A Local Void and the Accelerating Universe

ABSTRACT

Corresponding to the recent observational claims that we are in a local void (an underdense region) on scales of 200-300 Mpc, the magnitude-redshift relation in a cosmological model with a local void is investigated. It is already evident that the accelerating behavior of high-z supernovae can be explained in this model, because the local void plays a role similar to the positive cosmological constant. In this paper the dependence of the behavior on the gaps of cosmological parameters in the inner (low-density) region and the outer (high-density) region, the radius of the local void, and the clumpiness parameter is studied and its implication is discussed.

Key words: cosmology: observations – large-scale structure of Universe

1 INTRODUCTION

One of the most important cosmological observations at present is the [m,z] relation for high-z supernovae (SNIa), which play a role of standard candles at the stage reaching epochs $z\gtrsim 1$. So far the observed data of SNIa have been compared with the theoretical relation in homogeneous and isotropic models, and many workers have made efforts to determine their model parameters (Garnavich et al. 1998, Schmidt et al. 1998, Perlmutter et al. 1999, Riess et al. 1998, 2000, Riess 2000).

Here is, however, an essentially important problem to be taken into consideration. It is the homogeneity of the Universe. According to Giovanelli et al. (1998, 1999) and Dale et al. (1999) the Universe is homogeneous in the region within $70h^{-1}$ Mpc (the Hubble constant H_0 is 100h km s⁻¹ Mpc⁻¹). On the other hand, recent galactic redshift surveys (Marinoni et al. 1999, Marzke et al. 1998, Folkes et al. 1999, Zucca et al. 1997) show that in the region around 200 - $300h^{-1}$ Mpc from us the distribution of galaxies may be inhomogeneous. This is because the galactic number density in the region of z < 0.1 or $< 300 h^{-1}$ Mpc from us was shown to be by a factor > 1.5 smaller than that in the remote region of z > 0.1. Recently a large-scale inhomogeneity suggesting a wall around the void on scales of $\sim 250h^{-1}$ Mpc has been found by Blanton et al. (2000) in the SDSS commissioning data (cf. their Figs. 7 and 8). Similar walls on scales of \sim $250h^{-1}$ Mpc have already been found in the Las Campanas and 2dF redshift surveys near the Northern and Southern Galactic Caps (Shectman et al. 1996, Folkes et al. 1999, Cole et al. 2000). These results mean that there is a local void with the radius of $200 - 300h^{-1}$ Mpc and we live in it.

Moreover, the measurements by Hudson et al. (1999) and Willick (1999) for a systematic deviation of clusters' motions from the global Hubble flow may show some in-

homogeneity on scales larger than $100h^{-1}$ Mpc. Another suggestion for inhomogeneity comes from the periodic wall structures on scales of $\sim 130h^{-1}$ Mpc, as have been shown by Broadhurst et al. (1990), Landy et al. (1996), and Einasto et al. (1997). This is connected with the anomaly of the power spectrum around $100-200h^{-1}$ Mpc (so-called "excess power") which was discussed by Einasto et al. (1999). This fact also may suggest some inhomogeneity in the above nearby region.

If the local void exists really, the Hubble constants also must be inhomogeneous, as well as the density parameters, and the theoretical relations between observed quantities are different from those in homogeneous models. At present, however, the large-scale inhomogeneity of the Hubble constant has not been observationally established yet because of the large error bars in the various measurements (cf. Tomita 2001).

In my previous papers (Tomita 2000a and 2000b) cited as Paper 1 and Paper 2, I showed various models with a local void and discussed the bulk flow, CMB dipole anisotropy, distances and the [m, z] relation in them in the limited parameter range. It was found that the accelerating behavior of supernovae can be explained in these models without cosmological constant. On the other hand, Kim et al. (1997) showed that the difference between the local and global values of the Hubble constant should be smaller than 10% in homogeneous cosmological models in order to be consistent with the SNIa data. However, this does not impose any strong condition on the difference in inhomogeneous models, because their analyses were done using the luminosity distance in homogeneous models and so they are incomplete. In fact my previous papers showed concretely that in inhomogeneous models larger differences can be consistent with the data. The possibility that the above difference may explain the behavior of SNIa was later discussed also by Goodwin et al. (1999).

