(Dated: August 13, 2024)

We theoretically study the impact of light-driven structural changes via nonlinear phononics on the magnetic order of untwisted bilayer van der Waals materials. We consider an illustrative example of the AA-stacked bilayer honeycomb lattice and show that high-intensity light in resonance with selected phonons induces large amplitude phonon displacements that modify the magnetic Hamiltonian of the system. We performed a group theory analysis to identify the vibrational modes of the honeycomb bilayer and the nonlinear couplings among them in the strongly driven regime. We find that the structural changes in the strongly driven regime lower the symmetry relative to the equilibrium lattice and produce changes in the magnetic interactions between the local moments. In particular, the lattice symmetry changes permit a non-zero interlayer Dzyaloshinskii-Moriya interaction that induces a magnetic state with canted local moments. Using a spin-wave analysis about the new magnetic configuration we study the corresponding changes in the magnon spectrum and identify a protocol for engineering topological band transitions using a combination of nonlinear phononics and an external magnetic field. Our work suggests a strategy to induce interlayer Dyzaloshinskii-Moriya interactions in a class of layered van der Waals materials, the effect of which is to modify the magnetic ground state, magnon dispersions, and related band geometric properties, including topological invariants.

I. INTRODUCTION

The allowed magnetic exchange interactions on a particular lattice are constrained by symmetry. The Dzyaloshinskii-Moriya interaction (DMI),

$$
H_{\text{DMI}} = \sum_{i,j} \vec{D}_{ij} \cdot (\vec{S}_i \times \vec{S}_j),\tag{1}
$$

where \vec{S}_i is a spin on site i in the lattice and \vec{D}_{ij} is a lattice symmetry-determined vector depending on the positions of site i and j , is permitted in the absence of a center of inversion[\[1,](#page-7-0) [2\]](#page-7-1), either in bulk or at an interface [\[3,](#page-7-2) [4\]](#page-7-3). As seen from Eq.[\(1\)](#page-0-0), the DMI tends to favor spin configurations where local moments exhibit a perpendicular relative orientation, in contrast to the collinear orientations favored by Ising exchange interactions, and Heisenberg/XY exchange interactions in the absence of frustration. (Frustration can produce noncollinear ground state spin arrangements in spin Hamiltonians with a continuous spin rotational symmetry, such as occurs on the triangular lattice with nearest-neighbor antiferromagnetic Heisenberg interactions [\[5,](#page-7-4) [6\]](#page-7-5).) Through competition with Heisenberg exchange interactions, the DMI can lead to interesting magnetic textures, such as skyrmions [\[7\]](#page-7-6), which could find applications in spintronics [\[8–](#page-7-7)[10\]](#page-7-8).

The majority of studies on magnetic systems with a DMI have focused on the intralayer DMI, but recent theoretical predictions [\[11\]](#page-7-9), followed by experimental realizations [\[12](#page-7-10)[–15\]](#page-7-11), have shown the emergence of interlayer

DMI (IL-DMI) in layered magnetic systems. Furthermore, experiments have demonstrated the possibility of controlling the IL-DMI in synthetic antiferromagnets via electric currents [\[16\]](#page-7-12), which could enable the manipulation of three-dimensional magnetic textures [\[17\]](#page-7-13).

In this work, we explore how to generate an IL-DMI with optical control, namely by irradiating quantum materials with lasers, which previously has been demonstrated to induce and control various ordered states [\[18–](#page-7-14) [23\]](#page-8-0). In particular, the laser excitation of infrared lattice vibrations has allowed researchers to predict, induce and manipulate magnetic states [\[24–](#page-8-1)[26\]](#page-8-2) (including magnetic order switching [\[27,](#page-8-3) [28\]](#page-8-4)), ferroelectric states [\[29–](#page-8-5)[33\]](#page-8-6), and enhance superconductivity in organic materials [\[34–](#page-8-7)[39\]](#page-8-8), cuprates [\[40–](#page-8-9)[44\]](#page-8-10) as well as in more traditional BCS systems [\[45\]](#page-8-11). Additionally, theoretical proposals have shown that cavities, instead of lasers, could also lead to phononinduced ordered electronic states [\[46–](#page-8-12)[49\]](#page-8-13). The laser illumination strategy has the additional advantage of ultrafast (and reversible) control of the magnetic Hamiltonian.

Prior theoretical works have shown that light coupled directly to the electronic or spin degrees of freedom can induce and control the (intralayer) DMI in 2D magnetic materials described by the Kane-Mele-Hubbard model [\[50\]](#page-8-14), and in multiferroics [\[51\]](#page-8-15). After analyzing crystallographic point groups in two-dimensional insulating magnets, a subsequent symmetry analysis showed that lightinduced symmetry lowering universally results in a DMI [\[52\]](#page-8-16). However, introducing a mechanism that allows one to control the intralayer and IL-DMI interaction via the

⁴Department of Physics and HK Institute of Quantum Science \mathcal{C} Technology,

lattice vibrations could bypass (or at least minimize) the heating effects associated with such direct laser-electron coupling.

We consider an insulating AA-stacked bilayer honeycomb lattice with localized classical moments with collinear order from Heisenberg interactions. In equilibrium, symmetry considerations forbid an IL-DMI between nearest neighbors. We show that applying an intense enough laser in resonance with specific infrared active phonons lowers the symmetry of the non-equilibrium structure via non-linear coupling with Raman active phonons. The out-of-equilibrium lattice structure permits a non-zero IL-DMI between nearest neighbors, which, in turn, leads to a canted magnetic state. We also analyze the corresponding changes to the magnon spectrum as well as the magnon band topology.

The remainder of the paper is organized as follows. In Sec[.II B,](#page-2-0) we introduce a bilayer honeycomb lattice model and perform a symmetry (group theory) analysis to identify the normal modes of lattice vibrations (phonons) and their non-linear interactions. We then select the phonons that break the symmetry which forbids the existence of IL-DMI in equilibrium to allow the IL-DMI in the outof-equilibrium lattice configuration. In Sec. [III,](#page-3-0) we introduce the equilibrium magnetic Hamiltonian and the form of the phonon-induced IL-DMI. We perform a spinwave (magnon) analysis showing the effects of the IL-DMI. We suggest possible material candidates to observe the effects discussed in our work. Finally, in Sec. [IV,](#page-6-0) we present the main conclusions of our work.

