ABSTRACT

Aims. We aim at characterizing the population of low-luminosity X-ray sources in the Galactic plane by studying their X-ray spectra and periodic signals in the light curves.

Methods. We are performing an X-ray survey of the Galactic disk using *XMM-Newton*, and the source XMMU J173029.8–330920 was serendipitously discovered in our campaign. We performed a follow-up observation of the source using our pre-approved *NuSTAR* target of opportunity time. We used various phenomenological models in xspec for the X-ray spectral modeling. We also computed the Lomb-Scargle periodogram to search for X-ray periodicity. A Monte Carlo method was used to simulate 1000 artificial light curves to estimate the significance of the detected period. We also searched for X-ray, optical, and infrared counterparts of the source in various catalogs.

Results. The spectral modeling indicates the presence of an intervening cloud with $N_{\rm H} \sim (1.5 - 2.3) \times 10^{23} \text{ cm}^{-2}$ that partially absorbs the incoming X-ray photons. The X-ray spectra are best fit by a model representing emission from a collisionally ionized diffuse gas with plasma temperature $kT = 26^{+11}_{-5}$ keV. Furthermore, an Fe K_{α} line at $6.47^{+0.13}_{-0.06}$ keV was detected with an equivalent width of the line of 312 ± 104 eV. We discovered a coherent pulsation with a period of 521.7 ± 0.8 s. The 3–10 keV pulsed fraction of the source is around ~50–60%.

Conclusions. The hard X-ray emission with plasma temperature $kT = 26^{+11}_{-5}$ keV, iron K_{α} emission at 6.4 keV and a periodic behavior of 521.7 ± 0.8 s suggest XMMU J173029.8–33092 to be an intermediate polar. We estimated the mass of the central white dwarf to be 0.94 – 1.4 M_{\odot} by assuming a distance to the source of ~ 1.4 – 5 kpc.

Key words. X-rays:binaries – Galaxy:center – Galaxy:disk – white dwarfs – novae, cataclysmic variables

1. Introduction

Galactic X-ray emission is a manifestation of various highenergy phenomena and processes. Studying discrete X-ray sources is essential to understand stellar evolution, dynamics, end-products, and accretion physics. Initial X-ray scans of the Galactic plane revealed a narrow, continuous ridge of emission, the so-called Galactic ridge X-ray emission (GRXE; Worrall et al. 1982; Warwick et al. 1985), which extends either side of the Galactic disk up to $\sim 40^{\circ}$. A copious amount of 6.7 keV line emission from highly ionized iron was detected from selected regions of the GRXE (Koyama et al. 1989; Yamauchi et al. 1990). The study of the 6.7 keV emission indicated an optically thin hot plasma distributed mainly along the Galactic plane. The Galactic diffuse X-ray emission can be described by a two-component emission model with a soft temperature of ~ 0.8 keV and a hard component of ~ 8 keV (Koyama et al. 1996; Tanaka et al. 2000). The origin of the ~ 8 keV plasma is less certain. The Galactic potential is too shallow to confine such hot plasma that would escape at a velocity of thousand km s⁻¹. The Deep Chandra observations of the Galactic Center (GC) by Wang et al. (2002) $(2^{\circ} \times 0.8^{\circ})$ and a region south of the GC $(16' \times 16')$ by Revnivtsev et al. (2009), pointed out that the hard $kT \sim 8$ keV diffuse emission is primarily due to unresolved cataclysmic variables (CVs) and active binaries. However, later, close to the GC within $\pm 0.8^{\circ}$ a significant diffuse hard X-ray emission was detected up to energies of 40 keV (Yuasa et al. 2008). In addition, some studies pointed out that the hard GC emission is truly diffuse by comparing stellar mass distribution with the Fe XXV (6.7 keV) line intensity map (Uchiyama et al. 2011; Nishiyama et al. 2013; Yasui et al. 2015). A recent study by our group showed that this diffuse hard emission in the GC can be explained if one assumes the GC stellar population with iron abundances ~ 1.9 times higher than those in the Galactic bar/bulge (Anastasopoulou et al. 2023).

