(Dated: July 9, 2024)

We derive, and validate numerically, an analytical model for electron-only magnetic reconnection applicable to strongly magnetized (low-beta) plasmas. Our model predicts sub-ion-scale reconnection rates significantly higher than those pertaining to large-scale reconnection, aligning with recent observations and simulations. We apply this reconnection model to the problem of inverse magnetic-energy transfer at sub-ion scales. We derive time-dependent scaling laws for the magnetic energy decay and the typical magnetic structure dimensions that differ from those previously found in the MHD regime. These scaling laws are validated via two- and three-dimensional simulations, demonstrating that sub-ion scale magnetic fields can reach large, system-size scales via successive coalescence.

Introduction. Decaying turbulence in plasmas is sometimes accompanied by the transfer of energy from small to large scales; a so-called inverse transfer. Though poorly understood, this phenomenon is thought to be crucial to magnetic field evolution at cosmological scales $[1-3]$ $[1-3]$ as well as in various astrophysical systems such as the solar wind $[4]$ and the heliosphere $[5, 6]$ $[5, 6]$. The standard explanation for inverse energy transfer appeals to the conservation of net magnetic helicity [\[7–](#page-4-5)[9\]](#page-4-6). However, recent studies have shown that this process can also occur in non-helical turbulent systems [\[10,](#page-4-7) [11\]](#page-4-8). It has been proposed that this may be due to the successive merger of magnetic structures via magnetic reconnection, thus transferring energy to progressively larger scales [\[12–](#page-4-9)[17\]](#page-4-10).

So far, investigations of this topic have mostly been restricted to the resistive MHD framework. This implies they cannot be directly applied to the (mostly) collisionless environments often encountered in astrophysical contexts. For example, recent in-situ spacecraft measurements have provided substantial evidence for the existence of numerous rope-like magnetic structures at ion scales, with substructures within these flux ropes observed at electron scales (e.g., $[18-21]$ $[18-21]$). As such, the existing understanding of inverse energy cascade needs to be extended to account for (i) kinetic modifications to turbulent dynamics; and (ii) changes to magnetic reconnection — as compared to resistive MHD systems.

The latter is of particular importance given the observation that the physics of reconnection between subion-scale structures is expected to be substantially different: when the reconnection region is sufficiently small, the ions can become unresponsive, and a transition to so-called "electron-only reconnection" is expected. This variant of magnetic reconnection has been recently observed in the Earth's magnetosphere [\[22,](#page-4-13) [23\]](#page-4-14), and is numerically found to exhibit substantially higher reconnection rates compared to conventional scenarios [\[24–](#page-5-0)[30\]](#page-5-1).

The goal of this Letter is thus to generalize the current resistive-MHD-based understanding of inverse energy transfer via magnetic reconnection to kinetic, collisionless plasma environments.

Equations. We employ a two-field isothermal fluid model valid for low-beta plasmas [e.g., [31–](#page-5-2)[35\]](#page-5-3). The dynamics of this system are described by equations for the perturbed electron density δn_e and the parallel (to the guide-field B_z) vector potential A_z , which read [\[36\]](#page-5-4):

$$
\frac{1}{n_{0e}} \frac{d \delta n_e}{dt} = \hat{\mathbf{b}} \cdot \nabla \frac{e}{c m_e} d_e^2 \nabla_{\perp}^2 A_z, \qquad (1)
$$

$$
\frac{d}{dt}\left(A_z - d_e^2 \nabla_{\perp}^2 A_z\right) = -c \frac{\partial \varphi}{\partial z} + \hat{\mathbf{b}} \cdot \nabla \frac{\delta n_e}{n_{0e}}.\tag{2}
$$