II. IL-DMI FROM NONLINEAR PHONONICS

A. Brief review of nonlinear phononics

We begin our discussion by studying phonons, which are quantized modes of lattice vibrations. In a system with inversion symmetry they can be categorized into two types. One type is infrared active (IR) modes which are directly related to the electric dipole moment and thus can be directly excited by an electric field with the correct frequency. The other type is Raman modes, which are related to the polarizability of the phonon mode. In a centrosymmetric crystal, only infrared active modes can be directly controlled by an electric field, while Raman modes require a second order photon process to excite [\[53\]](#page-8-17). However, Raman active modes can be controlled indirectly via non-linear couplings to infrared active modes - an approach called nonlinear phononics [\[32,](#page-8-18) [54\]](#page-9-0). In particular, the nonlinear couplings between the two modes can be used to shift the equilibrium position of the Raman modes which are typically lower in frequency by looking at the average effect of the "fast" IR active modes. This approach allows one to modify lattice symmetries and enable new forms of magnetic exchange terms in a local moment Hamiltonian on the lattice.

In our work we will assume a frozen phonon picture as

well as a Born-Oppenheimer approximation [\[55\]](#page-9-1) for electrons responding to the transient lattice changes from light. This is well justified based on the light mass of the electrons relative to the lattice ions as well as the characteristic frequencies of phonons compared to electron energies (phonon frequencies are typically two orders of magnitude or more smaller). We also treat the interaction between light and infrared active modes, as well as the interaction between phonon modes themselves, as classical.

One can understand the qualitative effects from nonlinear phononics in a simple heuristic model: When one takes into account up to cubic order terms in the lattice displacements the effective potential of a single interacting IR and Raman phonon reads [\[56,](#page-9-2) [57\]](#page-9-3),

$$
V_{eff} = \frac{1}{2} \Omega_R^2 Q_R^2 + \frac{1}{2} \Omega_{IR}^2 Q_{IR}^2 - \frac{1}{4} g Q_{IR}^2 Q_R - F \Phi(t) \sin(\Omega t) Q_{IR},
$$
\n(2)

where Q_{IR} and Q_R are infrared and Raman lattice vibrational mode amplitudes, and Ω_R and Ω_{IR} are their corresponding frequencies. We assume that incident laser light on the material has a Gaussian envelope intensity $\Phi(t) \propto e^{-t^2/2\sigma^2}$ where σ is the characteristic value for the pulse length. The strength of an incoming laser field is determined by the parameter $F = \mathcal{Z}^* \cdot E$, where \mathcal{Z}^* is the so-called Born effective charge $[57]$ and E the peak electric field amplitude of the laser pulse. The parameter g is the coupling constant between Raman and infrared modes, appearing in the third term of Eq.[\(2\)](#page-1-0).

In the impulsive limit $\Omega \sigma \ll 1$, solving the equation of motion for the infrared mode, one has [\[56\]](#page-9-2),

$$
Q_{IR} = -\sqrt{2\pi} F \Omega_{IR} \sigma^3 \cos \Omega_{IR} t, \tag{3}
$$

which shows the IR active mode oscillates with frequency Ω_{IR} . In the same limit the equilibrium position of the Raman mode is displaced as $Q_R \to Q_R + \Delta Q_R$ [\[56\]](#page-9-2), where

$$
\Delta Q_R = \frac{\pi}{2} \left(\frac{\Omega_{IR}}{\Omega_R} \right)^2 g F^2 \sigma^6.
$$
 (4)

Therefore, the equilibrium position of the Raman mode can be shifted by an amount depending on the square of the ratio of IR to Raman frequencies, $\left(\frac{\Omega_{IR}}{\Omega_R}\right)^2$, and the square of the force, F^2 , acting on the IR mode. Broader pulses lead to a larger Raman equilibrium shift, ΔQ_R . These principles were recently shown to result in coherent excitation of phonon modes in $La_{0.7}Sr_{0.3}MnO_3[58],$ $La_{0.7}Sr_{0.3}MnO_3[58],$ $La_{0.7}Sr_{0.3}MnO_3[58],$ changing ferroelectric polarization at the surface of $LiNbO₃[59]$ $LiNbO₃[59]$, forming ferrimagnetic order in $CoF₂[60]$ $CoF₂[60]$ and a dynamical control of interlayer magnetic exchange cou-pling in bilayer CrI₃ [\[61\]](#page-9-7) and bilayer MnBi₂Te₄ [\[62\]](#page-9-8), as well as a topological band transition in the latter [\[62\]](#page-9-8). It has also been shown to be applicable in enhancing superconductivity in organic materials [\[34](#page-8-7)[–39\]](#page-8-8), cuprates [\[40–](#page-8-9)[44\]](#page-8-10) as well as in more traditional BCS systems [\[45\]](#page-8-11).

B. Nonlinear phononics in bilayer honeycomb lattice

Group theory constrains the real space displacement of the phonon modes and their effective potential, which generally contains non-harmonic terms. The group theory perspective provides a intuitive understanding of how the magnetism is related to lattice symmetry and thus how it can be directly controlled by the nonlinear phononics mechanism. A transient change in the lattice structure from the nonlinear phononics mechanism changes the inter-atomic hopping parameters for electrons, which in turn produces a modification in the magnetic exchange interaction.

This article focuses on bilayer honeycomb lattice system to illustrate the physics in a simple yet relevant setting. Specific to this system, a symmetry change of the lattice induced by non-linear phononics produces an IL-DMI which is absence in the equilibrium lattice structure. This IL-DMI produces a non-collinear ground state with canting and result in topological magnon bands for a certain range of parameters.