Magnetic CVs (mCVs) are categorized into two types based on the magnetic field strength of the white dwarf (WD): intermediate polars (IPs) and polars (see Cropper 1990; Patterson 1994; Mukai 2017, for reviews). In polars, the magnetic field is strong (> 10 MG) enough to synchronize the spin and orbital period of the system. Whereas in IPs, the magnetic field is less strong; therefore, their spin and the orbital period are less synchronized. Most hard X-ray emission from mCVs originates close to the WD surface. The accreting material from the companion star follows the magnetic field lines of the WD and, while approaching the WD polar cap, reaches a supersonic speed of 3000–10000 km s^{-1} . A shock front is developed above the star, and the in-falling gas releases its energy in the shock, resulting in hard X-ray photons (Aizu 1973).

The Galactic Center (GC) region hosts many energetic events, like bubbles and super-bubbles from young and old stars and various supernovae remnants (Ponti et al. 2015) as well as large-scale structures like Galactic Chimneys (Ponti et al. 2019, 2021), Fermi bubbles (Su et al. 2010), and eROSITA bubbles (Predehl et al. 2020). Currently, we are performing an X-ray survey of the Galactic disk using XMM-Newton. The main aim of this survey is to constrain the flow of hot baryons that feed the large-scale structures from the GC. The survey region extends from $l \ge 350^{\circ}$ to $l \le 7^{\circ}$ and covers a latitude of $b \sim \pm 1^{\circ}$. The survey has an exposure of 20 ks per tile. During this survey, we detected thousands of X-ray point sources of various types. Our survey is sensitive enough to detect sources as faint as 10^{-14} erg cm⁻² s⁻¹. The nearby bright X-ray point sources with flux > 10^{-11} erg cm⁻² s⁻¹ are well-known thanks to several decades of monitoring by RXTE, Swift-BAT, MAXI, and INTE-GRAL. The bright IPs in the solar neighborhood have a typical luminosity of $10^{33} - 10^{34}$ erg s⁻¹ (Downes et al. 2001; Ritter & Kolb 2003; Suleimanov et al. 2022) and its unabsorbed flux at the GC would be $\sim 10^{-13} - 10^{-12}~erg~cm^{-2}~s^{-1}.$ Furthermore, the high extinction towards the GC makes it even more difficult to detect these faint sources in the GC. Our XMM-Newton observations are deep enough to detect these faint X-ray sources. During our XMM-Newton campaign, we detected a faint X-ray source, XMMU J173029.8–33092, with a 3–10 keV X-ray luminosity of $\sim 7 \times 10^{-13}$ erg cm⁻² s⁻¹. In this paper, we report the detailed spectral and timing study of this source.

2. Observations and data reduction

The source XMMU J173029.8–330920 (R.A. = $17^{h}30^{m}29^{s}29$, DEC = $-33^{\circ}09'20''_{9}$) was discovered in our *XMM-Newton* (Jansen et al. 2001) *Heritage* survey of the inner Galactic disk (PI: G. Ponti). The source was detected in one of our *XMM-Newton* pointings on 2023-03-28 (ObsID: 0916800201) with an exposure of 18.3 ks (Mondal et al. 2024). We analyzed the *XMM-Newton* data and discovered an X-ray pulsation and a tentative iron 6.4 keV line emission that suggested a possible identification with an IP. To confirm this, we triggered our pre-approved 35 ks *NuSTAR* target of opportunity observation to follow up on this source.

The XMM-Newton observation data file was processed using XMM-Newton Science Analysis System (SASv19.0.0¹). The point source detection and source list creation were performed using the SAS task emldetect. The source detection was performed simultaneously in five energy bands (0.2–0.5 keV, 0.5–1 keV, 1–2 keV, 2–4 keV, and 4–12 keV) for each detector EPIC-pn/MOS1/MOS2 (Strüder et al. 2001; Turner et al. 2001). While extracting the source products, we only selected events with PATTERN≤4 and PATTERN≤12 for EPIC-pn and MOS2 detectors, respectively. The source was out of the field of view of the MOS1 detector. We applied barycenter correction for light curve extraction using the SAS task barycen. We used a circular region of 25″ radius for the source product extraction. The background products were extracted from a nearby source-free circular region of radius 25″.

The *NuSTAR* (Harrison et al. 2013) observation was performed on 2023-04-24 (ObsID: 80801332002, PI: S. Mondal).

