Can human decision-makers learn from AI feedback? Using data on 52,000 decision-makers from a large online chess platform, we investigate how their AI use affects three interrelated long-term outcomes: Learning, skill gap, and diversity of decision strategies. First, we show that individuals are far more likely to seek AI feedback in situations in which they experienced success rather than failure. This AI feedback seeking strategy turns out to be detrimental to learning: Feedback on successes decreases future performance, while feedback on failures increases it. Second, higher-skilled decision-makers seek AI feedback more often and are far more likely to seek AI feedback after a failure, and benefit more from AI feedback than lowerskilled individuals. As a result, access to AI feedback increases, rather than decreases, the skill gap between high- and low-skilled individuals. Finally, we leverage 42 major platform updates as natural experiments to show that access to AI feedback causes a decrease in intellectual diversity of the population as individuals tend to specialize in the same areas. Together, those results indicate that learning from AI feedback is not automatic and using AI correctly seems to be a skill itself. Furthermore, despite its individual-level benefits, access to AI feedback can have significant population-level downsides including loss of intellectual diversity and an increasing skill gap.

Keywords. AI, future of work, learning from success and failure, skill gap, inequality.

"Success is a lousy teacher. It seduces smart people into thinking they can't lose." Bill Gates

1. Introduction

AI is changing how we work. Of particular interest to strategy scholars is the possibility that humans decision-makers can learn from AI (Helfat *et al.*, 2023; Joseph and Sengul, 2024; Puranam, 2021; Tong *et al.*, 2021). That is, not only may AI support strategic decision-making directly through its use during the decision-making process but AI may also provide valuable feedback to decision-makers that improves the quality of their decisions, even when AI is not available. AI may thus become a pathway to increase organizational learning, which is a key contributor to strategy (Teece, Pisano, and Shuen, 1997). This form of organizational learning could lead to important compound effects and is critical to long-term productivity gains. However, when left to their own devices, decision-makers may use AI in ways that reinforce, rather than alleviate, human decision-making biases (Choudhury, Starr, and Agarwal, 2020; Morewedge *et al.*, 2023) and reliance on AI may have deskilling effects (Hendrycks, Mazeika, and Woodside, 2023; Russell, 2022) thus undermining potential learning effects. This has led to various speculations as to whether AI will mostly benefit those who are high-skilled or low-skilled (Acemoglu and Autor, 2011; Autor, Levy, and Murnane, 2003; Choudhury *et al.*, 2020).

We adopt an abductive, question-driven approach (Graebner *et al.*, 2023; Sætre and Van de Ven, 2021) to answer a set of interrelated, multi-level research questions around a central phenomenon: What happens when decision-makers have access to AI feedback? We investigate who seeks such AI feedback, whether decision-makers can learn from AI feedback, whether higher-skilled or lower-skilled decision-makers benefit more, and what the broader societal impact of widespread AI-adoption may be. This question-driven research approach is well suited to address multi-level questions in a novel and causally complex area (Graebner *et al.*, 2023).

We use data from an online chess platform (lichess.org) spanning over five years and 52,000 individuals. The platform offers a feature where decision-makers can use AI to retrospectively analyze completed games. During this analysis, decision-makers receive feedback from a highly accurate AI about the quality of each move they and their opponent made. The AI feedback quantifies how much strategic advantage they gained (or lost) with each move and what the best move in each situation would have been. While this AI feature is available to everyone, it is up to each human decision-maker to decide whether, and for which game, to seek such AI feedback. Our setting focusing on the endogenous choice to seek AI feedback complements other studies that have relied on randomized experiments which exogenously vary access to AI (Chen and Chan, 2024; Dell'Acqua *et al.*, 2023). We first explore who (high- vs. low-skilled) seeks such AI feedback and in which situations (success vs. failure). Next, we explore whether human decision-makers learn from this AI feedback and whether this can help close the existing skill gap. We then explore specialization as a plausible mechanism behind learning. Finally, we leverage 42

major platform updates as natural experiments to explore whether AI-driven specialization causally changes the intellectual diversity of strategic decisions on the population level.

We find that decision-makers have a tendency to seek AI feedback for situations in which they succeeded—they are looking for a pat on the back—as opposed to situations in which they failed. This, however, is detrimental to their future performance: We find individuals learn only from AI feedback on failures but not successes. The tendency to seek feedback on successes is particularly pronounced among lower-skilled decision-makers. Higher-skilled decision-makers are significantly more likely to seek AI feedback overall, and more likely to seek it in cases of failures. Using a control function approach we find signs of endogeneity suggesting a negative bias, where time-variant shocks that promote losses (e.g., lower motivation) are correlated with lower likelihood to seek AI feedback. Together, those results indicate that learning from AI feedback is not automatic and can be undermined by seeking AI feedback in the wrong situations. Using AI correctly seems to be a skill itself.

We then show that putting the effect of feedback seeking and learning together, access to AI increases, rather than decreases, the skill gap between high- and low-skilled human decision-makers. We provide some suggestive evidence that increased specialization is one potential mechanism that explains learning from AI feedback. Finally, we find that whereas learning and specialization resulting from AI feedback is beneficial on the individual level, it leads to negative downstream effects on the aggregate level: Access to AI feedback causes a decrease in intellectual diversity of the population overall. Receiving feedback from the same, centralized AI system, individuals appear to specialize in the same way, thus reducing the diversity of strategic decisions that are employed in the population.

Our study addresses several important gaps in the research on AI in strategic management. First, much research has focused on primary outcomes: the effect of using AI during a task on performance. In contrast, secondary and longer-term outcomes, such as the effect of AI on learning—acquiring new and improved skills—are much less well understood. How, exactly, humans will use AI and how they can learn from AI to search for profitable strategies is an important question for strategic management that is so far little understood (Csaszar and Levinthal, 2016; Puranam, 2021). Second, much research has focused on experiments with exogenous variation in access to AI, leaving open questions about endogenous decisions to engage with AI. When it is up to individual human users to decide when and how to use AI systems, existing inequalities may get amplified. In the context of generative AI, for example, substantial inequalities have emerged as women appear much less likely to adopt AI (Humlum and Vestergaard, 2024). Such outcomes may be especially likely if using AI systems "the right way" itself requires skill. Deeper understanding on whether AI will mostly benefit the high- or low-skilled will help better anticipate AI's labor market impact (e.g., Autor, 2015; Brynjolfsson and McAfee, 2014; Choudhury *et al.*, 2020), and its effects regarding social equality and justice

(e.g., Wilson and Daugherty, 2018). Finally, far too little is known about fundamental AI risks and unintended society-level downstream consequences (Bengio *et al.*, 2024). Few studies connect individual-level behavioral micro-foundations with broader effects on the population level (Krakowski, Luger, and Raisch, 2023). However, as our results show, drawing such connections is crucially important to understand how positive individual-level learning effects could have negative population-level effects of increased inequality and lower intellectual diversity.

We follow a tradition of using chess as a controlled setting for studying decision-making in competitive interactions (Gaessler and Piezunka, 2023; Krakowski *et al.*, 2023) and a model system for AI (Chase and Simon, 1973; McIlroy-Young *et al.*, 2020). Chess is often considered a prototypical example of strategic interaction due to the interactive, zero-sum nature of the game; complex tasks tend to involve a sequence of individual judgments; with long sequences of moves and countermoves and which requires similar managerial cognitive capabilities such as solving well-defined but complex problems, and strong reliance on pattern recognition and ability to interpret ambiguous information difficulty to ascribe overall outcomes to individual actions over the course of the game (Helfat and Peteraf, 2015; Saloner, 1991). This matches contemporary decision environments which are increasingly characterized by volatility, uncertainty, complexity, and ambiguity (Bennett and Lemoine, 2014; Mack *et al.*, 2015). Chess is also a particularly relevant context to study AI because of its long history and tradition of using AI. AI is already widely adopted in chess and its high-quality is well known (Kasparov, 2020).