The honeycomb lattice model we study in this paper is motivated by a broad classes of materials with a layered honeycomb lattice structure. Common examples are the transition-metal dichalcogenides $V_{\text{X}_2}(X=S, S_e)$, and Te.), $RuI_3[63]$ $RuI_3[63]$, $RuCl_3$, and MoS_2 . For simplicity, we consider a honeycomb bilayer as a minimal model. Before we examine the effect that Raman modes can have on the DM interaction, we will study which vibrational modes are possible in a honeycomb bilayer. There are two most common stacking for a bilayer honeycomb lattice, referred to as AA and AB stacking (Bernard stacking). The point group for AA stacking is D_{6h} while the point group for AB stacking is D_{3d} . Both symmetries enforce the nearest neighbor interlayer DM interaction to be zero in equilibrium [\[2\]](#page-7-1).

Both AA and AB stacked bilayer honeycomb lattices have twelve phonon modes since there are four atoms in the unit cell and three spatial directions in which atoms can move. In the case of AB stacking, the inversion center of the bilayer is the same as the nearest neighbor interlayer bond center, and thus all Raman modes are inversion symmetric at the bond center, forbidding the emergence of the nearest-neighbor IL-DMI. (See Appendix [A](#page-10-0) for details.) Although, thermodynamically, for most materials, AB stacking is energetically more favorable [\[64\]](#page-9-10), only in the case of AA stacking one can generate IL-DMI between the layers through non-linear phononics. In AA stacking, the system has $D_{6h} = D_6 \otimes i$ point group symmetry where D_6 has the symmetry operations $\{E, 2C_6, 2C_3, C_2, 3C'_2, 3C''_2\}$ and i represents inversion symmetry. The irreducible representations are $A_{1g(u)}, A_{2g(u)}, B_{1g(u)}, B_{2g(u)}, E_{1g(u)}, E_{2g(u)}$. The $g(u)$ subscripts represent modes even (Raman) or odd (IR) under inversion symmetry. We now compute the irreducible representations of the vibrational modes in AA stacking, given by $\chi_{vibration} = \Gamma^{equivalence} \otimes \Gamma_{vec}$

 $A_{1g} \oplus A_{2u} \oplus B_{2g} \oplus B_{1u} \oplus E_{2g} \oplus E_{1u} \oplus E_{1g} \oplus E_{2u}$, where $\Gamma^{equivalence} = \Gamma^{atom\ site}$ keeps track of the number of atoms that are mapped onto their same positions under point group operations, and Γ_{vec} is the vector representation whose basis functions are x, y, z [\[53\]](#page-8-17).

FIG. 1: AA stacking of a bilayer honeycomb lattice. Each atom sits either directly above or below an atom in the adjacent layer.

Three of these modes are acoustic: the A_{2u} mode and both E_{1u} modes, which correspond to center-of-mass (COM) motion in the z, x, y directions. Besides these COM modes, there are modes that can break crucial symmetries enabling the existence of interlayer DM interactions. Among them, singly degenerate modes A_{1g} and B_{2g} exhibit out-of-plane motions while doubly degenerate E_{1g} and E_{2g} modes have in-plane motion only. In this article, we will focus on the E_{2g} modes since the E_{1q} mode is a shearing motion between layers, whose effect has been explored in an earlier work [\[62\]](#page-9-8).

To determine the corresponding real space displacements (up to a unitary change of basis), we use the projection operator [\[53\]](#page-8-17)

$$
\hat{P}_{kl}^{(\Gamma_n)} = \frac{l_n}{h} \sum_{C_\alpha} \left(D_{kl}^{(\Gamma_n)}(C_\alpha) \right)^* \hat{P}(C_\alpha), \tag{5}
$$

where $D_{kl}^{(\Gamma_n)}(C_\alpha)$ is the irreducible matrix representation of the group element C_{α} , h is the order of the group, l_n is the dimension of the irreducible representation, and $\hat{P}(C_{\alpha})$ is the representation of C_{α} constructed by the permutation matrix and the $O(3)$ symmetry operations. The computed real space displacements of the $E_{2g,y}$ mode are shown in Fig[.2,](#page-3-1) which change the bond length in the y-direction. The degenerate partner $E_{2g,x}$ changes the bond length in the x-direction.

The $E_{2a,y}$ modes break the 3-fold axis which allows an inter-layer DM interaction, with the symmetry requirement $\vec{D} \perp yz$ -plane, where \vec{D} appears in Eq.[\(1\)](#page-0-0). The character table (from group theory) shows the E_{2g} mode has quadratic generating functions: $x^2 - y^2$ and xy , which identifies it as a Raman mode. The E_{1u} mode has linear generating function (x, y) identifying it is an IR mode.

By a group theory analysis [\[53\]](#page-8-17), symmetry-allowed anharmonic coupling between the E_{1u} IR mode Q_{IR} and

FIG. 2: E_{2g} oscillation in the y-direction for an AA stacked honeycomb bilayer, effectively changing the bond length in y-direction

the E_{2g} Raman mode Q_R can be written as,

$$
V_{anharmonic} = (Q_{IR}^{y^2} - Q_{IR}^{x^2})Q_R^a + 2Q_{IR}^{x^2}Q_{IR}^yQ_R^b.
$$
 (6)

where the "a" and "b" refer to orthogonal vibration modes, which could be taken as a linear combination of x and y -directional vibrations. The average positions of Raman modes when coupled to the IR modes with an external electric field are shifted as [\[57,](#page-9-3) [65\]](#page-9-11),

$$
Q_R^a \propto \left(\frac{\Omega_{IR}}{\Omega_R}\right)^2 (E_y^2 - E_x^2), \tag{7}
$$

$$
Q_R^b \propto \left(\frac{\Omega_{IR}}{\Omega_R}\right)^2 (2E_x E_y \cos \Delta \phi), \tag{8}
$$

where E_x and E_y are the electric field components in the x and y-directions which couple to the electric dipole of the IR modes, and $\Delta\phi$ is the phase difference between the x and y -components. Detailed calculations are given in Radaelli [\[57\]](#page-9-3).

