CONUS employs p-type point contact germanium detectors (PPCs, [1]) to search for Coherent Elastic Neutrino-Nucleus Scattering (CE $\nu$ NS) from reactor (anti)neutrinos. In this context the CE $\nu$ NS signal has an endpoint at approximately 0.3 keVee. Microphonic and electronic noise events are strongly dominant for PPCs in this energy regime. Demonstrating a complete rejection of these is crucial for this type of measurement. This has been emphasized in our [2], which reports on a similar search using a large-mass PPC. Ackermann et al. [3] claim to exclude the findings in [2]. As described below, the information in [3] is insufficient to back up this claim.

Fig. 3 in [3] purports to show the "measured reactor on and reactor off spectra" for CONUS detector C2, one of three involved. This omits the correction for signal acceptance (SA) near threshold, i.e., does not portray reconstructed spectra that would allow a reader to assess if any background contamination survives in the critical < 0.3 keVee region of interest (ROI). The CONUS collaboration has nevertheless displayed this missing information in recent presentations. For instance, in slide #12 at [4], where inspection is also facilitated by an expanded energy region. It is apparent there that a rapid rise in the reconstructed spectrum takes place near the 0.21 keVee threshold, with an inflection point at around 0.3 keVee. Applying the SA curve for C2 in [4] to the data in Fig. 3 of Ackermann et al. reproduces this behavior, generating the same reconstructed signal rate of ~100 counts/keV-kg-day at threshold. To our knowledge, no source of radiation is expected to produce this rise [5]. A recent study of CONUS backgrounds [6] does not predict such sources. In this situation, it is natural to entertain a concern that a fraction of accepted events below 0.3 keVee might originate in unrejected electronic noise and/or microphonics. As discussed in our work, the latter are highly correlated to PPC cryocooler power.

Slide #11 in [4] shows CONUS detector pulses at 0.3 keVee. These can be used to estimate how similar a 0.21 keVee signal would be to an upwards noise excursion in an energy region where rise-time pulse-shape discrimination (PSD) cuts, described as "conservative" in [3], range from lax to non-existent (see bottom-left panel in this same slide #11). At this point it is important to emphasize a key issue: unrejected low-energy microphonic events commonly display the same long rise-time of surface events in a PPC. This is nowhere mentioned by Ackermann et al., while acknowledging a large acceptance of long rise-time backgrounds. Microphonic-rejection methods based on time spanned between events,

used by CONUS, do not eliminate a necessarily finite fraction [7] of temporally-isolated signals of this type [2]. Hence the importance of a truly conservative rise-time cut [8] and the reality of the concern expressed above.

Ackermann et al. assert "highly stable conditions" during these runs. However, inspection of their Fig. 2 reveals a noticeable increase in both detector electronic noise and cryocooler power during reactor OFF periods, compared to reactor ON runs. A recently added appendix to [3] confirms that this extends to all detectors. While these variations might seem modest at first sight, the CONUS collaboration has quantified the magnitude of microphonic contamination in their detectors in Figs. 3.6a and 3.21 of [9]: at 0.21 keVee, the raw count rate prior to any cuts against microphonics is of order 6,000-40,000 counts/keV-kg-day, or up to several thousand times the irreducible background shown in Fig. 3 of Ackermann et al. The "almost linear correlation" between microphonic event rate below 0.28 keVee and minuscule changes in cryocooler power, smaller than those in [3], can be ascertained in Fig. 3.22 of [9]. In these conditions, even a small remanent noise contamination would be able to increase the reactor OFF event rate in the < 0.3 keVee region with respect to reactor ON periods, encumbering the observation of a CE $\nu$ NS excess in the ON-OFF residual or leading to tighter constraints on it. The rise in reconstructed spectra discussed above indicates that this contamination can be sizeable, as one third or more of the event rate at the intended 0.21 keVee analysis threshold originates in long rise-time backgrounds.