We make several contributions at the intersection of learning, AI, and strategy research. We contribute to research on an important outcome of AI use besides direct performance benefits (Chen and Chan, 2024; Dell'Acqua et al., 2023; Kawaguchi, 2021). By illustrating that AI can not only serve as a decision-making tool but that AI feedback can help decision-makers learn (Maula, Heimeriks, and Keil, 2023; Riedl and Seidel, 2018), we contribute to a better understanding of how AI affects organization beyond lowering prediction costs; that is we shed light on AI's effects on the firms knowledge basis and competitive advantage (Csaszar and Steinberger, 2022; Krakowski et al., 2023). On a micro-level, our work contributes to a better understanding of patterns in how humans seek feedback from AI, emphasizing that learning from AI does not happen automatically but is subject to endogenous decisions which, unfortunately, decision-makers do not always get right. On a higher-level, we contribute to the debate about complementarity between AI and skill and whether AI will mostly benefit the high-skilled or low-skilled. Our work casts some doubt on optimistic hope that AI can help level the playing field and close the skill gap. Our focus on learning effects may also explain why there may be negative long-term effects of AI on inequality despite no apparent negative effects in the short run (Alderucci et al., 2024).

We also contribute to research on the role of AI in management and strategy. While research has focused on AI for automation and productivity gains (Brynjolfsson and Mitchell, 2017; Choudhury *et al.*, 2020; Raisch and Krakowski, 2021), we contribute to a deeper understanding of augmented intelligence that results when humans learn from AI. This, however, may lead to potentially negative downstream consequences that need to be considered: Learning from AI may reduce intellectual diversity, thus undermining organizations' ability to flexibly deal with diverse situations. This last point draws into doubt previous theorizing that human-AI collaboration would increase problem-solving search depth due to the increasing intellectual diversity (Raisch and Fomina, 2023). It also connects with the insight that AI can only be the source of sustainable competitive advantage if it is used in unique or firm-specific ways (Felin and Holweg, 2024; Helfat *et al.*, 2023). Generic AI systems that are universally available can undermine, rather than enhance, competitive advantage.

2. Theoretical Background

2.1 Seeking Feedback from AI

AI may not only provide direct input into decision making processes. Interacting with AI may also offer decision-makers important feedback on their own judgements. Research on feedback seeking has extensively studied who seeks feedback, in which situations, and from who (see Ashford, Blatt, and VandeWalle, 2003 for a review). Feedback provides a crucial information resource for managers and other knowledge workers to achieve goals and achieve mastery; that is, in order to adapt and learn (Ashford, 1986). Feedback seeking is the conscious devotion of effort to determine the correctness and adequacy of behavior for attaining valued goals (Ashford and Cummings, 1983). Research suggests that individuals carefully evaluate the costs and benefits of asking for feedback considering aspects such as the availability of feedback, the cost of feedback, and also emotional responses of what to do with the feedback once it is received (Ashford *et al.*, 2003).

Several differences stand out when considering seeking feedback from AI compared to from other humans such as friends, peers, or bosses. First, once deployed, AI systems can easily scale (Bengio *et al.*, 2024). While a human expert may be able to provide detailed feedback on only a few decision situations for a few decision-makers, AI systems have the capacity to provide detailed feedback to many more decision-makers in more situations. AI feedback may become instantly available. Second, as AI systems approach expert-level decision quality, they can provide feedback to even the highest-skilled decision-makers who may otherwise face difficulty in getting access to elite mentors and coaches. Third, compared to asking humans for feedback, AI feedback comes without social cost such as concerns to appear confident and self-assured (Ashford, 1986). Individuals may feel higher psychological safety asking for corrective feedback from an AI due to the absence of negative social consequences (Edmondson, 1999). These differences suggest potential benefits from AI due to its scale and access, but could also imply

different patterns in how humans seek feedback from AI compared to from other humans. When high-quality feedback is readily available without social cost, who will be more likely to seek AI feedback (higher vs. lower skilled), and in which situations (successes vs. failures)?

Based on the feedback seeking (from humans) literature, it is not obvious who will be more likely to seek feedback from AI: Those with higher or those with lower skill. On the one hand, the higher the skill level, the more frequent feedback seeking is (Wanberg and Kammeyer-Mueller, 2000). One reason for this is goal importance. The higher the importance of the goal to the performer, the more frequently the performer seeks feedback (Ashford, 1986). Since higher-skilled decision-makers tend to identify more strongly with the task (and hence value it more highly) they may be more likely to seek AI feedback than lower-skilled individuals (Deci and Ryan, 2000). On the other hand, feedback can hurt the performers' pride, ego, and vanity which may be higher developed in those of higher skill, thus increasing the need to protect the ego and seek less feedback. Furthermore, when feedback is sought from humans it comes with social costs such as concerns to appear confident and self-assured (Ashford, 1986) which may be a particular concern for higher-skilled individuals. While AI feedback may come without such social cost, the need to protect the ego from the potentially harsh and objective AI feedback may be particularly high.

In which situations may people seek feedback from AI: successes or failures? Individuals are motivated to defend and protect their egos (Baumeister, 2010). This generates a motive to avoid negative feedback (Ashford and Cummings, 1983; Wood, 1989). The tendency to avoid negative feedback may be particularly strong when the feedback is actively solicited (rather than provided without asking) as it may be more difficult to disregard (Ashford *et al.*, 2003). Even in situations in which honest feedback about oneself is crucial to achieve one's goals, it seems that people strongly favor receiving positive feedback that reinforces their positive self-perception, rather than negative feedback that challenges it. Consequently, individuals carefully choose situations that expose the self to positive feedback and use a variety of mental strategies to avoid feedback that threatens their positive self-image (Ashford and Cummings, 1983; Baumeister, 2010).

Patterns of feedback seeking across successes and failures may also interact with patterns across skill levels. Higher skilled individuals who identify more with the task are also likely to have higher task-related self-esteem (Stets and Burke, 2000) and may thus be more likely to seek feedback in challenging situations. High self-esteem performers are resilient, have great confidence reserves, are higher promotion focused (Lanaj *et al.*, 2012), and therefore, can "take" negative feedback and will be more likely to seek feedback, even after experiencing failures. On the other hand, since negative feedback can hurt the performers' ego the potential for injury from negative feedback may be higher for higher skilled who identify more with the task. As a result, higher skilled may be less likely to seek feedback in challenging situations to protect their egos and avoid social costs associated with negative feedback. Seeking feedback from AI could affect

both the ego protection mechanism as well as the image defense mechanism. AI feedback can be expected to be objective and delivered less diplomatically or tactfully. AI feedback could thus be expected to be especially hard and ego bruising, thus strengthening the need to avoid it, especially when it is expected to be negative. On the other hand, individuals may also feel higher psychological safety asking for corrective feedback from an AI due to the absence of negative social consequences (Edmondson, 1999). This could alleviate image concerns and increase the desire to seek AI feedback. Taken together, access to AI systems alone may not be sufficient as feedback seeking is not automatic and the nature of AI feedback (compared to human feedback) may further alter the pattern of feedback seeking.

2.2 Learning from AI Feedback Across Skill Levels

Long before the current interest in AI, research has investigated the returns to technological advances more generally (Acemoglu and Autor, 2011; Autor et al., 2003). With the recent rise in capability of AI, this question has received new urgency and interest (Autor, 2024). Several recent studies have explored the impact of access to AI on direct outcomes such as productivity (Brynjolfsson, Li, and Raymond, 2023), task performance (Dell'Acqua et al., 2023), decision accuracy (Boyacı, Canyakmaz, and de Véricourt, 2024; Kawaguchi, 2021), and quantity/quality in the context of brainstorming (Chen and Chan, 2024). In practice, gains from access to AI can be lower than expected because human decision-makers often do not follow algorithmic recommendations and instead rely on their own judgment (Kawaguchi, 2021; Kim et al., 2024) or use AI in the wrong way (Alderucci et al., 2024; Chen and Chan, 2024). However, those are short-term effects of AI use "in-the-moment" of task performance, not long-term learning effects (i.e., skill acquisition that improves performance in situations in which AI may not be available) and not from naturalistic settings in which the endogenous decision of when and how to use AI may play a larger role than in more controlled experimental settings. Whether and how AI affects learning and skill development itself is unclear.¹ In the context of decision-making, learning implies that at two different points in time given the same input, a decision-maker may make different (better) decisions (Puranam, 2021). Brynjolfsson et al. (2023) document performance improvements over pre-AI baseline even when AI recommendations are unavailable providing one indication of learning from AI. Another notable exception is the work by Gaessler and Piezunka (2023) who investigate whether AI can help decision-makers learn by serving as an artificial training partner. Their study exploits exogenous variation in access to AI training partners (chess computers) by contrasting players in Western Europe (where chess computers became available in 1977) from those in the Soviet Union (where they did not) in a difference-indifference model. They find positive learning from AI. However, their study analyzes playeryear level data, without analysis of micro-level data of specific situations in which decisionmakers used AI or how those specific uses affect their learning.