Here, $\hat{\mathbf{b}} \cdot \nabla \equiv \partial/\partial_z - 1/B_z \{A_z,...\}$ is the parallel (to the total field) gradient operator, and $d/dt \equiv \partial/\partial t +$ $c/B_z\{\varphi,\ldots\}$ denotes the convective time derivative, with φ the electrostatic potential; both operators feature a Poisson bracket, defined as $\{P, Q\} \equiv \partial_x P \partial_y Q - \partial_y P \partial_x Q$. These equations are closed via the gyrokinetic Poisson law [\[37\]](#page-5-5),

$$
\frac{\delta n_e}{n_{0e}} = \frac{T_{0e}}{T_{0i}} (\hat{\Gamma}_0 - 1) \frac{e\varphi}{T_{0e}},\tag{3}
$$

where $\hat{\Gamma}_0$ denotes the inverse Fourier transform of $\Gamma_0(\alpha) = I_0(\alpha)e^{-\alpha}$, with I_0 the zeroth-order modified Bessel function of the first kind and $\alpha = k_{\perp}^2 \rho_i^2/2$, where $\rho_i = v_{\text{th}i}/\Omega_i$ is the ion Larmor radius, with $v_{\text{th}i}$ = $\sqrt{2T_{0i}/m_i}$ the ion thermal velocity and $\Omega_i = eB_z/m_ic$ the ion Larmor frequency. Lastly, $d_e = c/\omega_{pe}$ is the electron skin depth, with $\omega_{pe} = \sqrt{4\pi n_{0e}e^2/m_e}$ the electron plasma frequency. In the following, we refer to "perpendicular" as the direction perpendicular to the guide field B_z , i.e., the xy plane.

Electron-only Reconnection. We now use these equations to derive a two-dimensional reconnection model valid at scales below the ion Larmor radius. We consider

 $2P$ roxima Fusion GmbH, Munich, 81671, Germany

two identical magnetic islands with typical magnetic field B_{\perp} and radius R such that $d_e \ll R \ll \min(\rho_i, \rho_s),$ merging in the x direction, where $\rho_s = \rho_i / \sqrt{2T_{0i}/T_{0e}}$ is the ion sound Larmor radius. The total magnetic flux to be reconnected is $A_{z,\text{total}} = B_{\perp}R$, and the time for this process to occur (reconnection time) is denoted as τ_{rec} . The width of the current sheet between the islands during reconnection is denoted as δ_x , assumed comparable to d_e (the scale at which the frozen flux condition is broken in our model), and the length of the current sheet is denoted as δ_y . In the current sheet, $A_z = A_{z,\text{sheet}} \sim B_{\perp} \delta_x$, consistent with an upstream reconnecting field $B_y = \partial_x A_z \sim B_\perp$. The out-of-plane current in the sheet is then $-(4\pi/c)J_z = \nabla_{\perp}^2 A_z \sim B_{\perp}/\delta_x$.

In the limit $k_{\perp} \rho_i \gg 1$, Eq. [\(3\)](#page-0-0) reduces to $\delta n_e/n_{0e} =$ $-e\varphi/T_{0i}$. Thus the advection of δn_e term in Eq. [\(1\)](#page-0-1) vanishes. The advection of A_z term in Eq. [\(2\)](#page-0-2), i.e., $\{\varphi, A_z\},\$ becomes $-(cT_{0i}/eB_z)\{\delta n_e/n_{0e}, A_z\}$, which can be com-bined with the R.H.S. of Eq. [\(2\)](#page-0-2). Taking $\partial_x \sim 1/\delta_x$ and $\partial_y \sim 1/\delta_y$ and balancing both sides of Eq. [\(1\)](#page-0-1) within the sheet, we find $(\delta n_e/n_{0e})/\tau \sim (ed_e^2/B_z cm_e)(B_\perp^2/\delta_x \delta_y)$, where τ is the time it takes to reconnect the magnetic flux $A_{z,\text{sheet}}$. A similar term-balancing procedure for Eq. [\(2\)](#page-0-2) yields $A_z/\tau \sim (c(T_{0e} + T_{0i})/eB_z n_{e0}) (B_\perp \delta n_e/\delta_y)$. Note that the electron inertia term does not affect this balance since $d_e^2 \nabla_{\perp}^2 A_z \sim (d_e/\delta_x)^2 A_z \sim A_z$.