Fig. 1: The spectra of XMMU J173029.8–330920, fitted with various partially absorbed models plus a Gaussian component at ~6.4 keV. The black, red, green, and blue data points are from EPIC-pn, MOS2, FPMA, and FPMB detectors. tbabs and tbpcf represents the Galactic and partial absorption component. po (a simple power law) and apec (a collisionally ionized diffuse gas) are the two continuum models tested in the spectral modeling; more details are given in Sect. 3.1.

The *NuSTAR* data reduction was performed using the *NuSTAR* data analysis pipeline software (NUSTARDAS v0.4.9 provided with HEASOFT). The unfiltered event files from FMPA and FPMB detectors were cleaned, and data taken during passages through the South Atlantic Anomaly were removed using nupipeline. The source products were extracted from a circular region of radius 40" using nuproducts. The background was selected from a source-free region of 40" radius.

3. Results

3.1. XMM-Newton and NuSTAR joint spectral modeling

We performed a time-averaged spectral modeling using XSPEC (Arnaud 1996), including the data from EPIC-pn, MOS2, FPMA, and FPMB detectors in a joint fit. While doing the fit, we added a constant term for cross-calibration uncertainty, which we fixed at unity for the EPIC-pn detector and free for others. The best-fit parameters are listed in Table 1 with the quoted errors at the 90% confidence level. All the models are convolved with a Galactic absorption component tbabs (Wilms et al. 2000) with solar abundance.

Before we started fitting the data from XMM-Newton and NuSTAR jointly, we checked for any variation in flux, as the two observations are separated by nearly 27 days. We chose a common energy band of 3-10 keV in XMM-Newton and NuS-TAR to estimate the flux and fit the spectra using a simple power law model. The power law model provides 3–10 keV flux in *XMM-Newton* and *NuSTAR* is $7.1_{-1.7}^{+0.7} \times 10^{-13}$ erg s⁻¹ cm⁻² and $7.4_{-1.0}^{+0.6} \times 10^{-13}$ erg s⁻¹ cm⁻², respectively. As we do not see any indication of flux variation, we jointly modeled the spectra from XMM-Newton and NuSTAR. First, we fit the data with an absorbed power law model that leads to a high $N_{\rm H} = (16 \pm 3) \times$ 10^{22} cm⁻² and $\Gamma = 1.9 \pm 0.2$. Fitting the data with this model reveals residuals at energies below 3 keV. The partial covering component improves the fit by $\Delta \chi^2 = 17$ for two additional degrees of freedom (d.o.f). The significance of the partial covering component is 99.84% in an F-test. The fitted parameters are $N_{\rm H} = 3^{+2}_{-1} \times 10^{22} \text{ cm}^{-2}, N_{\rm H,pcf} = 23^{+8}_{-6} \times 10^{22} \text{ cm}^{-2}, \text{ pcf} = 0.93^{+0.04}_{-0.07}$ and $\Gamma = 2.1 \pm 0.2$. Next, we add a Gaussian that further improves the fit by $\Delta \chi^2 = 13$ for an additional one *d.o.f* that gives a detection significance of 99.90% in an F-test. The line width is consistent with zero; therefore, we set the line width at zero keV, and the centroid of the line is estimated as $E_{\rm g} = 6.47^{+0.13}_{-0.06}$ keV. The equivalent width of the line is 312 ± 104 eV. We checked the presence of Fe XXV and Fe XXVI by adding two Gaussians at 6.7 and 6.9 keV; however, there is no significant improvement in the fit. The best fit is obtained when the data is fitted with an absorbed apec model, representing the emission from collisionally-ionized diffuse gas. The apec model does not include the neutral Fe K_{α} emission at 6.4 keV. Therefore, we add a Gaussian at 6.4 keV when fitting with this model. The plasma temperature obtained from this model is 26^{+11}_{-5} keV.