¹ Exceptions are found in the context of AI in educational settings, with AI specifically designed to achieve educational outcomes (Bastani *et al.*, 2024; Dolata *et al.*, 2023).

One possible pathway through which AI may affect skill development could be by inducing individuals to become more reflective (Abdel-Karim *et al.*, 2023). However, promoting human reflection through AI may be difficult to trigger (e.g., Ma *et al.*, 2024) and may depend on other supportive cognitive structures, thus limiting potential learning. For example, when AI judgements diverge from initial human judgements without the ability to provide explanations, decision-makers may experience increased uncertainty (Lebovitz, Lifshitz-Assaf, and Levina, 2022) and thus potential lower future performance. Other studies have documented similar cognitive challenges in benefitting from AI advice. The ability to reap decision-making benefits from AI advice can depend on the human-decision makers' ability to cognitively engage with the advice (Jussupow *et al.*, 2021). Only individuals who developed AI interrogation practices were able to overcome the challenge of AI opacity.

This suggests that learning from AI does not happen automatically but requires deep and deliberate engagement with the information provided by AI. Existing studies on the immediate performance benefits from AI use do not provide satisfactory answers whether humans can learn from AI, who is most likely to learn from it, and in which situations. This is an important question because of worries that reliance on AI may lead to loss of human skill (Hendrycks *et al.*, 2023; Raisch and Krakowski, 2021; Russell, 2022). A better understanding of learning effects would be crucial to understand downstream labor-market effects (Eloundou *et al.*, 2023; Kim *et al.*, 2024).

Besides the question of a main effect of AI on skill development, a key question is whether highor low-skilled workers and decision-makers benefit more from AI and whether, as a result, AI will increase or decrease the existing skill gap (and as a result related outcomes like income inequality; Furman and Seamans, 2019). Two competing theories persist. On the one hand, lower-skilled decision-makers may benefit most. AI could act as an equalizer that helps close the skill gap. This is because the marginal impact of the quality of advice is decreasing in the ability of the decision-maker who receives it (Chade and Eeckhout, 2018). Several empirical studies report that lower-skilled workers benefited more from access to AI than higher skilled (Choi and Schwarcz, 2024; Dell'Acqua *et al.*, 2023; Kanazawa *et al.*, 2022; Noy and Zhang, 2023). In several of these studies, as a result, inequality between workers decreased. This marginal impact logic may also work for learning. Intuitively, since learning increases at a decreasing rate (Allen and Choudhury, 2022; Becker, 1962; Foster and Rosenzweig, 1995; Mithas and Krishnan, 2008), learning from AI should improve the skill of lower-skilled individuals faster and could thus help close the skill gap and reduce inequality.

On the other hand, research has also shown that this may not happen in practice. High-skill and AI often act as complements (Acemoglu and Autor, 2011; Autor, 2024; Autor *et al.*, 2003). Drawing benefits from AI may depend on the human decision-makers ability to correctly judge

quality of AI input (Agrawal, Gans, and Goldfarb, 2022) and request AI input in the right situations (see section above on feedback seeking). Learning from AI may itself depend on relevant prior experience (Brynjolfsson *et al.*, 2023). Understanding when and how to best use AI systems may constitute an important skill itself. For example, in a study of chess players, Bouacida et al. (2024) find that lower-skilled decision-makers often fail to heed the advice they receive due to overconfidence or intrinsic preference. Prior theory has suggested that inexperienced humans suffer even more from their limited understanding of AI outputs which would make it harder to leverage AI assistance in the right way and learn from it (Kellogg, Valentine, and Christin, 2020). Similarly, Wang et al. (2023) show that workers with more task-based experience benefit more from AI. That is, the ability to learn from AI may itself be a valuable skill of high practical importance as small differences in competence at learning tend to accumulate (Levitt and March, 1988).

2.3 Specialization and Strategy Diversity

If humans can successfully learn from AI, what might be a plausible mechanism behind such learning? We theorize that specialization—the process by which individuals focus on a narrow area of expertise-could be a key driver. Specialization is a well recognized mechanism behind learning (Cohen, Levinthal, and others, 1990; Levinthal and March, 1993). While specialization may be beneficial individually, it may lead to unintended downsides on the group (or organizational) level. If the individuals of a group specialize in different areas, group-level intellectual diversity would increase, improving the capacity of the group to solve complex problems (Fazelpour and De-Arteaga, 2022). However, if individuals in a group specialize in the same areas, intellectual diversity on the group level would decrease. The resulting homogeneity in mental patterns and loss of strategic diversity among human decision-makers would have negative effects on long-term problem solving ability of firms (Levinthal and March, 1993; Page, 2019) and may undermine firms' competitive advantage (Felin and Holweg, 2024). Such a homogenization risk seems especially probable in the context of generic and centralized AI systems where many individuals (both within and across firms) are exposed to generic and nonspecific AI output. Access to the same feedback from a single centralized AI system (such as AI foundation models) could lead to such homogenization. Here, it seems especially likely that learning from AI feedback could result in homogeneous (rather than diverse) group-level specialization. The potential risks of decreased population-level intellectual diversity as an unintended consequence of learning from AI feedback poses a crucial alignment problem with important risks on the larger societal level (Bengio et al., 2024). This risk has been termed "outcome homogenization" and is a recurring theme in work discussing risks of algorithmic monoculture (Bommasani et al., 2022). However, those discussions have been mostly speculative as high-quality empirical evidence from real-world settings is lacking. This implies that it is important to also study the impact of AI on the broader ecosystem level like the effect on an entire population of users of AI systems.

2.4 Research Questions

The arguments above raise several interrelated research questions, which we examine empirically. We aim to investigate the issue of AI feedback on decision-making holistically spanning the entire decision-making cycle.

- First: When do human decision makers seek AI feedback and do they use AI in the "right" way? That is, in which situations (successes vs. failures) are decision-makers most likely to seek AI feedback and does the propensity to seek AI feedback differ across skill levels? We specifically focus on a setting in which decision-makers are free to choose in which situations they seek AI feedback or forgo such feedback. Following Gaessler and Piezunka (2023), we explore this question "in the field" in which other modes of learning are also available to decision-makers.
- Second: *Which forms of AI feedback are most useful for learning and do higher- and lower-skilled decision-makers learn at the same rate?* We explore if AI feedback on successes is equally beneficial as AI feedback on failures. Focusing on higher- and lower-skilled decision-makers allows us to investigate the important question of skill-based inequality: Does access to AI feedback increase or decrease the skill gap over time?
- Third: Is *specialization* a plausible *mechanism* behind learning? And if so, what effect does AI induced specialization have on *long-term sustainability* of human cognitive diversity? In other words, we explore whether AI-induced specialization on the individual level has negative consequences on intellectual diversity on the group level.

3. Setting and Data

We use chess as a sample research domain of strategic decision-making in which AI is already widely adopted and the superhuman skill of AI is well known. Chess has been a focal point of AI research for decades (Shannon, 1950; Turing, 1953). Chess has been used to study cognitive performance over human life spans (Strittmatter, Sunde, and Zegners, 2020) the effect of masks on performance (Smerdon, 2022), gender differences in competition (De Sousa and Hollard, 2022), personal bests as reference points (Anderson and Green, 2018), the joint effect of intelligence and practice on skill development (Vaci *et al.*, 2019), and in hundreds of other studies on cognition, strategy, and artificial intelligence.