Combining these results, we find $\tau \sim$
 $(\sqrt{1+T_{0i}/T_{0e}})(\delta_u/\rho_s)(d_e/v_{A,\perp}),$ where $v_{A,\perp} =$ $(1/\sqrt{1+T_{0i}/T_{0e}})(\delta_y/\rho_s)(d_e/v_{A,\perp}),$ where $v_{A,\perp}$ = $B_{\perp}/\sqrt{4\pi n_0 m_i}$ is the (ion) Alfvén speed. The last step is to relate the reconnection time, τ_{rec} , and τ via $\tau_{\rm rec}/\tau \sim A_{z,\rm total}/A_{z,\rm sheet} \sim R/d_e$. Writing the reconnection time in the form of $\tau_{\text{rec}} \sim \mathcal{R}_{\text{rec}}^{-1} R/v_{A,\perp}$, we obtain the normalized reconnection rate:

$$
\mathcal{R}_{\text{rec}} \sim \sqrt{1 + \frac{T_{0i}}{T_{0e}} \frac{\rho_s}{\delta_y}} \sim \sqrt{1 + \frac{T_{0i}}{T_{0e}} \frac{\rho_s}{R}},\tag{4}
$$

where we have assumed $\delta_y \sim R$ (see Supplemental Material for validation). When $\rho_s > R$, the (normalized) reconnection rate can become much larger than the value of ∼ 0.1 typically associated with collisionless reconnec-tion [\[38](#page-5-6)[–40\]](#page-5-7) (but may not exceed $\sim \rho_s/d_e$).

The outflow velocity, u_{out} , can be calculated as $u_{\text{out}} \sim (c/B_x)E_z \sim cR/(d_e B_\perp)(B_\perp R/c\tau_{\text{rec}})$ $\begin{array}{l} u_{\rm out} \;\sim\;\;\; (c/B_x) E_z \;\;\sim\;\;\; cR/(d_e B_\perp) (B_\perp R/ c \tau_{\rm rec}) \;\;\sim\ \sqrt{1+T_{0i}/T_{0e}} (\rho_s/d_e) v_{A,\perp} \;\;\sim\;\;\; \sqrt{1+T_{0i}/T_{0e}} \sqrt{\beta_e} v_{Ae,\perp}, \end{array}$ with $v_{Ae,\perp} \equiv B_{\perp}/\sqrt{4\pi n_{0e}m_e}$ the electron Alfvén speed based on perpendicular magnetic field. The conclusion that the outflow velocity is proportional to electron Alfvén speed is consistent with previous laboratory observations [\[41\]](#page-5-8). Therefore, if instead we normalize the reconnection time to the outflow time, i.e., $\tau_{\text{rec}} \sim \mathcal{R}_{\text{rec},e}^{-1} R/u_{\text{out}}$, we obtain, unsurprisingly,

$$
\mathcal{R}_{\text{rec,e}} \sim d_e/R;
$$
 (5)

i.e., the aspect ratio of the reconnecting current sheet.

We now proceed to validate this model via direct numerical simulations. Eqs. $(1,2,3)$ $(1,2,3)$ $(1,2,3)$ are solved numerically using the pseudo-spectral code GX $[42, 43]$ $[42, 43]$. Hyperdiffusive terms of the form $\nu_H \nabla^6_{\perp}$ are added to the R.H.S. of Eqs. [\(1,](#page-0-1)[2\)](#page-0-2), with $\nu_H = 1/\Delta t (\Delta x/\pi)^6$; this value ensures that these terms are only significant at scales comparable to the grid scale. These details apply to all the simulations we include in this Letter.