From Eq. (7) and Eq. (8) , it is evident that one can excite Raman modes in a specific direction through a choice of the electric field direction. In the Sec. [II C,](#page-3-3) we will see how these modes influence the intra-layer DM interaction and spin ground state. Note that in the usual experimental situation, most bilayer structures energetically favor AB stacking, but under pressure and with topological defects [\[66\]](#page-9-12), one can still achieve AA stacking.

C. Nonzero DMI from a driven E_{2g} mode

The key observation is that if one excites the E_{2g} Raman mode in the y-direction, the point group of the AA stacked bilayer effectively changes from D_{6h} to D_{2h} . Taking the time average of the Hamiltonian over a period of the Raman oscillation, the nonlinear phononics coupling effectively changes the lattice configuration, and allows a non-zero DM vector, \vec{D} , for nearest neighbor inter-layer exchange interactions. This is one of the central results of this work. The DMI originates from the breaking of inversion symmetry along the bond connecting nearest

neighbors in the upper and lower layer of the AA stacked honeycomb lattices.

Considering the interlayer DM interaction, in the static case, it would be zero due to Moriya's rules: it has both a 3-fold rotational axis along the bond and a mirror plane including the bond. Breaking of C_3 symmetry could lower the symmetry to only mirror symmetry, allowing a DMI perpendicular to the mirror plane. To linear order in the Raman mode displacement,

$$
|\vec{D}| \propto \lambda Q_R d,\tag{9}
$$

where d is the distance separating the two layers, and λ is the strength of the spin-orbit coupling. The direction of \vec{D} is perpendicular to the yz-plane. An exact relation between the interlayer DM and phonon modes would need further detailed first principle calculations for a specific material. We are interested primarily in general considerations here.

In the following section, we will show that this lightinduced IL-DMI can change the magnetic order of the ground state and can result in a gap opening for spinwave excitations, *i.e.* the magnons, above the ground state, leading to a topological magnon band transition.

III. MODEL SPIN HAMILTONIAN

The above discussion on driven phonons depends only on lattice symmetry rather than an explicit spin Hamiltonian. To explore the consequences of the generation of an IL-DMI we choose a spin Hamiltonian with an easyaxis exchange interaction, where the intra-layer exchange interaction is ferromagnetic and the inter-layer exchange is chosen to be either ferromagnetic or anti-ferromagnetic to represent different possibilities for material realizations.

In the presence of the symmetry lowering from the E_{2g} shear mode described in the previous section, an IL-DMI and bond-dependent nearest-neighbor exchange interactions are induced. The effective light-driven spin Hamiltonian can be written as,

$$
H = \sum_{\langle i,j\rangle,\eta} \left[J_1 \vec{S}_{i,\eta} \cdot \vec{S}_{j,\eta} - \Delta (S^z_{i,\eta})^2 \right] + \sum_{\langle \langle i,j\rangle \rangle,\eta} \left[D_z \hat{z} \cdot \left(\vec{S}_{i,\eta} \times \vec{S}_{j,\eta} \right) \right] + \sum_i \left[J_2 \vec{S}_{i,b} \cdot \vec{S}_{i,t} + \vec{D}_i \cdot (\vec{S}_{i,b} \times \vec{S}_{i,t}) \right], \quad (10)
$$

where $\eta = t, b$ is the top or bottom layer index, i, j are site indices, and $J_1 < 0$ corresponds ferromagnetism within the plane. Here $J_2 < 0$ corresponds to the ferromagnetic coupling between layers, and $J_2 > 0$ antiferromagnetic coupling. We also include a second nearestneighbor intralayer DMI $D_z\hat{z}$ that is generally allowed by the symmetry. As indicated in Fig[.3,](#page-4-0) \vec{D}_i in the last term

FIG. 3: The ground state magnetic configuration showing the spin orientation of the two basis atoms in the unit cell for the upper and lower layers of the honeycomb bilayer. The IL-DMI vector \vec{D} is perpendicular to the yz plane. Here, (a) shows the angles' sign convention. (b) shows the IL-DMI produces a coplanar canting of the spins in the yz plane when one has FM interlayer exchange interaction. (c) shows the IL-DMI produces a coplanar canting of the spins in the yz-plane, when one has AFM interlayer exchange interaction.

of Eq.[\(10\)](#page-3-4) is perpendicular to the yz -plane. We choose Δ < 0 which favors all spins pointing in the z-direction for simplicity. In principle, all the exchange parameters can change when driving the system, but we focus on the IL-DMI term, $\vec{D}_i \cdot (\vec{S}_{i,b} \times \vec{S}_{i,t}).$

To obtain a better sense of the scale of the exchange interactions for some representative materials, note that $|J_2|/|J_1|$ is about 0.004 and 0.06 in CrI₃ and CrBr₃, re-spectively [\[67\]](#page-9-13). The lowering of the symmetry via nonlinear phonics produces the new IL-DMI term which changes the symmetry of the magnetic ground state. The interlayer DM must be perpendicular to the y -axis and parallel to the xy-plane, so IL-DMI takes the following form: $\vec{D}_i = (D, 0, 0)$. The sign of D depends on material details and is related to the direction of the effective electric field contributing to the spin-orbit coupling [\[2\]](#page-7-1).

Since the DMI, which originates from SOC, is usually one order of magnitude smaller than J_1 , we assume the DMI only contributes small canting to the original collinear ordering rather than producing spiral orders or other spin textures that enlarge the unit cell. The lowestenergy magnetic configuration can be calculated classically under the ansatz that the magnetic order does not enlarge the unit cell by minimizing the classical energy for different configurations of the magnetic moments. The lowest-energy configuration, when no external magnetic field is added, is illustrated in Fig. [3.](#page-4-0) The canting structure is coplanar when there is no external field. When the interlayer coupling is ferromagnetic (*i.e.*, $J_2 < 0$), $\theta_1 = \theta_4 = -\theta_3 = -\theta_2$. For the AFM interlayer coupling case (*i.e.*, $J_2 > 0$), $\theta_1 = -\theta_3 = \pi - \theta_2 = \theta_4 - \pi$. Applying an external magnetic field for directions not in the plane of the canting makes the spin stucture non-coplanar.