In this paper I describe first (in §2) a simplified cosmological model with a local void and treat distances in light paths with nonzero clumpiness (smoothness) parameter α . In the previous paper (Paper 2), I considered only distances in full-beam light paths ($\alpha=1$), but in the realistic paths there are deviations from $\alpha=1$ due to lensing effects from inhomogeneous matter distributions. In §3, I show the dependence of the [m,z] relation on model parameters such as the radius of the local void, the ratios of density parameters and Hubble constants in the inner (low-density) and outer (high-density) regions, and the clumpiness parameter. The constraints to the parameters are derived in comparison between the above relations in the present models and the relations in homogeneous models.

Finally (in $\S4$), we discuss the remaining problems and describe concluding remarks.

2 DISTANCES IN MODELS WITH A LOCAL VOID

The inhomogeneous models we consider consist of inner (low-density) region V^I and outer (high-density) region V^{II} which are separated by a single shell. It is treated as a spherical singular shell and the mass in it compensates the mass deficiency in V^I . So V^I and the shell are regarded as a local void and the wall, respectively. The line-element in the two regions are

$$\begin{array}{lcl} ds^2 & = & g^j_{\mu\nu}(dx^j)^\mu(dx^j)^\nu \\ & = & -c^2(dt^j)^2 + [a^j(t^j)]^2 \Big\{ d(\chi^j)^2 + [f^j(\chi^j)]^2 d\Omega^2 \Big\}, \end{array} (1)$$

where j (= I or II) represents the regions, $f^j(\chi^j) = \sin \chi^j, \chi^j$ and $\sinh \chi^j$ for $k^j = 1, 0, -1$, respectively, and $d\Omega^2 = d\theta^2 + \sin^2\theta d\varphi^2$. In the following the negative curvature is assumed in all regions. The Hubble constants and density parameters are expressed as $(H_0^{\rm I}, H_0^{\rm II})$ and $(\Omega_0^{\rm I}, \Omega_0^{\rm II})$, where we assume that $H_0^{\rm I} > H_0^{\rm II}$ and $\Omega_0^{\rm I} < \Omega_0^{\rm II}$. The distances of the shell and the observer O (in V^I) from the centre C (in V^I) are assumed to be 200 and $40h_1^{-1}$ as a standard case. This shell corresponds to the redshift $\bar{z}_1 = 0.067$ (see Figure 1).

In Paper 2 we derived the full-beam distances (\overline{CS}) between the centre C and a source S, and the distances (\overline{OS}) between an observer O and S. The two distances are nearly equal in the case when \overline{CS} or \overline{OS} is much larger than \overline{CO} . Since we notice this case alone in the following, we treat the light paths \overline{CS} for simplicity. Then the angular-diameter distance d_A is

$$d_{\mathcal{A}} = a^{\mathcal{I}}(\bar{\eta}_{\mathbf{s}}^{\mathcal{I}})\sinh(\bar{\chi}_{\mathbf{s}}^{\mathcal{I}}),\tag{2}$$

if a source S is in V^I , where $(\bar{\eta}_s^I, \bar{\chi}_s^I)$ are the coordinates of S, and η is the conformal time coordinate. Here bars are used for the coordinates along the light paths to the virtual observer at C. If S is in V^{II} , we have

$$d_{A} = a^{I}(\bar{\eta}_{1}^{I}) \sinh(\bar{\chi}_{1}^{I}) + \begin{bmatrix} a^{II}(\bar{\eta}_{s}^{II} \sinh(\bar{\chi}_{s}^{II}) \\ - a^{II}(\bar{\eta}_{1}^{II}) \sinh(\bar{\chi}_{1}^{II}) \end{bmatrix},$$
(3)

where $(\bar{\eta}_1^{\rm I}, \bar{\chi}_1^{\rm I})$ stand for the shell, and we have

$$a^{\mathrm{I}}(\bar{\eta}_{1}^{\mathrm{I}})\sinh(\bar{\chi}_{1}^{\mathrm{I}}) = a^{\mathrm{II}}(\bar{\eta}_{1}^{\mathrm{II}})\sinh(\bar{\chi}_{1}^{\mathrm{II}}) \tag{4}$$

Figure 1. Model with a spherical single shell. Redshifts for observers at O and C are z and \bar{z} .

from the junction condition.