In what follows, all quantities are presented in dimensionless units. The simulations are performed in a doubly periodic box of dimensions $L_x \times L_y$, where $L_x = L_y = 2\pi$. The initial condition consists of two identical magnetic islands of Gaussian shape, specified as $A_z = A_0 \exp(-(2\pi a(x - 0.25L_x)/L_x)^2 - (2\pi a(y (0.5L_y)/L_y)^2$ + $A_0 \exp(-(2\pi a(x - 0.75L_x)/L_x)^2$ - $(2\pi a(y - 0.5L_y)/L_y)^2)$ [\[44\]](#page-5-11). We set $a = 1.5$ so that the root-mean-squared width of each island is about 1.1, i.e., $R \approx 0.55$. Multiple simulations are performed by varying the values of ρ_i (we set $T_{i0}/T_{e0} = 1$ in all the simulations so $\rho_s = \rho_i / \sqrt{2}$ and d_e to encompass both the regime where $R \gtrsim \rho_i > d_e$ (traditional ion-coupled reconnection) and $\rho_i > R \gg d_e$ (electron-only reconnection). The numerical resolution is adjusted across simulations to resolve the d_e scale adequately (see the Supplemental Material for more information).

FIG. 1: Dimensionless peak reconnection rates, \mathcal{R}_{rec} , from simulations with different values of ρ_i/R . In the electron-only regime $(d_e < R \leq \rho_i)$, red, orange, and yellow symbols refer to simulations with $d_e/R = 0.05, 0.1, 0.2$, respectively. In the ion-coupled regime $(d_e < \rho_i < R)$, we set $d_e/\rho_i = 0.1$ (except for the leftmost data-point, where $d_e/\rho_i = 0.2$). The dashed line is Eq. [\(4\)](#page-1-0) (with $T_{i0}/T_{e0} = 1$).

For each simulation, we calculate the reconnection rate as the time derivative of the magnetic flux between the X- and the O-points. The peak reconnection rates are plotted in Fig. [1](#page-1-1) against the parameter ρ_i/R . Along the horizontal axis, the progression from left to right signifies a transition from MHD to sub- ρ_i scales in terms of the initial island size. At MHD scales, we observe that the reconnection rate converges to a constant value \sim 0.2, somewhat higher than the often quoted value of 0.1 [e.g., $38-40$, $45-49$] but consistent with previous results for collisionless reconnection in the strong guidefield limit [\[50,](#page-5-14) [51\]](#page-5-15). However, upon transition to sub-ion scales (i.e., $R < \rho_i$), the reconnection rates exhibit a substantial increase, aligning almost perfectly with our model's prediction, Eq. [\(4\)](#page-1-0), represented by the dashed line in Fig. [1.](#page-1-1) Consistently, at fixed ρ_i/R , the reconnection rate depends only weakly on the value of d_e (and such dependence weakens as d_e becomes smaller). We also note that the reconnection rate starts to significantly deviate from the large-scale (ion coupled) value (\sim 0.2) at around $R \sim 10\rho_i$. This observation is consistent with the analysis in [\[52\]](#page-5-16) and with simulation results [\[25\]](#page-5-17), where it is predicted that ions start to decouple from the reconnecting magnetic field at scales of around 10 ion-scales. However, it is not until $R \sim \rho_i$ that the reconnection rate perfectly aligns with Eq. [\(4\)](#page-1-0).

Lastly, we note that although our focus here is on lowbeta plasmas, it is relatively straightforward to extend our analytical model to the $\beta_e \sim 1$ case; see Supplemental Material for details.

Magnetic Flux Tube Coalescence. We now apply the electron-only reconnection model to the problem of inverse transfer of magnetic energy at sub-ion scales within the framework of Eqs. [\(1-](#page-0-1)[3\)](#page-0-0). We first address twodimensional dynamics in the perpendicular plane. Consider two identical circular magnetic islands of radius R such that $\rho_i > R \gg d_e$. Each carries the magnetic flux RB_{\perp} , which is assumed to be conserved by their merger [\[12,](#page-4-9) [13\]](#page-4-15). The lifetime of these two islands is determined by the reconnection time, $\tau_{\text{rec}} \sim (R/\rho_s)(R/v_{A,\perp}),$ as shown above.