A. Magnon spectrum in the driven lattice

To compute the magnon spectrum we perform a Holstein-Primakoff transformation [\[68\]](#page-9-14) in the noninteracting magnon limit which is the leading order in a $1/S$ expansion for fluctuations around the lowest-energy magnetic configuration, where S is the magnitude of the spin. For the case of a non-collinear ground state, before expanding in the magnon basis, one needs to perform a local spin-rotation transformation so that the local zaxis points along the direction of the spin in the classical ground state. To express the spin orientations resulting from the classical energy minimization, we use the standard cylindrical coordinate system,

$$
\vec{S}_i = S(\sin \theta_i \cos(\pi/2 + \phi_i), \sin \theta_i \sin(\pi/2 + \phi_i), \cos \theta_i). \tag{11}
$$

In this way, we rewrite the spin Hamiltonian to a local basis such that we could perform the Holstein-Primakoff transformation on a local basis.

$$
\begin{pmatrix} S_x \\ S_y \\ S_z \end{pmatrix} = R_z(\frac{\pi}{2} + \phi_i) R_x(-\theta_i) \begin{pmatrix} S_{x_L}(i) \\ S_{y_L}(i) \\ S_{z_L}(i) \end{pmatrix}, \quad (12)
$$

where R_x and R_z are the standard rotational matrices in three-dimensional space. The values of θ and ϕ are determined through classical energy minimization.

The spin component in the local coordinates are related to Holstein-Primakoff bosons as,

$$
S_L^+ = \hbar \sqrt{2S} \sqrt{1 - \frac{b^{\dagger} b}{2S}} b, \qquad (13)
$$

$$
\approx \hbar \sqrt{2S} b,
$$

$$
S_L^- = \hbar \sqrt{2S} b^{\dagger} \sqrt{1 - \frac{b^{\dagger} b}{2S}},
$$
\n
$$
\approx \hbar \sqrt{2S} b^{\dagger},
$$
\n(14)

$$
\approx \hbar \sqrt{2Sb^{\dagger}},
$$

\n
$$
S_L^z = \hbar (S - b^{\dagger} b),
$$
\n(15)

where b are the Holstein-Primakoff bosons, and the sublattice bases should be thought of as carried implicitly. The canting induced from the IL-DMI breaks the spin $U(1)$ symmetry of the collinear state down to \mathbb{Z}_2 , leading to the pairing of bosons. Therefore, one needs to introduce the Bogoliubov de Gennes (BdG) basis [\[69\]](#page-9-15), $\Psi^{\dagger}_{\vec{k}}=(b^{\dagger}_{At,\vec{k}},b^{\dagger}_{Bt,\vec{k}},b^{\dagger}_{Bb,\vec{k}},b_{At,-\vec{k}},b_{Bt,-\vec{k}},b_{Ab,-\vec{k}},b_{Bb,-\vec{k}})$. After a Fourier transformation to reciprocal space, the magnon Hamiltonian can be written in BdG form as,

$$
H_{\text{magnon}} = \int_{BZ} d\vec{k} \Psi_{\vec{k}}^{\dagger} H_{BdG}(\vec{k}) \Psi_{\vec{k}}.
$$
 (16)

In the absence of an external magnetic field, the groundstate satisfies $\theta_3 = \theta_4 = -\theta_1 = -\theta_2 = -\theta$ and $\phi_{1(2,3,4)} =$

0, the explicit form of the BdG Hamiltonian is

$$
H_{BdG}(\vec{k}) = -\frac{1}{4} \left[\Delta + (6J_1 - 2J_2 + 3\Delta) \cos(2\theta) \right] + \frac{D}{2} \sin(\theta) \tau_z \xi_y + J_2 \cos(\theta)^2 \tau_x \xi_x + \frac{J_2}{2} \sin(\theta)^2 \xi_x - \Delta \sin(\theta)^2 \tau_x + f_1(\vec{k}) J_1 \cos(\theta)^2 \sigma_x - f_2(\vec{k}) J_1 \cos(\theta)^2 \sigma_y + f_1(\vec{k}) J_1 \sin(\theta)^2 \tau_x \sigma_x - f_2(\vec{k}) J_1 \sin(\theta)^2 \tau_x \sigma_y + D_z \cos(\theta) f_3(\vec{k}) \tau_z \xi_z \sigma_z,
$$
(17)

where τ , ξ and σ are matrices in particle-hole, layer, and sublattice subspaces respectively. The lattice basis vecsubtattice subspaces respectively. The factice basis vectors are chosen as $\vec{R}_1 = -\frac{a}{2}\vec{i} + \frac{\sqrt{3}a}{2}\vec{j}$, $\vec{R}_2 = \frac{a}{2}\vec{i} + \frac{\sqrt{3}a}{2}\vec{j}$, and sublattice basis is $\vec{R}_{AB} = \frac{\sqrt{3}a}{3} \vec{j}$, also $f_1(\vec{k}) = Re[f(\vec{k})]$, and $f_2(\vec{k}) = Im[f(\vec{k})], f_1 + i f_2 = f(\vec{k}) = \frac{1}{2} \sum_i e^{i \vec{k} \cdot \vec{a}_i}$ $\frac{1}{2}\sum_i e^{ik\cdot \vec{a}_i},$ \vec{a}_i are the three NN bonds $\vec{a}_1 = -\frac{\sqrt{3}a}{3} \vec{j}, \ \vec{a}_2 = \frac{a}{2} \vec{i} + \frac{\sqrt{3}a}{6} \vec{j}, \ \vec{a}_3 = -\frac{a}{2} \vec{i} + \frac{\sqrt{3}a}{6} \vec{j}, \ \vec{f}_3(\vec{k}) = Im[\sum_i e^{i\vec{k} \cdot \vec{b}_i}] =$ $\left(2\cos\left(\frac{\sqrt{3}k_y}{2}\right)\sin\left(\frac{k_x}{2}\right)-\sin(k_x)\right), \vec{b}_i$ are the three NNN bonds, $\vec{b}_1 = \frac{a}{2}\vec{i} - \frac{\sqrt{3}a}{2}\vec{j}$, $\vec{b}_2 = \frac{a}{2}\vec{i} + \frac{\sqrt{3}a}{2}\vec{j}$, $\vec{b}_3 = -a\vec{i}$.