Our data come from lichess.org, a popular and free online chess platform. On average, more than 90 million games are played each month on the platform.² It is distinct among the major chess platforms because it is a nonprofit, and makes every platform feature available for free.³ Our study centers around a specific platform feature: The platform allows players to seek AI feedback on games they played on the platform. This AI feedback is powered by a chess AI

² See <u>https://database.lichess.org/#standard_games</u> for the full database of Lichess games

³ Competitor platforms such as Chess.com offer similar AI features but only behind paywalls.

called Stockfish. Stockfish is free, open source, and the strongest chess AI in the world.⁴ That is, the AI feedback players receive can be considered feedback from a chess expert of the highest caliber. The current (in 2024) version is Stockfish 16, and has a chess skill (called Elo) of 3,641 (see more on the chess Elo skill measure further below). For comparison, if Magnus Carlsen, widely regarded as the best player in history, played against this AI at his peak rating (Elo = 2,882), he would be expected to win just 12 out of 1,000 games.

The AI feedback informs players of the strength of every move they played, and the strategic advantage they gained (or lost) with each move. The AI feedback also informs players what the best moves would have been in each position and how much these alternative moves would have strengthened their position. The AI feedback feature allows decision-makers to "replay" a game, move by move, and receive AI feedback on every move (Figure A1 in the Appendix shows an annotated example of the AI feedback). We refer to the process of having an AI analyze a game as AI feedback and AI analysis interchangeably.

We then exploit a unique feature of the Lichess platform: Lichess allows anyone to see whether a given game has been analyzed by a human using the AI feedback feature. We collected this data to investigate individual-level performance returns to seeking AI feedback on games. Unfortunately, the platform does not show *who* analyzed the game. To overcome this limitation we focus on games played by humans against bots. For those games we can be reasonably certain that if a human played against a bot, the human player in the match was the person who analyzed the game. Technically, other humans could also seek such AI feedback but since games against AI bots are predominantly played for training purposes (Gaessler and Piezunka, 2023), the sheer number of those games, and that only a few of these games are played by famous players, this is highly unlikely. Around 15% of all games in our sample had players request AI feedback.

Consequently, the starting point of our data collection are AI bots. We identified every AI bot on Lichess in September 2022 (n = 129). We then collect every game played by each bot using Lichess' API. We had 1,054,640 games after removing games between AI bots (with no human player), games that were not "normal" chess games (e.g., 4 player games) and unrated games. We removed unrated games because players likely used more effort in their rated games. Finally, we included every game up to the human player's 50th game. We chose this cutoff because only 5% percent of players played more than 50 games. This cutoff increases the generalizability of our results, as they are less influenced by a few players who have played unusually many games. On average, it took 53 days for a player to play 50 games against a bot, with a standard deviation of 144 days. As a robustness check, we look at cutoffs of up to a player's 30th game and up to a player's 70th game and find substantially the same results (see Table A1 in the Appendix).

⁴ <u>https://chessify.me/blog/top-chess-engines</u>

The final dataset contains 403,010 game-level observations from 52,251 human players. For each game, we have information on whether the game was analyzed (i.e., whether the human player sought AI feedback for the game), the performance of the human player in the game, and several other game- and individual-level attributes (see more details below). Notice that the number of observations in the different regression models will deviate from this number for two reasons. First, by using lagged variables on the right hand side, the first observation for every individual will drop out (e.g., the first game observed by an individual has no meaningful count of prior AI feedback). Second, when we use logistic regression, instances with no variation in the dependent variable are collinear with the individual-level fixed effect and cannot be used for estimation (e.g., individuals who either analyzed all games or no games).

Dependent Variables. Our study relies on two key dependent variables: AI feedback, and performance. AI feedback is a simple dummy indicator which is 1 if a human player sought AI feedback on a given game, and 0 otherwise. To capture human performance we construct a measure of overall move accuracy. First, for each game we collect the entire move-by-move sequence of play from the Lichess' API. We then use Stockfish 16 to analyze the quality of each move in every game in our sample (this corresponds to 70,037,446 moves total, or about 35 moves per game). To assess the quality of each individual move, Stockfish simulates up to 1,500,000 moves to assess what the best strategy is for each side (this is the same setting as the AI feedback feature on the Lichess website). Move quality is expressed as the probability that white or black would win the game after that move. Finally, we transform this move-level performance measure into an aggregate game-level performance measure using the same formula employed by Lichess.⁵

Control Variables. We collected both game- and individual-level data as control variables. Game-level data includes the length⁶ and type of the game (e.g., bullet or classic), whether the game was won or lost, whether the game used a common chess opening, and the skill of the bot opponent. Individual-level data includes the human player's skill level (measured through Elo, see Appendix Equation A2 for details), and tenure and experience of the human player (Table 1). We also measure both a player and a bot's skill using their Elo scores. An Elo score measures how good a player is, with higher numbers indicating more skill. Most bots have a consistent underlying skill that only changes when the bot is updated, which rarely happens, but the bot Elo still varies slightly based on games they have won and lost. Since moving first gives players more control over the direction of the game, we include an additional dummy indicating whether the focal player moved first (playing white) or second (playing black, omitted category) as an

⁵ <u>https://lichess.org/page/accuracy</u>

⁶ 107 games in our dataset last longer than 100,000 seconds. These games are "correspondence" games, which are one of the six game types in our data. Correspondence games give each player a long time (usually one day) to make a move. This explains the very large maximum value on game length in Table 1.

important control variable (the Section *Defining Control Variables* in the Appendix provides detailed explanation of each measure).

We include a control variable $Tenure_{it}$ and its squared term, which captures the number of years an individual *i* has been active on the platform at time *t*. This allows us to distinguish between learning from AI Feedback and changes in performance that occur because of other factors (Argote and Epple, 1990; Thornton and Thompson, 2001). $Tenure_{it}$ effectively captures the general passage of time and thus incorporates possible experience accumulated outside the platform through playing in-person games, games played on other platforms, other forms of chess training, education, or other activities outside the online platform (Riedl and Seidel, 2018). We also include a count of total games played against bots, which we call *experience*, because prior experience is a critical determinant of learning (Riedl and Seidel, 2018).

4. Analysis

4.1 Choice to Seek AI Feedback

4.1.1 Empirical Model

We investigated who sought AI feedback, and in which situation by analyzing whether a game was analyzed as our dependent variable (1 = analyzed, 0 = not analyzed). We use logistic panel regression with fixed effects for the human player, the bot opponent,⁷ the year, the month, the time control, and a dummy variable indicating whether a bot was among the top 100 most popular bots, with clustered standard errors on the human player level. We estimate

 $Pr(AI \ Feedback_{it} = 1) = logit^{-1} (\beta_1 Loss_{it} + \beta_2 Skill_{it} + \beta_3 Loss_{it} \times Skill_{it} + controls$

 $\alpha_i + \alpha_{bot} + \alpha_{year} + \square \alpha_{month} + \alpha_{GameType} + \epsilon_{it})$

where $Pr(AI \ Feedback_{it} = I)$ is the probability that player *i* seeks AI feedback for the game played at time *t*. Loss_{it} is an indicator whether the game to be analyzed was a win or a loss, Skill_{it}

⁷ To avoid overspecifying our model with too many fixed effects, bots with less than 100 games were grouped together in a single category "other".

is the player *i*'s Elo rating at time *t*, and *controls* are our control variables. Finally, α are fixed effects for the individual, bot, year, month, and game type.