Here we treat the following equation for the angulardiameter distance to consider the clumpiness along paths into account (Dyer and Roeder 1973, Schneider et al. 1992, Kantowski 1998, Tomita 1999):

$$\frac{d^{2}(d_{A}^{j})}{d(z^{j})^{2}} + \left\{ \frac{2}{1+z^{j}} + \frac{1}{2}(1+z^{j}) \left[\Omega_{0}^{j}(1+3z^{j}) + 2 - 2\lambda_{0}^{j} \right] \right. \\
\times F^{-1} \left\{ \frac{d(d_{A}^{j})}{dz^{j}} + \frac{3}{2}\Omega_{0}^{j}\alpha(1+z^{j})F^{-1}d_{A}^{j} = 0, (5) \right.$$

where j = I and II, z^j is the redshift in the region V^j , α is the clumpiness parameter, and

$$F \equiv (1 + \Omega_0^j z^j)(1 + z^j)^2 - \lambda_0^j z^j (2 + z^j). \tag{6}$$

Here and in the following the bars are omitted for simplicity. The two redshifts at the shell are equal, i.e.

$$z_1^{\mathrm{I}} = z_1^{\mathrm{II}} \ (\equiv z_1) \tag{7}$$

for the comoving shell (cf. Paper I).

The distances $d_{\rm A}^{\rm I}$ in ${\bf V}^{\rm I}$ is obtained solving Eq.(5) under the conditions at $z^{\rm I}=0$:

$$(d_{\rm A}^{\rm I})_0 = 0, \quad (d_{\rm A}^{\rm I}/dz^{\rm I})_0 = c/H_0^{\rm I},$$
 (8)

and $d_{\rm A}^{\rm II}$ in V^{II} is obtained similarly under the conditions at $z^{\rm II}=0$:

$$(d_{\rm A}^{\rm II})_0 = const, \quad (d_{\rm A}^{\rm II}/dz^{\rm II})_0 = c/H_0^{\rm II},$$
 (9)

where *const* is determined so that the junction condition $d_{\rm A}^{\rm I}(z_1)=d_{\rm A}^{\rm II}(z_1)$ may be satisfied at the shell. Then the distance $d_{\rm A}(z_s)$ from C to the source S is

$$d_{\mathcal{A}}(z_s) = d_{\mathcal{A}}^{\mathcal{I}}(z_s) \qquad \text{for } z_s \le z_1, \tag{10}$$

and

$$d_{\mathcal{A}}(z_s) = d_{\mathcal{A}}^{\mathcal{I}}(z_1) + d_{\mathcal{A}}^{\mathcal{I}\mathcal{I}}(z_s) - d_{\mathcal{A}}^{\mathcal{I}\mathcal{I}}(z_1) \quad \text{for } z_s > z_1, \tag{11}$$

where $z_s = z_s^{\rm I}$ and $z_s^{\rm II}$ for $z_s \leq z_1$ and $z_s > z_1$, respectively. The luminosity distance $d_{\rm L}$ is related to the angular-diameter distance $d_{\rm A}$ by $d_{\rm L} = (1+z)^2 d_{\rm A}$.

As for the clumpiness parameter α , we studied the distribution function $N(\alpha)$ as a function of z in our previous

Figure 2. The [m, z] relation in cosmological models with a local void. The solid line denotes the case with a standard parameter set given in (12). The dotted and dash lines stand for homogeneous models with $(\Omega_0, \lambda_0) = (0.3, 0.7)$ and (0.3, 0.0), respectively, for comparison.

papers (Tomita 1998, Tomita 1999). To obtain $N(\alpha)$, we first derived model universes consisting of galaxies and halos using a N-body simulation technique, secondly calculated the angular-diameter distance by solving null-geodesic equations along many light paths between an observer and sources at epoch z, and finally derived a statistical distribution of α determined in a comparison with the Friedmann distance ($\alpha = 1.0$) and the Dyer-Roeder distance ($\alpha = 0.0$). As the result of these studies, it was found that the average value $\bar{\alpha}$ of α is 1.0, which represents the Friedmann distance, and the dispersion σ_{α} can be ~ 0.5 for z < 2.0. If the detection of high-z supernovae is done in completely random directions, the observed average value of α is equal to the above theoretical average value $\bar{\alpha}$. But if the detections are biased to the directions with less galactic number per steradian to avoid the dust obscuration, we may have the value of $\alpha \sim \bar{\alpha} - \sigma_{\alpha}$. Then the angular-diameter and luminosity distances are somewhat longer than the average Friedmann distances. In the next section we show the cases with $\alpha = 1.0, 0.5$, and 0.0 for comparison. The lensing effect on the [m, z] relation of SNIa was discussed also by Holz (1998), Porciani and Madau (2000), and Barber (2000).