In determining the magnon band structure and eigenstates, one must take into account the bosonic statistics of the magnons,

$$
[\Psi_{\vec{k}}, \Psi_{\vec{k}}^{\dagger}] = \text{diag}(1, 1, 1, 1, -1, -1, -1, -1) \equiv \Sigma_z. \quad (18)
$$

To diagonalize the magnon BdG Hamiltonian without changing the bosonic commutation relation, we use a para-unitary matrix $T_{\vec{k}}$ [\[70\]](#page-9-16), such that the BdG Hamiltonian can be diagonalized by the matrix $T_{\vec{k}}$ as

$$
T_{\vec{k}}^{\dagger} H_{BdG}(\vec{k}) T_{\vec{k}} = \begin{pmatrix} E_{1,\vec{k}} & & & & \\ & \ddots & & & & \\ & & E_{4,\vec{k}} & & \\ & & & E_{1,-\vec{k}} & \\ & & & & \ddots & \\ & & & & & E_{4,-\vec{k}} \end{pmatrix},
$$
(19)

with

$$
T_{\vec{k}} \Sigma_z T_{\vec{k}}^{\dagger} = \Sigma_z, \tag{20}
$$

to preserve the bosonic commutator.

Because of the particle-hole symmetry of the BdG basis, $E_{n,\vec{k}}(E_{n,-\vec{k}})$ is the eigenenergy of the n^{th} particle (hole) band. Since $T^{\dagger}_{\vec{r}}$ $\overrightarrow{k} = \sum_z T_{\vec{k}}^{-1} \Sigma_z$, we have

With this transformation, the eigenproblem of solving the BdG Hamiltonian can be reduced to solving the eigenproblem of the non-Hermitian Hamiltonian $\Sigma_z H_{BdG}$.

 2.8 2.6 2.4 Energy/J 2.2

FIG. 4: Magnon spectrum with FM interlayer coupling $J_2 = -0.3$, other model parameters are: intralayer exchange couplings $J_1 = -1$, easy axis anisotropy $\Delta = -0.8$, intralayer DMI strength $D_z = 0.05$, (a) IL-DMI $\vec{D}_i = -0.1, \vec{B} = (0, 0, 0),$ (b)IL-DMI $\vec{D}_i = 0\hat{x}$, $\vec{B} = (-0.2, -0.2, -0.2),$ (c)IL-DMI induces a gap between middle two bands when $\vec{D}_i = -0.1\hat{x}$, $\vec{B} = (-0.2, -0.2, -0.2)$. Here, (a) and (b) show the band structure of the case with only the phonon-driven IL-DMI applied or an external magnetic field applied, respectively. (c) show a gap opening between the two middle bands when we have a combination of both the IL-DMI and an external magnetic field.

In Fig. [4,](#page-5-0) we show the magnon dispersion with and without the phonon-induced IL-DMI. In general, the phonon-induced IL-DMI favors a co-planar canted magnetic groundstate, yet either an external magnetic field $(Fig. 4(b))$ $(Fig. 4(b))$ $(Fig. 4(b))$ or the IL-DMI $(Fig. 4(a))$ $(Fig. 4(a))$ $(Fig. 4(a))$ alone does not open up the gap between the middle two bands. However, a combination of both the IL-DMI and an external magnetic field favors a non-coplanar canting and opens a gap between the two middle bands (Fig. [4](#page-5-0) (c)).

With this transformation the problem of solving the BdG Hamiltonian has been reduced to solving the eigenproblem of the non-Hermitian Hamiltonian $\Sigma_z H_{BdG}$. The positive eigenvalues are the physical magnon spectrum. The non-Hermiticity modifies the inner product in this symplectic vector space $\langle \cdot, \cdot \rangle : V \times V \to \mathbb{R}$ as $\langle \phi, \psi \rangle := \phi^{\dagger} \Sigma_z \psi$ which in turn modifies the definition of the magnon Berry connection and Berry curvature [\[70\]](#page-9-16),

$$
\vec{A}_{n\tau}(\vec{k}) = i\tau \nu_{n\tau}^{\dagger}(\vec{k}) \Sigma_z \vec{\nabla}_{\vec{k}} \nu_{n\tau}(\vec{k}), \qquad (22)
$$

where $\nu_{n\tau}(\vec{k})$ is the eigenvector of $\Sigma_z H_{BdG}(\vec{k})$ with eigenenergy $E_{n, \vec{k}}, \tau = +(-)$ for particle(hole) bands. And the berry curvature is given by

$$
\vec{\Omega}_{n\tau}(\vec{k}) = \nabla_{\vec{k}} \times \vec{A}_{n\tau}(\vec{k}). \tag{23}
$$

The numerical evaluation of the Berry curvature is done following Fukui's method [\[71\]](#page-9-17). The integration of the Berry curvature over the first BZ is the Chern number,

$$
\mathcal{C}_{n\tau} = \int_{1^{st} BZ} \Omega_{n\tau}(\vec{k}) d\vec{k}^2,\tag{24}
$$

a topological invariant of the magnon bands which can only change with gap closings and re-openings.

Because a gap opens with non-zero IL-DMI in the presence of a magnetic field, it is natural to investigate the topological properties through magnon band Chern numbers. The IL-DMI gives an extra tuning knob of the system's properties that can be controlled with ultrafast precision using a laser drive. Some choices of Hamiltonian parameters with a gapped magnon spectrum and non-zero Chern numbers are listed in Table [I.](#page-6-1) The coexistence of IL-DMI and external B field is essential to gap out the middle two bands in the AFM and FM cases and enable a correct assignment of Chern number to each band.