4.1.1 Results

Who seeks AI feedback and in what situations? Higher-skilled individuals are significantly more likely to seek AI feedback than lower-skilled individuals (Table 2, Model 1, $\beta = 0.06$; p = 0.031). Furthermore, individuals have a strong aversion to seeking AI feedback in situations of failure (i.e., for games they have lost; $\beta = -1.61$; p < 0.001). There is only a 11% chance that an individual will seek AI feedback on a failure while there is a 21% likelihood to to seek AI feedback in case of success (average marginal predictions). None of the control variables have a significant effect on propensity to seek feedback with the exception of moving first (playing white). Looking at heterogeneity across individuals, we find a large significant coefficient of the interaction term ($\beta = 0.24$; p < 0.001) indicating that higher-skilled individuals are much more likely to seek AI feedback in situations of failure.

Our variables of interest, seeking AI feedback on games that were lost, gives rise to potential endogeneity concerns due to omitted variables as losing games itself is endogenous (i.e., individuals who experience more (less) failure, have more (less) opportunities seek AI feedback on those failures). The panel data structure and fixed effects specification underlying our analysis already accounts for measured and unmeasured individual-specific characteristics that are fixed over time. This includes important individual-level traits such as latent levels of ambition and learning goal orientation. Despite this approach, experiencing failure may potentially be endogenous due to time-variant omitted variables. We conduct a robustness test using a control function approach (Wooldridge, 2010) in the Appendix Table A2. We indeed find signs of endogeneity suggesting that the strong negative relationship between seeking AI in situations of failure is driven in large part by endogenous time-varying shocks (e.g., lower motivation). We find signs of a negative bias, where time-variant shocks that promote losses (e.g., lower motivation) are correlated with lower likelihood to seek AI feedback. The results imply that using AI feedback correctly follows endogenous processes where seeking AI feedback in challenging situations may depend on time-varying levels of motivation. As a result, when left to their own devices, decision-makers often pass up seeking AI feedback even though it is readily available to them which may curtail their ability to learn as we will explore in the next section.

4.2 Learning from AI Feedback

4.2.1 Empirical Model

In order to determine whether people improve as a result of using AI feedback, we use panel regression with user and time fixed effects. Like our prior model, this allows us to control for unchanging but unobserved user qualities, such as intelligence, sex, or number of games chess games played prior to arrival on Lichess.org. Our time fixed effects allow us to control for changes across the platform that affect all users. We estimate the equation

 $\begin{aligned} & Performance_{it} = \beta_{1}AI \ Feedback_{it-1} + \beta_{2}log(CumulativeGames_{it-1}) + \\ & \beta_{3}Tenure_{it} + \Box \ \beta_{4}Tenure_{it}^{2^{\Box}} + \beta_{5}Opponent \ Skill_{it} + controls \ + \\ & \alpha_{i} + \alpha_{bot} + \alpha_{year} + \Box \ \alpha_{month} + \alpha_{GameType} + \epsilon_{it} \end{aligned}$

where *Performance*, *Tenure*, and *Opponent Skill* are indexed by the game played at time t and individual *i*. AI Feedback and Cumulative Games are time lagged—indexed by time t-1—to capture learning from previous AI feedback and direct experience (cumulative games). We also estimate variations of this equation in which we split the total amount of AI feedback into separate counters for AI feedback on wins and losses. As before, α are fixed effects for the individual, bot, year, month, and game type.

4.2.1 Results

Do individuals learn from AI feedback? We find no effect of overall AI feedback (Table 3; Model 1; $\beta = 0.00$; p = 0.688). However, this overall null-effect hides two opposing heterogeneous effects. Whereas feedback on losses leads to performance improvements (Model 2; $\beta = 0.04$; p < 0.001), feedback on wins—seeking a pat on the back in situations in which individuals already succeeded—actually deteriorates performance (Model 3; $\beta = -0.02$; p = 0.002). When entering wins and losses simultaneously, respective effects are even stronger (Model 4). This indicates that AI feedback is effective to learn, but only when feedback is sought in situations of failures and not in success situations. In the Appendix Table A3 we show robustness tests indicating that these results also hold when considering performance against human players. That is, AI feedback is useful for broad-based learning that improves performance both against AI and human opponents.

Considering these results on learning from AI feedback in the context of the previous set of analyses—when decision-makers seek AI feedback—a stark conclusion stands out: Left to their own devices, individuals seek AI feedback in the wrong situations (wins) which hampers their learning and curtails their future performance: Decision-makers should seek AI feedback after experiencing failures not successes. Higher-skilled individuals appear to be in a much better position to benefit from AI feedback: They seek more feedback on failures, thus increasing their ability to learn from AI and improve their skill even more.

4.3 Heterogeneous Treatment by Skill

To further investigate whether higher- or lower-skilled decision-makers benefit from AI feedback more than high skill players, we use a Generalized Random Forest (GRF), a non-parametric method that estimates heterogeneous treatment effects (Athey, Tibshirani, and Wager, 2019). Because GRFs are non-parametric, a GRF ensures that choices around which parameters to include, such as interaction terms, are less likely to drive any effects that we observe. We estimate the Conditional Average Treatment Effect of cumulative numbers of AI feedback across individuals with different skill levels (we also include the same control variables as in our other analyses such as opponent skill, tenure, opponent skill etc.). Variable selection occurs automatically with GRFs. As before, we use performance (human accuracy in a chess game) as the dependent variable.

We find statistically significant and practically significant heterogeneity in the effect of AI analysis on performance (i.e., the conditional average treatment effect). We compare the average treatment effects of AI feedback for high vs. low skilled decision-makers using a median split

(i.e., those above and below median 1,575 Elo). The average treatment effect among high-skilled individuals is 0.037 [95% CI: 0.034 - 0.040]. The average treatment effect among low-skilled individuals is 0.021 [95% CI: 0.019 - 0.023]. Showing the effect visually, we find a U-shaped relationship (Figure 1). Low-skilled individuals benefit more from AI feedback than those of medium skill, whereas high-skilled benefit the most. That is, high-skilled individuals benefit from AI feedback substantially more than low-skilled individuals: They learn faster than lower-skilled individuals. This may be driven by higher skilled individuals being more likely to seek AI feedback on failures and the strong effect this has on performance (as shown above), whereas less skilled decision-makers are more likely to seek feedback on successes. As a result, the introduction of AI feedback in this setting amplifies the already existing skill gap between high and low-skilled individuals.

Figure 1. Strength of the conditional average treatment effect of learning from AI feedback across a range of skill levels.

4.4 AI Feedback Leads to Specialization

We propose that specialization is one contributing mechanism behind how decision-makers learn from AI feedback. To explore specialization as a potential mechanism, we focus on the opening moves of a chess game, known as "chess openings." Openings are important in chess because they set the stage for the middle game, thus narrowing the space of strategies that need to be considered in later phases. They are widely studied and cataloged. Many opening sequences have well-known names such as the "Queen's Gambit" and the "Sicilian Defense" (Hooper and Whyld, 1992). Most players specialize in certain openings, focusing on a repertoire of set openings that they favor (Chassy and Gobet, 2011). While a narrow repertoire allows for deeper specialization it also makes players less flexible to deal with different opponents (Webb, 2013). If our prediction about specialization as a mechanism behind learning is true, we would expect some form of homogenization in strategies that human decision-makers employ as they hone their skills through AI feedback. We use a simple logistic regression framework to study individuals' likelihood to repeat the same opening strategy that they used in one of the previous five games (see Appendix Equation A1 for exact regression equation). We classify all opening strategies using three character Encyclopaedia of Chess Openings (ECO) codes.⁸ The dependent variable is set to 1 if a player reuses an opening strategy that they have played recently (at least once in the previous five games), and 0 otherwise. Our main explanatory variable is the logged count of how many previous games the individual has analyzed using AI (Table 4). Since moving first gives players more control over the direction of the game, we include an additional dummy indicating whether the focal player moved first (playing white) or second (playing black, omitted category) as an important control variable.

 Table 4. Specialization as mechanism. Likelihood to repeat the same opening move strategy increases with AI feedback.