3.2. X-ray pulsation search

For a primary analysis and search for X-ray pulsation in *XMM*-*Newton* EPIC-pn and *NuSTAR* FPMA detectors, we chose a common energy band 3–10 keV to extract the light curve. The Xray light curves often suffer from gaps due to the South Atlantic Anomaly Passage. The gaps in the light curve are prominent for satellites in low earth orbit such as *NuSTAR* due to Earth occultation. We used the Lomb-Scargle (Lomb 1976) periodogram to search for periodicity. The Lomb-Scargle periodogram is well known for detecting periodicity in observations that suffer from gaps. Figure 2 shows the Lomb-Scargle periodogram for the EPIC-pn and FPMA detector. A peak at around a frequency of 1.918×10^{-3} Hz and 1.916×10^{-3} Hz is visible in EPIC-pn and FPMA detectors, respectively. The periods obtained from the EPIC-pn and FPMA data are 521.2 ± 3.6 and 521.7 ± 0.8 , respectively; both are consistent with each other.

The periodogram of accreting X-ray binaries displays red noise, which can mimic an artificial periodic or aperiodic vari-

Fig. 2: The Lomb-Scargle periodogram of the source XMMU J173029.8–330920. The top panel is for data from the *XMM-Newton* EPIC-pn detector, and the bottom panel is for the *NuS-TAR* FPMA detector. In both cases, a significant peak around 1.918×10^{-3} Hz is visible, which corresponds to the period of 521 s. The small insects show the 3–10 keV folded light curve. The red horizontal lines indicate the 3σ detection significance.

ability. Therefore, we did Monte Carlo simulations to test the detection significance. To begin, we computed the power spectral density (PSD) using the standard periodogram approach with an [rms/mean]² PSD normalization (Vaughan et al. 2003). Subsequently, we employed a power law model to characterize the source power spectrum, taking into account the presence of red noise. The power law model is expressed as:

$$P(v) = Nv^{-1} + C_{\rm p},\tag{1}$$

where *N* represents the normalization factor, and C_p accounts for the Poisson noise, which is influenced by the mean photon flux of the source. We fitted the PSD of the source using Eq. 1 with a Markov Chain Monte Carlo approach, employing the Python package *emcee* (Foreman-Mackey et al. 2013) to derive the bestfit parameters and their associated uncertainties. We simulated 1000 light curves for this best-fit power law model using the method of Timmer & Koenig (1995), which were re-sampled and binned to have the same duration, mean count rate, and variance as the observed light curve. The red horizontal lines in Fig. 2 indicate the 3σ detection significance.

The 3–10 keV pulsed fractions (PF) obtained from EPIC-pn and FPMA are 50.4 ± 15.5 and 59.3 ± 14.7 , respectively. The PF is calculated by using the formula PF = $\frac{F_{max} - F_{min}}{F_{max} + F_{min}}$, where F_{max} and F_{min} are the normalized count of the folded light curve. Next, we computed the PF of the source at different energies. Figure 3 shows the pulsed fraction at different energies. The 0.5–5 keV and 5–10 keV pulse fraction is $55 \pm 17\%$ and $42 \pm 16\%$, respectively.

Table 1: The best-fit parameters of the fitted models.

tbabs*Model	$N_{\rm H}$ ×10 ²²	$N_{\rm H,pcf}$ ×10 ²²	pcf	Γ/ <i>kT</i> -/keV	Ν	E _g keV	$N_{ m g}$	$\chi^2/d.o.f$
no	16 + 3			$\frac{19+02}{19+02}$	$4^{+2} \times 10^{-4}$			140/101
P0	10±5			1.9 ± 0.2	1-1 × 10			110/101
tbpcf*po	3^{+2}_{-1}	23^{+8}_{-6}	$0.93^{+0.04}_{-0.07}$	2.1 ± 0.2	$7^{+6}_{-3}\times 10^{-4}$			123/99
tbpcf*(po+g1)	3^{+2}_{-1}	19^{+7}_{-5}	$0.92^{+0.05}_{-0.08}$	1.9 ± 0.2	$5^{+4}_{-2} \times 10^{-4}$	$6.47^{+0.13}_{-0.06}$	$(3\pm1)\times10^{-6}$	110/98
tbpcf*(apec+g1)	2^{+2}_{-1}	15^{+5}_{-4}	$0.89^{+0.14}_{-0.07}$	26^{+11}_{-5}	$(8 \pm 1) \times 10^{-4}$	$6.45^{+0.09}_{-0.06}$	$(4 \pm 2) \times 10^{-6}$	106/97

Notes. $N_{\rm H}$ is given in units of 10^{22} cm⁻², N in photons keV⁻¹ cm⁻² s⁻¹ at 1 keV and $N_{\rm g}$ in photons keV⁻¹ cm⁻² s⁻¹ at the line energy. For the apec model, the metal abundance value is frozen to 1.0.