Temperature-dependent thermal Hall measurements are one possible route to experimentally gain indirect access to the Chern numbers and Berry curvatures of topological magnon bands [\[72](#page-9-18)[–74\]](#page-9-19). Because the population of the magnon bands depends on the temperature, the lowest-lying bands will determine the thermal transport properties [\[73\]](#page-9-20). However, since magnons are bosons, it is not possible to have completely "filled bands," and therefore, a quantized thermal Hall response is not expected (as it would be for fermions that completely occupy some set of bands). While transport properties are not the focus of this paper, we note here that it is possible to partially infer information about the Berry curvature and Chern numbers from the thermal Hall response. While such "fast" (on the scale of nano or even picoseconds) transport experiments are extremely challenging, recent progress in electron transport shows that capabilities are rapidly advancing [\[75\]](#page-9-21). Finally, we remark that magnetically sensitive light experiments (e.g., through frequencydependent light polarization rotation) could also be used to infer some properties of the magnon band structure.

TABLE I: Table of magnon particle band Chern numbers for various system parameters. The Chern numbers (either $+1$ or -1) for the magnon particle bands are expressed as $\mathcal{C} = {\mathcal{C}_{1,+}, \mathcal{C}_{2,+}, \mathcal{C}_{3,+}, \mathcal{C}_{4,+}}$. For all the calculations shown in this table, we have used $J_1=1, \Delta=-0.8$, and $D_z=0.05$. ND means that the Chern numbers are not well defined when there are

band touching points between bands.

IV. CONCLUSION AND OUTLOOK

In this work, we have theoretically studied a bilayer honeycomb lattice model subjected to a strong laser drive in resonance with infrared phonons. In this regime, phonon anharmonic couplings are relevant, and transient lattice distortions can be induced via cubic infrared-Raman phonon couplings. We further showed that the transiently distorted lattice possesses lower symmetry than an equilibrium lattice and that an interlayer Dyzaloshinkii-Moriya interaction is allowed. This is one of the central results of this work.

We then explored the resulting changes in the magnetic Hamiltonian, magnetic ground states, and excitations above the ground state. In particular, we found that the interlayer Dzyaloshinkii-Moriya interaction produces spin canting in the ground state which can endow the magnetic excitations (magnons) with topological properties. We explicitly computed the Berry curvature and Chern numbers of the magnon bands for selected parameters and demonstrated that topological transitions occur, such as when a static external magnetic field is applied.

For technological applications, it is beneficial to have control and tunability of material properties. We have discussed the advantages of using phonon-photon interactions to engineer magnetic systems (ultra-fast reversible control of the magnetic Hamiltonian). For example, because the energy scale of the phonon-photon interaction is smaller than the electron-photon one, and because the phonon energy scale is typically lower than the electronic energy scale, directly exciting phonons produces fewer undesirable heating effects in the system.

Our work serves as a proof of concept for the nonlinear phononics mechanism for modifying interesting magnetic phases and their excitations through the concrete protocol for inducing an interlayer Dyzaloshinkii-Moriya interaction in layered van der Waals materials. We hope this work will inspire further theoretical and experimental efforts in this direction.

Appendix A: Group Theory Analysis of Phonons

The lattice vibration modes can be determined by group theory from [\[53\]](#page-8-17),

$$
\chi_{vibration} = \Gamma^{equivalence} \otimes \Gamma_{vec}, \tag{A1}
$$

where Γ^{equivalence} counts the number of atoms within one unit cell which are mapped to themselves under spatial operations, and Γ_{vec} is the sum of the modes that transform as vectors.

The AB stacked honeycomb has a D_{3d} point group,

$$
\chi_{vibration} = 2A_{1g} \oplus 2A_{2u} \oplus 2E_g \oplus 2E_u, \tag{A2}
$$

and the AA stacked honeycomb has a D_{6h} point group,

$$
\chi_{vibration} = A_{1g} \oplus A_{2u} \oplus B_{2g} \oplus B_{1u} \oplus E_{2g} \oplus E_{1u} \oplus E_{1g} \oplus E_{2u}.
$$
\n(A3)

With this representation, one can determine the vibrational motion in real space [\[61,](#page-9-7) [62\]](#page-9-8). Both AA and AB stacked honeycomb lattices have twelve phonon modes since there are four atoms in the unit cell.

FIG. 5: E_{1g} mode of AA stacked bilayer honeycomb lattice in which atomic sites sit directly above or below one another. Here the E_{1g} mode exhibits oscillations producing a shearing motion in the plane of the bilayer as indicated by the arrows, where the blue arrow means the bottom layer shears in the "downwards" direction and the red arrow means the top layer shears in the "upwards" direction. All the atoms in one layer move together in the same phase.

The E_{1g} modes describe shearing between layers [\[2\]](#page-7-1). The shearing modes break the xy -plane mirror symmetry and all two-fold symmetries, as well as the three-fold symmetry in the z-direction normal to the plane of the bilayer. Therefore, a nearest neighbour DMI between the two closest interlayer atoms, one from the top layer and one from the bottom, is no longer forbidden. Symmetry requires that the DM vector be perpendicular to the yz plane.

a. Allowed phonon coupling in AA stacking

To see what kind of phonon interaction is allowed, we need to see if such interaction respect to crystal symme-

FIG. 6: E_{2g} oscillation in the y-direction for an AA stacked honeycomb bilayer, effectively changing the bonds length in y direction, where the B sublattice of both layers moving towards $-y$ and A sublattice of

both layers moving towards y.

