reliable if we focus on getting the maximal monetized arbitrage profit.

Fig. 6. Monetized arbitrage profit from the MaxPrice strategy vs that from the MaxMax strategy. The x-axis of each scatter plot is the monetized arbitrage profit from the MaxMax strategy and the y-axis of each scatter point denotes the monetized arbitrage profit from the MaxPrice strategy. One arbitrage loop corresponds to one red diamond point.

Fig. 7. Monetized arbitrage profit from the *Convex Optimization* strategy vs that from the *MaxMax* strategy. The *x*-axis of each scatter plot is the monetized arbitrage profit from the *Convex Optimization* strategy and the *y*-axis of each scatter point denotes the monetized arbitrage profit from the *MaxMax* strategy. One arbitrage loop corresponds to one red diamond point.

For the MaxMax strategy and the Convex Optimizationstrategy, both strategies get the maximal and almost equal monetized arbitrage profit in empirical data. For the MaxMaxstrategy, we need to calculate the monetized arbitrage profit several times and then choose the maximal one. If an arbitrage loop has n different tokens, then we need to calculate n times. However, the calculation is simple and fast because the object function is convex and we can use the bisection method to get the optimal number of inputs and the arbitrage profit even if we need to calculate it multiple times. For example, for an arbitrage loop with a length of 10, the time required is in milliseconds level. For the Convex Optimization strategy, we only need to calculate once to get the monetized arbitrage

Fig. 8. Arbitrage profit measured using the obtained net number of every token in the arbitrage loop, *Convex Optimization* strategy vs the *MaxMax* strategy. In this figure, we plot the arbitrage profit in the unit of each token in the arbitrage loop. For an arbitrage loop with length 3, the arbitrage profit will include a specific number of each of these three tokens. We can find that the points from the *MaxMax* strategy overlap with the points from the *Convex Optimization* strategy.

profit, and the monetized arbitrage profit is at least equal to the monetized arbitrage profit from the MaxMax strategy by the empirical analysis. However, the drawback of this *Convex Optimiazation* is the high computation complexity for computers especially when the arbitrage loop is long. For example, for an arbitrage loop with a length of 10, the time required can be several seconds. While the average block time is 10 seconds, which makes the *Convex Optimization* strategy not a perfect method in reality.

This paper proves that the monetized arbitrage profit from the *Convex Optimization* strategy is equal to or larger than that from the MaxMax strategy. However, we didn't give the discrepancy between these two kinds of strategies in theory, which can be a research direction in the future from the perspective of academic research.

### APPENDIX

We repeat the same profit comparing procedure as that in Section VI but focus on the arbitrage loop with length 4. The comparing results are similar to that in Section VI and are shown in Fig. 9 and 10.

Fig. 9. Monetized arbitrage profit, the *Convex Optimization* strategy vs the traditional strategies. The x-axis of each scatter plot is the monetized arbitrage profit from the *Convex Optimization* strategy and the y-axis of each scatter point denotes the monetized arbitrage profit from other traditional arbitrage strategies. One arbitrage loop corresponds to four different points with different shapes but the same value in x-axis.

Fig. 10. Monetized arbitrage Profit, the Convex Optimization strategy vs the MaxMax strategy. The x-axis of each scatter plot is the monetized arbitrage profit from the Convex Optimization strategy and the y-axis of each scatter point denotes the monetized arbitrage profit from the MaxMax strategy. One arbitrage loop corresponds to one point in this figure.