Now considering a "sea" of (volume-filling) magnetic islands with similar sizes in the sub- ρ_i regime and assuming the merging process to occur sequentially between island pairs, the evolution of total magnetic energy can be described by

$$
\frac{d\mathcal{E}}{dt} \propto \frac{dB_{\perp}^2}{dt} \sim -\frac{B_{\perp}^2}{\tau_{\rm rec}} \propto -B_{\perp}^5.
$$
 (6)

We thus find $\mathcal{E} = [a(t - t_0) + \mathcal{E}_0^{-3/2}]^{-2/3}$, where t_0 is the lifetime of the first island generation, a is a coefficient, and \mathcal{E}_0 is the initial magnetic energy. The perpendicular coherence scale and magnetic field strength can be derived in a similar way. The resulting long-term $(\tilde{t} \equiv t/t_0 \gg 1)$ evolution scaling laws are

$$
k_{\perp} \propto \tilde{t}^{-1/3}, \quad B_{\perp} \propto \tilde{t}^{-1/3}, \quad \mathcal{E} \propto \tilde{t}^{-2/3}.
$$
 (7)

When extending to the three-dimensional case (with a strong guide field), a magnetic island of radius R and magnetic field B_{\perp} becomes a magnetic flux tube with radius R, poloidal magnetic field B_{\perp} , and length l in the direction of the local mean field. The arguments above

leading to Eq. [\(7\)](#page-2-0) should remain valid (which we will confirm via direct numerical simulation). The length of the flux tube l can be estimated from the assumption that the inverse linear time scale, $\gamma_l \sim \omega_{KAW} \sim k_{\perp} \rho_s k_{\parallel} v_A$ (with $k_{\perp} \sim 1/R$ and $l \sim 1/k_{\parallel}$), should be comparable to the inverse nonlinear time scale, γ_{nl}^{-1} (critical bal-ance [\[53\]](#page-5-18)), where γ_{nl}^{-1} should be the smallest of the reconnection time, τ_{rec} , and the perpendicular advection time, R/u_{\perp} , with $u_{\perp} \sim (c/B_z)\varphi/R$ being the in-plane $(E \times B)$ velocity that pertains to Eqs. [\(1-](#page-0-1)[2\)](#page-0-2). By assuming scale-by-scale equipartition between the density and magnetic energy fluctuations, $(\delta n_e/n_{0e})^2 n_{0e} T_{0e} \sim$ $|\nabla_{\perp}A_z|^2/8\pi$ [\[35\]](#page-5-3) (see Supplemental Material for validation of this hypothesis), together with Eq. [\(3\)](#page-0-0) in the limit $k_{\perp} \rho_i \gg 1$, we find $\varphi \sim \sqrt{T_{0i}/T_{0e}} (\rho_i v_A/c) B_{\perp}$ and, thus, $R/u_{\perp} \sim (R/\rho_s)(R/v_{A,\perp}) \sim \tau_{\text{rec}}$. Therefore, we conclude that the nonlinear advection time and reconnection time are comparable within this regime, i.e., $\gamma_{nl} \sim \tau_{\text{rec}}^{-1} \sim k_{\perp} \rho_s k_{\perp} v_{A,\perp}$. This conclusion differs from that in the MHD regime, where reconnection is always slower [\[13\]](#page-4-15). Finally, balancing γ_l with γ_{nl} yields

$$
l \sim B_z/(k_\perp B_\perp) \propto \tilde{t}^{2/3}.\tag{8}
$$

To verify these predictions, we conducted a threedimensional simulation in a periodic domain with dimensions $L_x \times L_y \times L_z$, where $L_x = L_y = 2\pi$ and $L_z = 4L_x$ (in normalized units). We specify the initial equilibrium as $A_z(x, y, z, t = 0) = A_{z0} \cos(k_0 x) \cos(k_0 y)$ with $k_0 = 10$ with $A_{z0} = 0.1$, yielding a $2k_0 \times 2k_0$ static array of magnetic flux tubes with sequentially opposite polarities. We set $\rho_i = 2.0$ (and $T_{i0} = T_{e0}$) and $d_e = 0.04$. These choices ensure that all flux tubes satisfy $d_e \ll R < \rho_i$, and thus Eqs. [\(7](#page-2-0)[-8\)](#page-2-1) should be valid after an initial transient.