Fig. 3: The PF of the source as a function of energy. The error bars of the pulse fraction are on 1σ confidence level.

4. Counterparts

We searched for X-ray counterparts in *Chandra* CSC2.0² and Swift 2SXPS³ catalogs, however, no counterparts were found. We searched for optical and infrared counterparts in various catalogs. No Gaia counterpart was found within 5" from XMM-Newton position due to high ISM absorption. A source is found in the VVV Infrared Astrometric Catalogue (Smith et al. 2018); however, the source is located 2.7" away from the XMM-Newton position, which is off by more than 3σ (1") XMM-Newton positional uncertainty. So, we consider no infrared counterparts were detected. From the observed column density of absorption of $N_{\rm H} = 2^{+2}_{-1} \times 10^{22} \text{ cm}^{-2}$, we estimate the distance to the source by comparing this value to the absorption column density obtained from several other tracers (Planck Collaboration et al. 2016; Yao et al. 2017; Edenhofer et al. 2023). Assuming that all the observed column density in the X-ray band is due to interstellar absorption, we obtained the distance to the source is around $2.9^{+2.1}_{-1.5}$ kpc using $3D-N_{\rm H}$ -tool⁴ of Doroshenko (2024). In any case, the source should be closer to us than 5 kpc.

From the non-detections in the VVV and *Gaia* data, We can put a constraint on the nature of the companion star. The extinction along the line of sight in the optical and infrared band is $A_V = 6.36$ and $A_K = 0.61$, respectively (Doroshenko 2024). The *Gaia* G band and VVV Infrared survey have a detection limit of $m_G = 21$ and $m_{Ks} = 18.1$, respectively. Therefore, we obtained the absolute magnitude of the donor star should be $M_G > 2.3$ and $M_{Ks} > 5.1$. The donor star might be even fainter than the above estimates as often the optical emission from this type of system has a significant contribution from the accretion disk (Mukai & Pretorius 2023). Therefore, the upper limits of the optical and infrared magnitude suggest the companion star should be a low-mass main sequence star of spectra type later than A7/F0. Our *XMM-Newton* observation has simultaneous UV observation with UVW1 (291 nm) and UVM2 (231 nm) filters. We did not find any counterparts in the *XMM-Newton* UV data.

5. Discussion

The source XMMU J173029.8–330920 was discovered in March 2023 during our *XMM-Newton* campaign. Shortly afterward, in April 2023, we triggered our pre-allocated *NuSTAR* observation on following up on this source. We searched for a counterpart in *Swift* and *Chandra* source catalog but found no source association. We also looked for optical, infrared counterparts in *Gaia* and *2MASS* catalogs, but no counterparts were found.

When the X-ray spectra are fitted by a single Galactic absorption component, leaves residual in the ratio plot. The X-ray spectra are best fitted when we incorporate a partial covering component into the spectral models. The partial covering absorber has a column density of $N_{\rm H,pcf} = (1.5 - 2.3) \times 10^{23} \, \rm cm^{-2}$. The requirement of a partial covering is commonly seen in the spectra of magnetic CVs (Ezuka & Ishida 1999; Mondal et al. 2022, 2023). A partial covering absorption suggests a fraction of the photons are seen directly and the rest through an intervening absorber, which suggests the absorber size is of the same order as the X-ray emitting region located closer to the source. A simple absorber with column density of 10^{23} cm⁻² is so high that it completely absorbs the photons below 2 keV, yet most IPs show a good level of emission in the soft X-ray band 0.2–2 keV. Therefore, Norton & Watson (1989) introduced the concept of a partial covering absorber that improved the spectral fit and explained the observed energy-dependent spin modulation. The total Hydrogen absorption column density $(H_1+H_2)^5$ along the line of sight is $N_{\rm H_1+H_2} = 1.4 \times 10^{22} \text{ cm}^{-2}$ (Willingale et al. 2013).