3 PARAMETER DEPENDENCE OF THE MAGNITUDE-REDSHIFT RELATION

As for homogeneous models it is well-known from the comparison with observational data that the flat case with nonzero cosmological constant of $(\Omega_0, \lambda_0) = (0.3, 0.7)$ can represent the accelerating behavior of high-z SNIa, while an open model with (0.3,0) cannot explain their data for $z \approx 1.0$ (Garnavich, et al. 1998, Schmidt et al. 1998, Perlmutter et al. 1999, Riess et al. 1998, 2000, Riess 2000). In the present inhomogeneous models we have six model parameters $(\Omega_0^{\rm I}, \lambda_0^{\rm I}, H_0^{\rm I}, H_0^{\rm II}/H_0^{\rm I}, \Omega_0^{\rm II}/\Omega_0^{\rm I}, z_1)$, and their direct fitting with the observational data is much complicated in contrast to the homogeneous case with three parameters. In this paper the parameter dependence of [m, z] relations are examined for the preliminary study and the relations in these two homogeneous models are used as a measure for inferring how the relations in inhomogeous models with various parameters can reproduce the observational data. That is, we deduce that the model parameters are consistent with the observational data, if at the interval 0.5 < z < 1.0 the curve in the [m, z] relation is near that in the homogeneous model (0.3, 0.7) comparing with the difference between those for (0.3, 0.7) and (0.3, 0).

For the [m, z] relation in an inhomogeneous model, we first treat the case with the following *standard* parameters to reproduce the accelerating behavior in the above homogeneous model (0.3, 0.7) in a similar way:

$$\begin{array}{rcl} (\Omega_0^{\rm I},\Omega_0^{\rm II}) & = & (0.3,0.6), \\ H_0^{\rm I} & = & 71, \quad H_0^{\rm II}/H_0^{\rm I} = 0.82, \\ \alpha & = & 1.0, \quad z_1 = 0.067, \text{ and } \lambda_0^{\rm I} = \lambda_0^{\rm II} = 0. \end{array} \tag{12}$$

The radius of the local void is $r_1 \equiv (c/H_0^{\rm I})z_1 = 200(h_{\rm I})^{-1}$ Mpc. In Figure 2, the relation is shown for z = 0.01 - 2.0 in comparison with that in two homogeneous models with parameters: $(\Omega_0, \lambda_0) = (0.3, 0.7)$ and $(0.3, 0), H_0 = 71$ and $\alpha = 1.0$. For $z < z_1$ the relation is equal to that in the open model (0.3, 0.0).

It is found that the behavior in the case of $(\Omega_0^{\rm I}, \Omega_0^{\rm II}) = (0.3, 0.6)$ with $\lambda_0^{\rm I} = \lambda_0^{\rm II} = 0$ accords approximately with that in the flat, homogeneous model with $(\Omega_0, \lambda_0) = (0.3, 0.7)$ for $z_1 < z < 1.0$. Accordingly they is similarly fit for the observed data of SNIa.

Next, to examine the parameter dependence of the [m,z] relation, we take up various cases with following parameters different from the above standard case:

rameters different from the above standard case:
$$\begin{array}{rcl} \Omega_0^{\rm II} & = & 0.45 \text{ and } 0.80 & (\text{for } \Omega_0^{\rm I} = 0.3) \\ H_0^{\rm II}/H_0^{\rm I} & = & 0.80 \text{ and } 0.87 & (\text{for } H_0^{\rm I} = 71), \\ \alpha & = & 0.0 \text{ and } 0.5, \quad z_1 = 0.05 \text{ and } 0.167, \text{ and } \\ \lambda_0^{\rm II} & = & 0.4. \end{array} \tag{13}$$

Here, for $z_1 = 0.05$ and 0.167, we have $r_1 = (150 \text{ and } 500)(h_{\rm I})^{-1}$ Mpc, respectively. Since $\lambda_0^j \equiv \frac{1}{3}\Lambda(c/H_0^j)^2$, we have $\lambda_0^{\rm I} = \lambda_0^{\rm II}(H_0^{\rm II}/H_0^{\rm I})^2$.