Fig. [2](#page-3-0) presents the temporal evolution of some key quantities. The top panel of Fig. [2](#page-3-0) (a) shows the time evolution of the wavenumber at which the magnetic energy spectrum peaks, $k_{\perp,\text{max}}$; whereas the bottom panel shows the box-averaged magnetic energy, \mathcal{E} . Both quantities conform to the theoretical predictions after $t \approx$ $0.3\tau_A$, with the scaling laws of Eq. [\(7\)](#page-2-0) becoming applicable for $t \geq 1.0 \tau_A$ [\[54\]](#page-6-0). Likewise, the parallel coherence length l, estimated using the five-point second-order structure function [\[35,](#page-5-3) [55,](#page-6-1) [56\]](#page-6-2) (see the Supplemental Material for further details), aligns with Eq. [\(8\)](#page-2-1) after approximately $t \approx 2.0 \tau_A$ $t \approx 2.0 \tau_A$ $t \approx 2.0 \tau_A$, as evident from Fig. 2 (b) [\[57\]](#page-6-3).

Fig. [2](#page-3-0) (c) shows the evolution of the perpendicular magnetic-energy spectrum. A reasonable agreement with a $k_{\perp}^{-8/3}$ [\[35,](#page-5-3) [58\]](#page-6-4) inertial range power-law behavior is observed, suggesting that, in addition to the inverse cascade arising from the flux-tube merger, there is also a direct cascade driven by the nonlinear interaction of kinetic Alfvén wave packets. This observation is consistent with measurements of turbulence in the Earth's magnetosheath in instances where electron-only reconnection is prevalent [\[23\]](#page-4-14).

FIG. 2: Three-dimensional simulation results. (a) Temporal evolution of the wavenumber corresponding to the peak of the magnetic spectrum (top panel) and total magnetic energy (bottom panel). a, b, c, d are fitting parameters. We use the data to the right of the gray vertical dashed lines to avoid the transient stage. (b) Parallel coherence length l at different times. (c) The perpendicular magnetic spectra at progressively later times (from blue to green). The vertical dashed line denotes the d_e scale.

Lastly, we note that although the above results are obtained within the isothermal limit, we verify (see Supplemental Material) that the temporal power laws still hold in the non-isothermal case.

Transition to MHD scales. As the flux tube (or island) merging proceeds, structures get progressively larger and eventually transition to MHD scales, i.e., $R \gg \rho_i$. In this regime, electron-only reconnection no longer applies; instead, we expect the (normalized) reconnection rate to be a constant, independent of either the island size or the kinetic scales (Fig. [1](#page-1-1) indicates $\mathcal{R}_{\text{rec}} \approx 0.2$. This observation, together with flux conservation, is all that is required to conclude that, at this stage, the evolution scalings of resistive MHD [\[12,](#page-4-9) [13,](#page-4-15) [15\]](#page-4-16) should apply here as well. Namely, we expect

$$
k_{\perp} \propto \tilde{t}^{-1/2}, \quad B \propto \tilde{t}^{-1/2}, \quad \mathcal{E} \propto \tilde{t}^{-1}.
$$
 (9)

To directly investigate these predictions, we conducted a two-dimensional simulation for which the initial condition is $\hat{A}_z(\mathbf{k}_\perp) = A_{z0}(k_\perp^4/k_c^4) \exp(i\phi(\mathbf{k}_\perp))$ for $k_\perp \leq k_c$ and $\hat{A}_z(\mathbf{k}_\perp) = A_{z0} (k_\perp^4 / k_c^4) \exp(1 - k_\perp^4 / k_c^4) \exp(i \phi(\mathbf{k}_\perp))$ for $k_{\perp} > k_c$, where $\phi(\mathbf{k}_{\perp})$ is a random phase, $A_{z0} = 0.001$ and $k_c = 160$. The domain is a doubly periodic box of dimensions $L_x \times L_y$, with $L_x = L_y = 2\pi$, and the spatial grid size is 8192². We set $\rho_i = 0.025$ ($\rho_s \approx 0.0177$)

and $d_e = 0.002$, so that the initial condition satisfies $\rho_i^{-1} < k_c < d_e^{-1}$; thus, this simulation should first capture merging at kinetic scales (as in the 3D simulation discussed earlier), followed by a transition to MHD scales.