***p < 0.001; **p < 0.01; *p < 0.05; †p < 0.1

We find a significant effect of AI feedback on strategy specialization (Model 1, $\beta = 0.04, p = 0.028$). A 1% increase in AI feedback increases a decision-maker's likelihood to repeat the same strategy that they have played recently by about 4%. We also find a significant positive interaction with skill (Model 2, $\beta = 0.02, p = 0.034$) suggesting that the specialization effect of AI feedback is stronger for more skilled individuals. This also indicates that the specialization effect is not merely driven by beginner players learning to play common opening strategies (as

opposed to playing uncommon openings), but is even stronger among higher-skilled players who are already familiar with opening strategies.

4.5 Intellectual Diversity on the Platform Level

As decision-makers learn to specialize based on receiving AI feedback, an important question emerges: Across a larger population, do decision-makers specialize in the same or different ways? If many individuals in a group exposed to AI feedback specialize in the same way, grouplevel strategy diversity would decrease; whereas if they specialize in different ways, it would increase. We find that many individuals appear to specialize along the same dimensions, thus reducing group-level strategy diversity. We begin with a simple descriptive analysis (Figure 2). We group individuals by their level of past AI feedback. As individuals accumulate more exposure to AI feedback from analyzing more games, the diversity of opening move strategies they employ decreases (Pearson $\rho = -0.59$; $p = 4.9 \times 10^{-6}$). Next, we provide causal evidence for lower group-level intellectual diversity by analyzing a set of natural experiments.

Figure 2. Platform-level intellectual diversity decreases with more AI analysis experience.

Analysis Approach. To establish that this population-level decrease in intellectual diversity (strategy use) is causally driven by AI feedback we combine Regression Discontinuity in Time (RDiT; Hausman and Rapson, 2018) and natural experiments. First, we aggregate all chess openings played on the entire platform on a given day into a diversity metric (1 - Gini). This metric captures how likely it is that two games played on the same day and drawn at random use

the same opening sequence.⁹ This gives us a single time series of platform-level intellectual diversity.

Next, we compile a list of platform changes which we leverage as natural experiments to establish a causal relationship with the AI feedback feature on the platform. Between 2020 and 2023,¹⁰ the platform experienced 42 major updates.¹¹ We treat these updates as regression discontinuity events by comparing the platform-level time series of intellectual diversity across multiple small time windows around these 42 platform changes. Each time window compares intellectual diversity right before vs. right after the platform changes. Onto this RDiT analysis we layer a natural experiment lens: 18 platform changes did not affect the AI analysis feature and 24 did affect the AI analysis feature.¹² That means in addition to the dummy variable indicating whether a time series observation was obtained before vs. after a platform change, we introduce a second dummy variable indicating whether the platform change was related to the AI feature or not. This analysis then compares changes in daily platform-level strategy diversity from right before a platform change to that after the platform change while simultaneously accounting for the fact that some changes were related to the AI analysis feature and others were not. That is, days right before a platform change serve as control cases for days right after a platform change; and days after an AI unrelated platform change serve as controls for days after an AI related platform change.

Specifically, we estimate

 $Diversity_{et} = \beta_1 After_{et} + \beta_2 After_{et} \times AI \ Related_e + \alpha_e + \alpha_{et}$ where $Diversity_{et}$ is the platform-level strategy diversity on day *t* around the natural experiment *e* and α_e are fixed effects for each natural experiment (hence the main effect of the AI Related dummy will drop out). The coefficient $\beta_1 After$ captures the effect of an AI *unrelated* platform change (which we would expect to be insignificant if platform changes *unrelated* to the AI

⁹ To account for the fact that diversity of strategies may depend mechanically on the number of daily games we aggregate, we draw 100 random games, and compute the platform-level diversity index for this random subset. To minimize noise from this sampling procedure, we then repeat this process 100 times and average the diversity score.

¹⁰ We focus on days with at least 100 games (the period from 2020-11-27 through 2023-06-09) and exclude early days of the platform on which only few daily games were played.

¹¹ <u>https://lichess.org/changelog</u> accessed 2024-07-08.

¹² The fact that we observe many platform changes of which some are related to the AI analysis feature and others are unrelated creates a form of "cross-sectional" variation which casts this analysis as a kind of difference-in-difference analysis (Angrist and Pischke, 2009). That is, we have many observations before and after platform changes, where in some the relationship between AI analysis should be unchanged from the before-to-after period (because the platform change was unrelated to AI analysis), in others it should be affected. We classify a platform change as AI related if the release notes for the main platform changes mention the word "analysis", and unrelated otherwise.

feature do indeed not affect learning from AI feedback), and the coefficient β_2 for the interaction term of *After* × *AI Related* captures the effect of AI related platform changes on platform-level intellectual diversity. This analysis estimates three levels of effects: Diversity in the period before the platform change, after a platform change that was unrelated to the AI analysis feature, and after a platform change related to the AI analysis feature. In a robustness test, we also include *Time* and *Time*² controls (treating the entire estimate more as a continuous time regression discontinuity model rather than a plain regression discontinuity design without time as the running variable).

For each of the 42 natural experiments, we select small and precise time windows of the 15 days prior to the platform change, and the 15 days after. This strengthens our RD design with a mass of observations very close to the threshold where identification rests upon a conditional expectation as one approaches the threshold. Furthermore, since platform changes are unexpected for most users, individuals cannot easily sort across the threshold.¹³ That is, we believe we can make a credible claim to exogeneity: Most individuals will be unaware when platform changes are being released, and maybe in particular be unaware whether the platform changes will affect the AI analysis feature or not. As a result, selection across the threshold and strategic behavior seem unlikely. We think this natural experiment setting approaches the as-good-as-random interpretation of a cross-sectional RD.

Results. We find that platform changes unrelated to the AI analysis feature are indeed not statistically significant but have a tendency to increase platform-level intellectual diversity ($\beta = 0.12$; p = 0.115) while changes related to the AI feature decrease intellectual diversity significantly ($\beta = -0.28$; p = 0.005; Figure 3). Results are robust to using 15 day windows before/after the platform change or 30 days, and including time controls (Table A4).

¹³ We explicitly exclude platform changes related to so-called "community features" where individuals may have prior knowledge of the upcoming platform changes and could change their behavior in anticipation.

Figure 3. Analysis of natural experiments on platform-level intellectual diversity (coefficients from Table A4).

Discussion

Our analysis shows that decision-makers can learn from AI feedback. However, it also shows that when left to their own devices, decision-makers often use AI in the wrong way: They prefer to seek feedback after experiencing success rather than losses, which would provide more opportunities for learning. Despite positive individual-level learning effects, our analysis also shows compelling evidence of unintended consequences on the population-level. Higher-skilled individuals learn at a faster rate than lower-skilled individuals, due to their tendency to seek more AI feedback and in more challenging situations (after a failure). This implies that in our setting, access to AI feedback increases, rather than decreases, the skill gap between high and low-skilled individuals. Finally, access to AI feedback causes a decrease in intellectual diversity in the population as individuals tend to specialize in the same ways. We make several contributions to theory at the intersection of learning, AI, and strategy research.

We contribute to research on learning (Krakowski *et al.*, 2023; Maula *et al.*, 2023; Riedl and Seidel, 2018), which can be an an important outcome of AI use besides direct performance benefits (Chen and Chan, 2024; Dell'Acqua *et al.*, 2023; Kawaguchi, 2021). Whereas past research has started to shed some light on how AI use affects performance and productivity, effects of AI use on longer-term and population-level outcomes like learning have been mostly neglected (Mollick and Mollick, 2022). Here, we show that AI feedback can drive learning and thus affect competitive capabilities. Insights from our work complement two closely related

papers that have indicated that people learn from AI but that did not directly observe who was using AI and in what situations (Gaessler and Piezunka, 2023; Shin *et al.*, 2023). While we show that human decision-makers can learn from AI feedback, our micro-level analysis of AI feedback seeking behavior points to an important caveat: In many human-centered environments, humans are free to decide when and how to use AI. Not everyone may end up using AI feedback equally often or equally well. Using AI correctly itself may emerge as a valuable skill. We also point to specialization as a core mechanism through which individual-level learning from AI manifests.