In Figure 3 (curves a), the cases with $z_1 = 0.05, 0.067$, and 0.167 are shown in a model with $(\Omega_0^{\rm I}, \Omega_0^{\rm II}) = (0.3, 0.6), H_0^{\rm II}/H_0^{\rm I} = 0.82, \alpha = 1.0$, and $\lambda_0^{\rm I} = \lambda_0^{\rm II} = 0$. The range of z was changed to 0.3 < z < 2.0 to magnify the figures. From this Figure it is found that if $r_1 = 150$ and $200(h_{\rm I})^{-1}$ Mpc, the [m, z] relation is similar to that in the flat, homogeneous model with $(\Omega_0, \lambda_0) = (0.3, 0.7)$ for $z \sim 0.5$, but if $r_1 = 500(h_{\rm I})^{-1}$ Mpc, the relation is rather

Figure 3. The [m,z] relation in cosmological models with a local void. The solid lines denote (a) the cases with $z_1=0.05,0.067$, and 0.167 (from the top to the bottom), which correspond to the shell radius $r_1=150,200$, and $500(h_1)^{-1}$ Mpc, respectively, (b) the cases with $H_0^{\rm II}/H_0^{\rm I}=0.87,0.82$, and 0.80 from the top to the bottom, (c) the cases with $\Omega_0^{\rm II}=0.45,0.6$, and 0.8 from the top to the bottom, and (d) the cases with $\alpha=0.0,0.5$, and 1.0 from the top to the bottom. The other parameters are same as those in a standard parameter set given in (12). The dotted and dash lines stand for homogeneous models, as in Figure 2. Curves (a), (b) and (c) were depicted in the single figure together with (d) by shifting upward as $\Delta(5\log d_{\rm L})=6,4,2$, respectively.

different from that in the latter model. This means that r_1 must be $\lesssim 300(h_1)^{-1}$ Mpc to explain the [m,z] relation of SNIa. This observational constraint is consistent with the observationally estimated radius of the local void ($\lesssim 300h^{-1}$ Mpc) (cf. Marinoni 1999, Marzke et al. 1998, Folkes et al. 1999, Zucca et al. 1997).

In Figure 3 (curves b), the cases with $H_0^{\rm II}/H_0^{\rm I}=0.80,0.82$, and 0.87 are shown in a model with $(\Omega_0^{\rm II},\Omega_0^{\rm II})=(0.3,0.6),\ z_1=0.067,\ \alpha=1.0,$ and $\lambda_0^{\rm I}=\lambda_0^{\rm II}=0.$ In the cases with $H_0^{\rm II}/H_0^{\rm I}=0.82,0.87$, the relations are found to be consistent with the relation in the above flat, homogeneous model for z=0.5-1.0, but in the case with $H_0^{\rm II}/H_0^{\rm I}=0.80$ or <0.80, the [m,z] relation is difficult to explain the observed data.

In Figure 3 (curves c), the cases with $\Omega_0^{\rm II}=0.45,0.6$, and 0.8 are shown in a model with $\Omega_0^{\rm I}=0.3$, $H_0^{\rm II}/H_0^{\rm I}=0.82$, $z_1=0.067$, $\alpha=1.0$, and $\lambda_0^{\rm I}=\lambda_0^{\rm II}=0$. In the case with $\Omega_0^{\rm II}=0.45$ and 0.6, the relation are found to be consistent with those in the above flat, homogeneous model for

Figure 4. The [m,z] relation in cosmological models with a local void. The upper and lower solid lines denote (a) the cases with $\lambda_0^{\rm II}=0.4$ and 0.0, respectively, and (b) the cases with $H_0^{\rm II}/H_0^{\rm I}=0.87,0.82$, and 0.80 for $\lambda_0^{\rm II}=0.4$ from the top to the bottom. (c) The [m,z] relation in two homogeneous cosmological models with $(\Omega_0,\lambda_0)=(0.3,0.7)$ and (0.3,0.0). The upper and lower groups of three lines stand for models (0.3,0.7) and (0.3,0.0). The upper, middle and lower lines in each group are for $\alpha=0.0,0.5$, and 1.0, respectively. The other parameters are same as those in a standard parameter set given in (12). The dotted and dash lines stand for homogeneous models, as in Figure 2. Curves (a) and (b) were depicted in the single figure together with (c) by shifting upward as $\Delta(5\log d_{\rm L})=4,2$, respectively.

z=0.5-1.0, but in the case with $\Omega_0^{\rm II}=0.8$ we have less consistency.

Here let us examine the lensing effect to the [m,z] relation. In Figure 3 (curves d), the cases with $\alpha=0.0,0.5$, and 1.0 are shown in a model with $(\Omega_0^{\rm I},\Omega_0^{\rm II})=(0.3,0.6)$, $H_0^{\rm II}/H_0^{\rm I}=0.82$, $z_1=0.067$, and $\lambda_0^{\rm I}=\lambda_0^{\rm II}=0$. Compared with the case $\alpha=1.0$, the relations for $\alpha=0.0$ and 0.5, give larger magnitudes especially at epochs z>1.0. For $\alpha=0.5$, the magnitudes are by about 0.1 and 0.2 mag larger than those for $\alpha=1.0$ in the relations at epochs z=1.0 and 2.0, respectively. If the value $\alpha=0.5$ is realistic, the cases with larger $\Omega_0^{\rm II}$ and smaller $H_0^{\rm II}/H_0^{\rm I}$ may be consistent with the observed data.