Ackermann et al. offer in their Fig. 2 two parameters supposed to exemplify the stability of their detectors. The first is the reset rate of the transistor-reset preamplifier (TRP). This is a mere measure of the electronic leakage current of a PPC, which is typically highly constant over periods of up to a few years in conditions of relatively stable ambient temperature [2]. This parameter provides no information on the leading source of microphonic noise contamination, which are unrelated mechanical vibrations in the cryocooler, correlated to its power consumption and in turn even to minor changes in ambient temperature (this last is mentioned and noticeable in the information provided in [3]). The second parameter offered as an alleged measure of stability is the energy resolution of a 10.4 keV electron capture decay peak. As discussed in [10], at this energy the resolution of a PPC is mainly defined by the intrinsically-stable dispersion in the statistics of information carriers (electronhole pairs), which derives exclusively from the amount of energy deposited by the decay. Needless to say, this is a time-independent constant. Conversely, detector noise becomes entirely dominant in defining the resolution at the lower energy of the  $CE\nu NS$  ROI. In conclusion, these two parameters may communicate a superficial impression of PPC stability, but in reality no proof of signal rate stability in the  $\text{CE}\nu \text{NS}$  ROI and of its lack of correlation to dominant PPC noise sources is presently offered by Ackermann et al. [11]. This is in contrast to Fig. 2 of our [2], where the evolution of the accepted irreducible event rate in the relevant 0.2-0.3 keVee ROI and that of the rejected backgrounds in the same region was provided. Their correlation to noise sources was examined, excluded for the first and established for the second. These pertinent parameters and the mode of correlation analysis that we employed are also available to Ackermann et al. In view of the strong concerns expressed here, they must be provided to support their claims. To quote from [2], "This type of correlation analysis is of crucial importance prior to a  $CE\nu NS$  search using PPCs, in view of the dominance of microphonic noise in the ROI [27]" (where ref. 27 is the CONUS thesis pointed out in these Comments [9]).

Even if these deficiencies and omissions can be corrected to substantiate the central tenet in Ackerman et al., multiple other issues remain: i) it is claimed that in our [12] "the Migdal effect was proposed as a physical explanation for the enhancement" in a low-energy quenching factor (QF) for nuclear recoils in germanium. This description is incomplete: this effect was examined as just one of several possible "new physical process (or

processes)". Those were listed as "alternative paths leading to an enhanced ionization yield" and cited as references 71-73 in [12]. ii) A theoretical study (ref. 25 in [3]) is mentioned as "demonstrating" that the Migdal effect is negligible in the present context. Said study fails to recognize the relevance of ultra-low energy secondary recoils emphasized in Sec. VII of [12]. Other studies argue for an enhanced importance of Migdal for such recoils in semiconductors (e.g., ref. 40 in [12], or more recently [13]). This area of knowledge is still in a theoretical and experimental state of flux, one that is naïvely described by Ackermann et al. iii) Mention is made that "good agreement between experimental data and the Lindhard prediction was found recently", citing [14] (criticized in [15]) and unpublished thesis work. For completeness, Ackerman et al. should comment on most recent experimental work [16] that points to the contrary and supports the QF results in [12]. iv) Finally, the YBe QF cubic fit showed in Fig. 4 of Ackermann et al., employed to extract their  $\text{CE}\nu\text{NS}$  rate prediction in Table II departs from the QF data that we used and provided in [2]. No justification is given for this [17]. Rising faster at low recoil energy, this manipulated QF can cause a somewhat inflated rate prediction [18], facilitating the claim of (marginal) exclusion of our findings. It should be noted that the best-fit  $\text{CE}\nu\text{NS}$  signal found in [2] lays in close vicinity to the predictions from this YBe QF model (Fig. 4 in [2]). In this last respect, both this YBe QF model and that proposed by CONUS in [14] (Lindhard  $\kappa = 0.162$ ) generate statistically compatible predictions in Table II of [3], even when using this inaccurate cubic fit. There is a manifest dissonance between this fact and the conclusions in Ackermann et al., one that seems difficult to defend.

- [7] The time between events in a Poisson process is described by a negative exponential distribution. The abrupt noise pedestal visible in [4] but not in [3] is composed of unrejected, temporally-isolated events. The low event multiplicity within bursts of microphonic events ("intermediate" in [9]) in CONUS detectors limits the effectiveness of this rejection method: assuming a Poisson-type distribution, a mean multiplicity of ~ 1.15 can be inferred from fig. 3.13 in [9]. Notice also fig. 3.12.

- [11] A fig. 6 in the new appendix of [3] displays an irreducible rate evolution in the 0.21-1 keVee range. It is claimed that this demonstrates an overall stability. CE $\nu$ NS signals are essentially restricted to the 0.21-0.3 keVee region. The same applies to the majority of microphonic events (see figs. from [9] mentioned here). The *a priori* much more stable 0.3-1 keVee event rate is larger by a factor  $\sim$  15 than that in the relevant < 0.3 keVee ROI (Fig. 3 in [3]). Therefore, fig. 6 has a very limited value for its intended purpose.