We deepen the understanding around skill gaps and AI and the mixed results as to whether highskilled or low-skilled individuals benefit more from AI. Many authors have found that low-skill people benefit from AI when AI is available; i.e., when looking at short-term outcomes like performance and productivity (Alderucci et al., 2024; Brynjolfsson et al., 2023; Chen and Chan, 2024; Dell'Acqua et al., 2023). However, we are the first to find the decision to use AI is a skill unto itself. Because higher-skilled decision-makers seek AI feedback more often and in more fruitful situations, access to AI increases the skill gap in the longer-term due to its effect on learning. As a result, access to AI may fail to level the playing field. Despite the theoretical prediction that high-quality expert feedback from an AI has the potential to act as a "great equalizer" (Chade and Eeckhout, 2018) reducing the difference between high and low skilled individuals, we find that this is not what happens in practice (at least in our setting). Thus, our study supports the body of work suggesting that AI acts as a complement to high skill (Acemoglu and Autor, 2011; Autor, 2024; Autor et al., 2003) and may thus amplify the existing skill gap. Our focus on longer-term the outcome of learning may also explain why there may be negative long-term effects of AI on inequality despite no apparent negative effects in the short run (Alderucci et al., 2024).

We also contribute to research on the role of AI adoption on competitive capabilities. Our multilevel analysis helps connect insights on individual-level learning and specialization effects with organizational-level human capabilities (Krakowski *et al.*, 2023). While research has focused on AI uses for automation and productivity gains (Brynjolfsson and Mitchell, 2017; Choudhury *et al.*, 2020; Raisch and Krakowski, 2021), we contribute to a deeper understanding of augmented intelligence that results when humans interact with AI. Our research contributes to our understanding of how people recruit AI technologies to improve their thinking, and what effects unfold when these same people, in turn, are recruited into larger cognitive systems like organizations (Helfat *et al.*, 2023; Levinthal and March, 1993; Puranam, 2021). While prior work has mostly focused on downsides of deskilling due to AI-based automation (Raisch and Fomina, 2023), we point to downsides due to loss of intellectual diversity as a result of learning. We show that learning from AI may reduce intellectual diversity within a population, which could undermine that population's ability to flexibly deal with diverse situations (Fazelpour and De-Arteaga, 2022). That is, AI may not only undermine competitive advantage as a source of core rigidity (Leonard-Barton, 1992) but also by affecting the intellectual diversity of their human users. Reduction in strategy diversity may prove especially detrimental since organizational environments have become more global, dynamic, and competitive, thus increasing demand for flexibility and innovation (Smith and Lewis, 2011).

Prior theorizing on human-AI collaboration has suggested that the inherent differences between human and AI's cognitive structures could increase intellectual diversity and thus would increase problem-solving search depth (Raisch and Fomina, 2023). However, when we consider longer timeframes and mutual adaptation in human-AI teams (Puranam, 2021) this pattern may be reversed. As an entire population of AI users is exposed to feedback from the same, centralized AI system, human decision-makers may become more homogeneous in their decision strategies and intellectual diversity decreases. This may undermine an organization's ability to flexibly deal with diverse situations, reduce its problem-solving search (which benefits from intellectual diversity), and make it easier to exploit by outsiders. In chess, homogenization, particularly around the best strategy for the first moves, has been observed as well. To exploit the homogenization of openings, Magnus Carlsen famously tries to play a variety of moves in order to put his opponents in an unfamiliar position in which they cannot rely on memorization.¹⁴

Our study serves as real-world evidence of population-level homogenization and unintended downstream consequences, which are considered potential AI risks (Bengio *et al.*, 2024). Extending this insight beyond a single organization could further adversely affect competitive advantage. AI can only be the source of sustainable competitive advantage if it is used in unique or firm-specific ways (Felin and Holweg, 2024). Generic AI systems that have such a homogenizing effect on intellectual diversity may erode organizations' unique competitive advantage.

Generalizability and use cases. We argue that the form of AI feedback that we study, despite the rule-based environment of chess, generalizes to many other environments in which AI feedback can inform decision-makers of the quality of their past actions. For example, every time a user of ChatGPT requests feedback on how to improve the writing of a piece of text, they receive high-quality, sentence-by-sentence feedback of how the writing could be improved which is not dissimilar from the feedback in our setting (and AI systems have been shown to produce text perceived as "more human than human"; Jakesch, Hancock, and Naaman, 2023). Similarly, in the case of AI-based predictions for revenue optimization (Kawaguchi, 2021), AI can provide high-quality feedback on the product assortment decisions made by humans, quantify the quality of those decisions by contrasting actual and counterfactual revenue from randomized experiments or AI-based predictions. In all these settings, humans may learn over time from high-quality AI feedback. Users are already using large language models (LLMs) like ChatGPT as "sounding boards," in which the LLMs are prompted to offer feedback and assessments of human created content (Chen and Chan, 2024). It is plausible that decision-makers could learn

¹⁴ https://www.chessable.com/blog/openings-magnus-carlsen/

from AI feedback in those and many other settings in a similar fashion. Recently, AI systems gained new capabilities that improve their "reasoning" capabilities (e.g., ChatGPT's most recent Strawberry model introduced this capability).¹⁵ One way in which users are exposed to this is through "train of thought" feedback provided by the AI. This, again, is not dissimilar from our setting in which AI feedback provides step-by-step feedback for each decision. Furthermore, we speculate that the nature of a chess AI that provides high-quality, yet generic answers to all players in the same situation, is not dissimilar from the non-specific AI output produced by AI foundation models such as ChatGPT, Llama, or Gemini. As a result, the population-level effects we explore may generalize to other AI systems and can inform our understanding of downside risks like homogenization.

Limitations. Our study is not without limitations. Our research has a significant limitation in that we have provided empirical evidence of how humans recruit AI and learn from AI feedback from just one domain (chess). Since there is only limited prior work on how humans interact with AI feedback and learn from it, it is difficult to say how similar or different our setting is from others. Furthermore, our results may not generalize to other settings given the ability of AI right now. At least since IBM's DeepBlue AI beat Garry Kasparov (Kasparov, 2020), it is well known among chess players that AI performs at super-human level. So AI is both factually giving high quality feedback and people know that it is high quality. As such, aspects like trust in AI are likely to play a minor role in our setting while it may be more of an issue in other settings. While this may not be the case today in many AI application scenarios, our research gives insights as to what we can likely expect in potential *future* applications.

Managerial Implications. Our research has managerial implications. Most notably, it informs managers in organizations that they may look for ways to leverage AI-based feedback to enhance the collective intelligence of their organizations. However, our study also informs managers about potential traps. While AI systems can help scale learning and development interventions by providing detailed feedback in an automated fashion, they may amplify existing skill differences by giving more learning opportunities to higher skilled and highly motivated individuals. In order to "democratize" learning opportunities by expanding access to high-quality feedback, AI-based interventions may be unlikely to close the skill gap without complementary interventions that increase intrinsic motivation and create supportive learning environments. Finally, it cautions managers to be mindful of potential downsides of decreased intellectual diversity.

Conclusion. Much research has been focused on how machines can learn from humans. Our research focuses on the opposite—how humans can learn from AI. Focusing exclusively on teaching machines to do what humans can already do ignores an important potential benefit of AI to enhance collective intelligence. However, the potential risks of decreased population-level

¹⁵ <u>https://openai.com/index/learning-to-reason-with-llms/</u>

intellectual diversity as an unintended consequence of learning from AI feedback poses a crucial alignment problem with important risks on the larger societal level.

Appendix

AI Feedback on the Lichess Platform

The focal variable in our study is how often individuals seek AI to analyze their games. The example below shows the output of what the AI reports when it analyzes a game between two of the best players on Lichess. We have annotated some of the most important aspects. Every gray bubble with text and every gray every with a black outline was written by us. The arrow pointing from the knight to the bishop and the white arrow with the blue outline for the pawn on c2 are both part of the output Lichess gives to the player. These arrows change based on the move the player is currently analyzing.

Figure A1. Example output of Lichess' AI feedback.