FIG. 7: AB stacking of a bilayer honeycomb lattice. The top layer (shown in red) lies above a bottom layer (shown in blue) that is shifted so that the atoms of the top layer sit above the centers of the hexagons in the bottom layer.

try. For example in our case, we have $A_{1g} \subseteq E_{1u}^2 \otimes E_{2g}$, meaning that $Q_{IR}^2 Q_R$ is an allowed interaction between phonons. More specifically, we have

$$
V_{anharmonic} = (Q_{IR}^{y-2} - Q_{IR}^{x-2})Q_{R}^{a} + 2Q_{IR}^{x}Q_{IR}^{y}Q_{R}^{b},
$$
 (A4)

where Q_{IR} is a IR mode with E_{1u} irrep and Q_R is a Raman mode with E_{2g} irrep.

1. Real space displacement of phonon

The projection operator is constructed in the following way: [\[53\]](#page-8-17)

$$
\hat{P}_{kl}^{(\Gamma_n)} = \frac{l_n}{h} \sum_{C_\alpha} \left(D_{kl}^{(\Gamma_n)}(C_\alpha) \right)^* \hat{P}(C_\alpha), \tag{A5}
$$

where $D_{kl}^{(\Gamma_n)}(C_\alpha)$ is the irreducible matrix representation of the group element C_{α} , h is the order of the group, l_n is the dimension of the irreducible representation, and $\hat{P}(C_{\alpha})$ is the representation of C_{α} constructed by the permutation matrix and the O(3) symmetry operations. Once, we have this, the eigenmode for irreps γ_n can be calculated by finding the eigenvector of operator $\hat{P}_{ll}^{(\Gamma_n)}$. In E_{2g} mode, the lattice has the following displacement vectors:

2. Some comments on interlayer DM interaction

$$
E_{2g,x} : (\Delta Q_a^t, \Delta Q_b^t, \Delta Q_a^b, \Delta Q_b^b) = (-\vec{i}, \vec{i}, -\vec{i}, \vec{i}) \quad (A6)
$$

$$
E_{2g,y} : (\Delta Q_a^t, \Delta Q_b^t, \Delta Q_a^b, \Delta Q_b^b) = (-\vec{j}, \vec{j}, -\vec{j}, \vec{j}) \quad (A7)
$$

where $\Delta Q_a^{t(b)}, \ \Delta Q_b^{t(b)}$ $b_{b}^{(0)}$ are the displacement vectors for a, b sublattices in $t(b)$ layer in the unit cell respectively, \vec{i} and \vec{j} are unit vectors in the x and y-directions.

2. Pictorial understanding of the 3-fold symmetry breaking

FIG. 8: (Left): Interlayer DM vector $\vec{D} = 0$ when $Q_R = 0$. (Right): Interlayer DM vector is nonzero when $Q_R \neq 0$, due to the breaking of C_3 rotational symmetry

A 3-fold rotational symmetry guarantees a cancellation of all the contributions to the IL-DMI.

Appendix B: Magnon Hamiltonian and the magnetic space group of the groundstate

1. Comments on magnetic exchange parameters

In the main text, we chose the nearest neighbor bonds to have the same exchange interaction $J_{1a} = J_{1b}$. Although in the driven case this is only an approximation, the key physics remains the same.

FIG. 9: DM interaction model relevant to the atomic position shifts associated with an E_{2g} mode oscillating along the y-direction.

A simple model [\[76\]](#page-9-22) that takes into account a third atom that breaks the inversion symmetry is illustrated in Fig[.9,](#page-11-0) where a DM vector

$$
\vec{D}_{12} \propto \lambda \vec{x} \times \vec{r}_{12},\tag{B1}
$$

is generated from inversion symmetry breaking where λ is a coefficient reflecting the strength of spin-orbit coupling, \vec{r}_{12} is a vector connecting atom 1 and atom 2, \vec{x} is the perpendicular to \vec{r}_{12} that points toward the third atom. In our situation, atom 1 and 2 are located in the opposite layer, and atom 3 would be some environmental atom.

FIG. 10: IL-DMI has contributions from three NN atoms. (left) DM vector $\vec{D}_{12} = 0$ when $Q_R = 0$, the arrows show the IL-DMI between the top and bottom atoms from the mediations of neighboring atoms. (right) DM vectors when $Q_R \neq 0$, the arrows show the DM vector contribution from neighboring atoms.

3. Berry curvature and energy dispersion of magnon

Berry curvature and energy dispersion of magnon are reported in Fig. [11](#page-12-0) and Fig. [12.](#page-12-1)

FIG. 11: Magnon spectrum with AFM interlayer coupling $J_2 = 0.3$, other model parameters are: intralayer exchange couplings $J_1 = -1$, easy axis anisotropy $\Delta = -0.8$, intralayer DMI strength $D_z = 0.05$, (a) Two-fold degenerated bands, with IL-DMI $\vec{D}_i = 0$, $\vec{B} = (0, 0, 0)$. (b) External magnetic field splits the degeneracy, IL-DMI $\vec{D}_i = -0.1\hat{x}$, \vec{B} = (-0.2, -0.2, -0.2). (c)Gap opening in the middle two bands with the combination of IL-DMI and external \vec{B} field, IL-DMI $\vec{D}_i = -0.1\hat{x}, \vec{B} = (-0.3, -0.3, -0.3),$ (d) A zoom in for parameters chosen in (c).

FIG. 12: Berry curvature for the third magnon band with AFM interlayer coupling $J_2 = 0.3$, other model parameters are: intralayer exchange couplings $J_1 = -1$, easy axis anisotropy $\Delta = -0.8$, intralayer DMI strength $D_z = 0.05$, The combination of IL-DMI and external magnetic field produces a gap between the middle two

bands and ensures well-defined Chern numbers. External magnetic field switches the signs for the Chern number of each band. (a) shows the berry curvature

distribution of a Chern -1 band, with IL-DMI $\vec{D}_i = -0.1\hat{x}, \vec{B} = (-0.2, -0.2, -0.2),$ (b) shows the berry curvature distribution of a Chern 1 band, with IL-DMI $\vec{D}_i = -0.1\hat{x}, \vec{B} = (0.2, 0.2, 0.2).$