FIG. 3: Temporal evolution of magnetic energy $\mathcal E$ (blue) and characteristic island radius R (red) from the two-dimensional simulation. The horizontal red dashed line denotes $R = \rho_i$.

Time traces of magnetic energy $\mathcal E$ and characteristic radius R of the magnetic structures, defined as R \equiv $2\pi/4k_{\perp,\text{max}}$, are presented in Fig. [3.](#page-3-1) Initially, these quantities are found to evolve according to the power laws $\tilde{t}^{-2/3}$ and $\tilde{t}^{1/3}$, respectively, in accordance with Eq. [\(7\)](#page-2-0). As R exceeds ρ_i (around $t \approx 0.2\tau_A$) the evolution of these quantities starts to deviate from those power laws. This threshold is consistent with the departure from the electron-only reconnection regime (i.e., Eq. [\(4\)](#page-1-0)) as ρ_i/R decreases identified in Fig. [1.](#page-1-1) Around $t \approx 10.0\tau_A$, R reaches $10\rho_i$, the scale at which the reconnection rate converges to the constant large-scale value and ions are fully coupled (see Fig. [1\)](#page-1-1). Consistently, transitions to $\mathcal{E} \sim \tilde{t}^{-1}$ and $R \sim \tilde{t}^{1/2}$ power-law scalings are observed, in agreement with the predictions of Eq. [\(9\)](#page-3-2).

Conclusions. We present an analytical model for electron-only strong-guide-field reconnection in low- β plasmas. Unlike large-scale collisionless reconnection, where the (normalized) reconnection rate is conjectured to be a constant of order 0.1 [\[39,](#page-5-19) [40\]](#page-5-7), we find that this regime is characterized by reconnection rates that scale as the ratio between the ion gyroradius and the size of the reconnecting structure and which can significantly exceed 0.1. This finding provides a theoretical explanation for previous observational and numerical studies [e.g., [25,](#page-5-17) [29,](#page-5-20) [30\]](#page-5-1). The validity of our model is confirmed through direct numerical simulations, which also reveal that deviation from the fully ion-coupled regime begins when $R \approx 10\rho_i$, consistent with previous numerical studies [\[25\]](#page-5-17) in a different plasma regime. Although our focus in this study is low beta plasmas, we also propose an extension of our derivation to $\beta_e \sim 1$ (see Supplemental Material) which appears to be consistent with existing numerical data.

Using this reconnection model, we derive timedependent scaling laws for inverse magnetic-energy transfer in the sub- ρ_i range, which we validate via a three-dimensional direct numerical simulation. Finally, through a two-dimensional simulation starting with random Gaussian magnetic fields, we demonstrate the ability of magnetic-island mergers to transport magnetic energy from kinetic to MHD scales, accompanied by predicted changes in the time-dependent scaling laws. In addition to its relevance to the understanding of the self-organization of systems dominated by flux-rope-like structures [e.g., [20,](#page-4-17) [59,](#page-6-5) [60\]](#page-6-6), this conclusion lends credence to recently proposed ideas for the viability of electron-scale seeds as the origin of large-scale magnetic fields [\[13,](#page-4-15) [61,](#page-6-7) [62\]](#page-6-8).

- [44] This initial configuration is approximately an equilibrium but it is unstable to coalescence instability [\[75\]](#page-6-9). We choose this configuration instead of the typical Harris sheet [\[76\]](#page-6-10) for consistency with the study of the inverse magnetic energy transfer problem discussed below. However, we do not expect the results to be sensitive to the specific configuration chosen.

- [57] Before the system settles into a natural state of decaying turbulence described by our theory, it undergoes a transient stage characterized by the development of strong turbulence. An essential indicator of strong turbulence is the establishment of critical balance, where flux tubes initially confined to box length break in the z-direction. This reduction in the parallel coherence length l is captured by the first two data points in Fig. [2](#page-3-0) (b).