Measuring Skill In Chess

One reason chess is studied so heavily is because a player's skill is accurately measured. Each player has a rating, usually called an Elo, that indicates how strong a player is (Elo 1,978). Stronger players have higher ratings. Equation A2 below demonstrates the percentage of points that player A is player is expected to earn against player B. Thus, if player B's Elo is 200 points

higher than player A's, then player B is expected to earn 24% of the points in a series of games (where a win is 1 point, a loss is 0 points, and a draw is 0.5 points).

Because Elo is a measure of skill, higher Elo players are expected to beat lower Elo players. In chess, all games conclude as either a win (1 point), a loss (0 points) or a draw ($\frac{1}{2}$ point). The percentage of points player A is expected to earn playing against player B is shown by the equation below.

Thus, if player A is 50 Elo higher than player B, player A is expected to win 57% of the available points in a match. If we exclude the possibility of draws, this means player A is expected to win 57% of the time.

$$E_A = \frac{l}{\frac{Rating_B - Rating_A}{1 + 10}}$$
Eq. A2

Defining Control Variables

We used characteristics of the human, the bot, and the game to identify the features of a game that are correlated with games being analyzed. The features included:

- The human's skill (measured by Elo, then z-scored against all other player Elos that ever played against bots)
- A dummy variable for whether the human lost the game (1 = lost, 0 = won or drew)
- The interaction of the human's skill and whether they lost
- Common Opening, a dummy variable indicating whether the game began with the two most common openings in chess in which white's queen pawn or king pawn moves forward two spaces (1 = either of those moves, 0 = neither of those moves)
- Game Type describes the time control, where each player gets this amount of time for all moves. We treated these as dummy variables and incorporated them in the fixed effects
 - Ultrabullet: less than 30 seconds
 - Bullet: more than 30 seconds and less than 3 minutes
 - Blitz: More than 3 minutes and less than 8 minutes
 - \circ Rapid: More than 8 minutes and less than 25 minutes
 - Classical: longer than 25 minutes
- Game Length, a continuous variable, measuring the number of seconds a game lasted
- Experience, a continuous variable, measuring the cumulative number of games a player has played against bots (logged)
- Tenure, a continuous variable, measuring the number of years the player had been on the platform at the time of the game

- Tenure², a continuous variable, measuring the number of years (squared) the player had been on the platform
- White: A binary variable indicating whether a player used the white pieces

Robustness Test: Using Different Cutoffs of Games Played

Our models in the main paper used up to a player's 50th game. We used that cutoff because only 5% of players played more than 50 games. Including longer histories, would imply that any effects we observe are driven by fewer and fewer individuals. For example, moving from histories of 50 games to 100 games, increases the number of observations in our dataset by 24%, but those additional observations come from only 5% of individuals making it harder to generalize to the overall population. The table below shows what the coefficients would be for Model 4, in Table 3 if we had used cutoffs at 30 games, 50 games, and 70 games.

Robustness Test: Endogeneity of Losing Games

We account for measured and unmeasured factors such as individual-level ambition and learning goal orientation with our panel data structure and fixed effects. Despite fixed effects controlling for time-invariant attributes, losing games may potentially be endogeneity due to omitted variables. For example, if *losing* games is a result of an unobserved time-varying attribute, such as low motivation, this may also influence an individual's choice to *seek AI feedback* games which would bias our estimates. To deal with endogeneity concerns of analyzing losses, we provide robustness checks using the control function approach (Wooldridge, 2010). Compared to the instrumental variable approach, the control function approach has the benefit that it can be easily applied to nonlinear models (binomial; Wooldridge, 2010). We construct individual-level instrumental variables following similar ideas as prior work in other settings of management research (van Angeren *et al.*, 2022; Kummer and Schulte, 2019). We used the average number of losses in the five previous games of the individual as our instrument. The idea behind this instrument is that it captures time-varying levels of motivation which may influence losing the focal game and seeking AI feedback. However, this fluctuation in motivation only affects the

likelihood to seek AI feedback on the focal game through the loss of the focal game (exogeneity). As an additional instrument we include the strength of the opponent.

We estimate first-stage models to predict the likelihood that human players would lose a game and then include the residuals from that regression as additional control variables in our main model estimating the likelihood to seek AI feedback (second-stage). There, the residuals represent the component of having lost the game that likely correlate with the error term. This approach ensures consistent second-stage estimates by directly controlling for the endogenous component of the problematic variable (Wooldridge, 2015).

We bootstrap standard errors for the second-stage based on 1,000 replications, randomly drawing individuals (rather than observations) to retain the panel data structure. Results are shown in Table A1 below. Contrary to two-stage least squares (2SLS) models, the control function approach does not allow for the direct test of relevance and exogeneity. However, we note that the instruments used in the first-stage are strong predictors of the (potentially) endogenous variable (Model 2). For example, playing against a (perceived) stronger opponent increases the likelihood of losing the focal game ($\beta = 0.45$; SE = 0.03; p < 0.001). Furthermore, after periods with more (fewer) lost games, individuals are less (more) likely to lose the focal game (this is the opposite sign than in the pooled data, where prior losses are positively correlated with losing the focal game clearly indicating individual-level trait of ambitiousness).

Including the control function residuals in the second-stage (Model 2), changes our results substantially. The likelihood to seek AI feedback on losses remains statistically significant and negative, but increases sixfold to now only $\beta = -0.24$ (from $\beta = -1.61$). This indicates a negative bias, where time-variant shocks that promote losses (e.g., lower motivation) are correlated with lower likelihood to seek AI feedback. The aversion to seek AI feedback after experiencing failure is much smaller after addressing the endogeneity issue, albeit still quite large. Next, we repeat the analysis to investigate high- and low-skilled individuals' tendencies to seek AI feedback on losses (Model 3). Here again we find a significant increase in the likelihood to seek AI feedback when we include the control function residual ($\beta = -0.38$; SE = 0.60) but the coefficient for the interaction term between loss and skill does hardly change ($\beta = 0.23$; SE = 0.02). This indicates that while endogeneity is a factor in explaining the general aversion against seeking AI feedback on losses, endogeneity is not a substantial factor explaining the difference between high- and low-skilled individuals.

Taking the substantive results, and the changes in coefficients due to control function approach together, our results indicate that using AI feedback correctly follows both exogenous (skill) and endogenous processes where higher skilled (and likely more motivated, more learning oriented individuals) are more likely to seek AI feedback in situations that were challenging for them.

Robustness Test: Performance Improvements when Playing against Human Players

It is possible that using an AI to analyze a game only benefits a player who is playing against AI, and that the benefit of analyzing a game vanishes when playing against a human. To test this possibility, we randomly sampled 3,000 players who played at least one game against a bot on Lichess. We then gathered every game a player played against a human and calculated the accuracy for every move in every game the humans played against other humans, exactly like our analysis against bots. Unfortunately, we cannot observe when a human analyzes a game against another human on Lichess - Lichess will only report that a game was analyzed, not who analyzed it. However, we can still observe when a human analyzes a game against a bot, which are our focal variables below. We then limited our sample to the first fifty games against humans that a player played against, like in our prior analyses.

***p < 0.001; **p < 0.01; *p < 0.05

Using panel data, we find that when humans analyze their wins against bots, they do not improve in future games (Model 4, $\beta = -0.07$, p > 0.05). However, just like our previous analyses

showed, when humans analyze their losses against bots, we find a positive and significant effect that humans improve in accuracy in future games (Model 4, $\beta = 0.15$, p < 0.05). Our analysis indicates that analyzing a single loss improves future accuracy the same amount as increasing a player's Elo by a standard deviation.

AI Feedback Leads to Specialization

We estimate the following regression equation to investigate individual-level specialization:

 $\begin{aligned} Pr(RepeatStrategy_{it} = I) \\ &= logit^{-1}(\beta_{I}Cumulative AI Feedback_{it-1} + \beta_{2}Tenure_{it} + \beta_{3}Tenure^{2}_{it} + \\ &\quad controls + \alpha_{i} + \alpha_{bot} + \alpha_{year} + \alpha_{month} + \overset{\square}{=} \alpha_{GameType} + \epsilon_{it}) \end{aligned}$