Next we consider the cases with a nonzero cosmological constant. In Figure 4 (curves a), the cases with $\lambda_0^{\rm II}=0.0$ and 0.4 are shown in a model with $(\Omega_0^{\rm I},\Omega_0^{\rm II})=(0.3,0.6),\ H_0^{\rm II}/H_0^{\rm I}=0.82,\ z_1=0.067,\ {\rm and}\ \alpha=1.0.$ In the case with $\lambda_0^{\rm II}=0.4$, the space in the outer region is spatially flat. In this case the role of the cosmological constant to the

accelerating behavior is not dominant, but supplementary to the role of the local void.

In Figure 4 (curves b), the cases with $H_0^{\rm II}/H_0^{\rm I}=0.80,0.82$, and 0.87 are shown in a model with $(\Omega_0^{\rm I},\Omega_0^{\rm II})=(0.3,0.6),\ z_1=0.067,\ \alpha=1.0,$ and $\lambda_0^{\rm II}=0.4.$ In this outerflat case also, larger $H_0^{\rm II}/H_0^{\rm I}$ gives larger magnitudes in the [m,z] relation.

Finally the lensing effect in homogeneous models is examined for comparison. In Figure 4 (curves c), the cases with $\alpha=0.0,0.5$, and 1.0 are shown in homogeneous models with $(\Omega_0,\lambda_0)=(0.3,0.7)$ and (0.3,0.7) for $H_0=71$. As in Figure 6, the magnitudes in the relation for $\alpha=0.5$ are by about 0.1 and 0.2 mag larger than those for $\alpha=1.0$ in the relations at epochs z=1.0 and 2.0, respectively.

4 CONCLUDING REMARKS

As for the [m,z] relation in cosmological models with a local void, we studied the parameter dependence of their accelerating behavior, and found that the local void with $r_1 \lesssim 200h^{-1}$ Mpc, $H_0^{\rm II}/H_0^{\rm I} \gtrsim 0.82$, and $\Omega_0^{\rm II} \lesssim 0.6$ is appropriate for explaining the accelerating behavior of SNIa without cosmological constant, that the lensing with $\alpha \sim 0.5$ is effective at epochs of $z \gtrsim 1.0$, and that the cosmological constant ($\lambda_0^{\rm II} \sim 0.4$) necessary for flatness in the outer region has a role supplementary to the accelerating behavior. On the basis of these results we can determine in the next step what values of the model parameters are best in the direct comparison with the observational data of SNIa.

In the Universe with CDM matter, the probability that the inhomogeneity of Hubble constant $\delta H/H \sim 0.2$ on scales ~ 200 Mpc associated with general density perturbations is realized is extremely small, as was clarified and discussed by Turner et al. (1992), Nakamura and Suto (1995), Shi and Turner (1998), and Wang et al. (1998). The constraint from CMB dipole anisotropy was also discussed by Wang et al.(1998). It should be noticed here that the *spherical* void which we are considering is exceptionally compatible with the constraint from CMB dipole anisotropy, in spite of the above large deviation of Hubble constant, as long as the observers are near the centre (cf. Paper 1). Inversely it may be suggested that the local void on scales ~ 200 Mpc must be *spherical* or *nearly spherical*, if its existence is real.

In comparison with observations of the galactic number count - magnitude relation, on the other hand, Phillips and Turner (1998) have once studied the possibility of an underdense region on scales of $\sim 300h^{-1}$ Mpc. However, a necessary wall for the mass compensation has not been considered in their simple models and, in the small-angle observations of the above relation the boundary between the inside region and the outside region was rather vague in contrast to the large-angle redshift surveys.

In the near future the void structure on scales of $\sim 200h^{-1}$ Mpc will be clarified by the galactic redshift survey of SDSS in the dominant part of whole sky. Then, observational cosmology will be developed taking into account that we are in a local void.

The author thanks K. Shimasaku for discussions on galactic redshift surveys and V. Müller for helpful comments. This work was supported by Grant-in Aid for Sci-

entific Research (No. 12440063) from the Ministry of Education, Science, Sports and Culture, Japan.