² http://cda.cfa.harvard.edu/cscweb/index.do

³ https://www.swift.ac.uk/2SXPS/index.php

⁴ http://astro.uni-tuebingen.de/nh3d/nhtool

⁵ https://www.swift.ac.uk/analysis/nhtot/

The Galactic absorption towards the source obtained from X-ray spectral fitting is $(2-3)\times 10^{22}$ cm⁻², which is slightly higher than the total Hydrogen absorption column density along the line of sight $N_{\rm H_1+H_2}$.

A pulsation period of 521.7 ± 0.8 s was found in both XMM-Newton and NuSTAR data sets. The period is likely to be associated with the spin period of the WD. Such a spin period is typical for an IP. Typically, the spin period of IPs ranges from ~ 30 s to ~ 3000 s with a median value around ~ 1000 s (Scaringi et al. 2010). The high energy 5–10 keV pulsed fraction of the source is $42 \pm 16\%$. The PF in IPs decreases with increasing energy. This is due to the fact that the light curve of IPs shows increasing modulation depth with decreasing energy (Norton & Watson 1989), and photoelectric absorption has been considered in some part responsible for this trend. Most IPs do not show large PF at higher energies; however, the source GK Per (Norton & Watson 1989), AO Psc, and FO Aqr (Hellier et al. 1993) show PF of the order of 25-35% at energies above 5 keV which is similar to the PF detected in 5-10 keV band for the source XMMU J173029.8-330920.

The source is most likely a strong candidate for IP. The upper limits estimate of the optical and infrared magnitude indicate the source is hosting a low-mass companion star. The optical extinction of $A_V = 6.36$ along the line of sight is not high enough for non-detection of the optical/infrared counterpart if the source contains a high-mass companion. Therefore, ruling out the neutron star high-mass X-ray binary (NS HMXRB) scenario. Furthermore, the source spectrum is extremely soft with $\Gamma \sim 1.9$, which is not typically seen in NS HMXRBs. The NS HMXRBs do not show strong ionized 6.7 and 6.9 keV lines and their spectra are best fitted by an absorbed power law model. On the other hand, the spectra of the source XMMU J173029.8-330920 are best fitted by an apec model that is typically used for fitting the spectra of IPs. Lastly, the source is also unlikely to be an ultracompact X-ray binary (UCXB). The UCXBs are low-mass Xray binaries usually containing a WD donor and a neutron star accretor with an ultra-short orbital period (<1 hr). The emission from NS-UCXBs is well characterized by blackbody emission with $kT \sim 1 - 3$ keV originating from the NS surface (Koliopanos 2015). In our case, a blackbody component does not fit the XMM-Newton +NuSTAR 0.5-50 keV spectrum and leaves excess above 10 keV in the ratio plot. Furthermore, a partial covering model is still required when fitting with the blackbody model, which is not typically seen when fitting the spectra of NS-UCXB. In addition to that the NS-UCXBs show little to no emission of Fe (Koliopanos et al. 2021).

5.1. WD Mass Measurement

As J1730 is an IP whose X-ray emission primarily originates from an accretion column, we measure the WD mass fitting MCVSPEC to the broadband X-ray spectra. First introduced in Vermette et al. (2023), MCVSPEC is an XSPEC spectral model developed for magnetic CVs assuming a magnetically confined 1D accretion flow. Largely based on the methodology of Saxton et al. (2005), MCVSPEC computes plasma temperature and density profiles varying along the accretion column between the WD surface and shock height. The model outputs an X-ray spectrum with thermal bremsstrahlung continuum and atomic lines by integrating X-ray emissivity over the accretion column. The input parameters for MCVSPEC are M, \dot{m} (specific accretion rate [g cm⁻² s⁻¹]), R_m/R where R_m is the magnetospheric radius and R is the WD radius, and Z (abundance relative to the solar value).

For IPs where the accretion disk is truncated by WD magnetic fields, we assume that the free-falling gas gains kinetic energy from the magnetospheric radius (R_m) to the shock height (*h*). At the shock height, the infalling gas velocity reaches v_{ff} = $\sqrt{2GM\left(\frac{1}{R+h}-\frac{1}{R_m}\right)}$, which exceeds the sound speed and forms a stand-off shock. As the shock temperature is directly related to *M* through $kT_{\text{shock}} = \frac{3}{8}\mu m_{\text{H}}v_{ff}^2$, both R_m and *h* affect the X-ray spectrum from the accretion column. In addition to MCVSPEC, the reflect, gaussian and pcfabs models in XSPEC are incorporated to account for X-ray reflection by the WD surface and X-ray absorption by the accretion curtain. A Gaussian line component for the Fe K- α fluorescent line is frozen at 6.4 keV with a fixed width of $\sigma = 0.01$ keV. For the reflect model, we linked the reflection scaling factor (r_{refl}) to the shock height h, which was determined self-consistently by the MCVSPEC model in each spectral fit, following the recipe suggested by Tsujimoto et al. (2018). Note that X-ray reflection is more pronounced when the accretion column is shorter. Overall, the full spectral model was set to tbabs*pcfabs*(reflect*MCVSPEC + gauss).

Before fitting the X-ray spectra, we constrained the range of input parameters, such as R_m/R and \dot{m} . Following Shaw et al. (2020), we constrained R_m/R by assuming that the WD is in spin equilibrium with the accretion disk at the magnetospheric radius. In this case, the magnetospheric radius is given by $R_m = \left(\frac{GMP^2}{4\pi^2}\right)^{1/3}$, where P = 521 s is the WD spin period. The specific accretion rate, however, is largely unconstrained due to the unknown source distance (d) and fractional accretion column area (f). The specific accretion rate is defined as $\dot{m} = \frac{\dot{M}}{4\pi f R^2}$ where \dot{M} is the total mass accretion rate [g s⁻¹]. Assuming that X-ray emission represents most of the radiation from the IP (i.e., $L \approx L_X$), \dot{M} can be calculated from $L = GM\dot{M}\left(\frac{1}{R} - \frac{1}{R_w}\right)$, where $L = 4\pi d^2 F_X$ is the total luminosity and F_X represents the unabsorbed X-ray flux. We assumed d = 1.4-5 kpc which is estimated from the Galactic absorption column density towards the line of sight from X-ray spectral fitting. We first estimated the minimum specific accretion rate \dot{m}_{\min} by assuming the shortest source distance (1.4 kpc) and maximum fractional accretion col-umn area (f_{max}). $f_{\text{max}} = \frac{R}{2R_m}$ is given for a dipole B-field geom-etry, assuming that the infalling gas originates from the entire accretion disk truncated at R_m (Frank et al. 2002).

Since some of the parameters described above depend on the WD mass, we adopted a handful of M values, namely, 0.6, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, and $1.35M_{\odot}$ as initial estimates. For each WD mass estimate, we computed R_m/R and the \dot{m}_{\min} . We then proceeded to fit the X-ray spectra by inputting these R_m/R and the $\dot{m}_{\rm min}$ values. This is not sufficient since the specific accretion rate may be larger than \dot{m}_{min} due to potentially larger source distance ($d \gtrsim 1.4$ kpc), smaller fractional accretion column area $(f \lesssim f_{\text{max}})$ and missing source luminosity below the X-ray band $(L \gtrsim L_X)$. Therefore, we also considered a large range of \dot{m} above \dot{m}_{\min} ($\dot{m} = 0.0043-83 \text{ [g cm}^{-2} \text{ s}^{-1}\text{]}$). For each \dot{m} value (frozen), we fit the X-ray spectra and determined the WD mass and statistical errors. We found that the fitted WD mass becomes saturated and independent of \dot{m} at higher \dot{m} values (typically $\gtrsim 10$ $[g \text{ cm}^{-2} \text{ s}^{-1}]$) when the shock height becomes only a small fraction of the WD radius. This saturation of the WD mass over \dot{m} results from the fact that both the shock temperature and X-ray reflection (both of which are functions of h/R) become less dependent on the shock height.

In each case, our model was well fit to the X-ray spectra with reduced $\chi^2 = 1.18-1.21$ (Fig. 4). In the end, we checked the

Fig. 4: The XMM-Newton and NuSTAR spec-XMMU J173029.8-330920, with tra of fit tbabs*pcfabs*(reflect*MCVSPEC + gauss). This fit utilized an initial mass of $1.2M_{\odot}$ and thus an R_m/R ratio of 26. The specific accretion rate for this fitting was 15 [g cm⁻² s⁻¹], resulting in the best-fit WD mass of ~ $1.28^{+0.12}_{-0.23}M_{\odot}$, which is consistent with the initially assumed value of $1.2 M_{\odot}$. The black, red, green, and blue data points are from EPIC-pn, MOS2, FPMA, and FPMB, respectively.

self-consistency of our fitting results by ensuring the measured WD mass was consistent with the assumed WD mass within statistical and systematic errors. The same method was applied to fit broad-band X-ray spectra of another IP obtained by XMM-Newton and NuSTAR (Salcedo et al. submitted to ApJ). The systematic errors stem from the range of the specific accretion rate we considered. We found that the initial mass estimates of $M \ge 1.0 M_{\odot}$ yielded self-consistent WD mass measurements. We were able to constrain the WD mass range to $0.94{-}1.4\,M_{\odot},$ which is comparable to or larger than the mean WD mass of magnetic CVs $(0.81^{+0.16}_{-0.20}M_{\odot})$; Pala et al. 2022). The large WD mass range is due to statistical and systematic errors, largely associated with the unknown source distance and fractional accretion column area. As emphasized in Vermette et al. (2023), it is desirable to constrain the source distance well and obtain better photon statistics (particularly above 10 keV) for determining the WD mass more accurately in the future.

5.2. Fe-K- α lines

There is an indication of Fe K_{α} line emission at 6.4 keV. The equivalent width of the line is 312±104 eV. Most IP-type sources also display the presence of ionized Fe lines at 6.7 (Fe XXV) and 6.9 (Fe XXVI) keV with an equivalent width higher than 50 eV (Xu et al. 2016). We checked the presence of the 6.7 and 6.9 keV lines and estimated an upper limit on the equivalent width. The upper limit on the equivalent width of Fe XXV and Fe XXVI lines are 134 and 147 eV, respectively, which can be confirmed with a longer observation in the future. The 6.4 keV iron K_{α} line is mainly created by irradiation of neutral ma-

terial by hard X-ray photons. Compact objects accreting matter through the accretion disk show X-ray reflection from the accretion disk. Whereas in the case of accreting WD, most of the hard X-rays are produced so close to the compact object that one might expect half of the photons to be directed toward the WD surface and reflected back to the observer. X-ray reflection in accreting compact objects shows the signature of Fe K_{α} fluorescence line and a Compton reflection hump in 10-30 keV. The Compton reflection hump was originally difficult to measure; however, with the launch of the NuSTAR satellite, the X-ray reflection was detected in a couple of magnetic CVs (Mukai et al. 2015). We also checked the presence of a reflection component in the X-ray spectrum of XMMU J173029.8-33092 by adding a convolution term reflect (Magdziarz & Zdziarski 1995) to the total model. However, the addition of the reflection component does not provide any improvement in $\Delta \chi^2$. On the other hand, the neutral Fe K_{α} line could have been produced by reprocessing when the hard X-ray passes through the partial covering medium. The hard X-rays traveling through the absorbing material will interact with the iron and create a Fe K_{α} fluorescence line. In such a scenario, the intensity of Fe K_{α} line will increase with the thickness of the ambient material. In a sample study of mCVs using Suzaku data, the column density of the partial absorber seems to correlate with the 6.4 keV line intensity (Eze 2014, 2015), which indicates that the emission of the neutral iron K_{α} is primarily caused by absorption-induced fluorescence from the absorber.

6. Conclusions

We serendipitously discovered the source XMMU J173029.8-330920 during our XMM-Newton Heritage survey of the Galactic disk. Later, we followed up on the sources using our preapproved NuSTAR ToO observation. We suggest that the identity of XMMU J173029.8-330920 is an IP based on XMM-Newton and NuSTAR data analysis. The X-ray spectra can be fitted by emission from collisionally ionized diffuse gas with plasma temperature of 26^{+11}_{-5} keV. One requires a partial covering absorption in addition to the Galactic absorption to model the X-ray spectrum. The X-ray spectra show the presence of neutral Fe K_{α} emission line at 6.4 keV, while the X-ray light curves show periodic modulation with a period of 521.7 ± 0.8 s. These features are commonly seen in accreting magnetic CVs of IP type.
