ABSTRACT

Eighteen days of MERLIN data and 42 hours of A-array VLA data at 1.4 GHz have been combined to image a 10-arcmin field centred on the Hubble Deep Field (HDF). This area also includes the Hubble Flanking Fields (HFF). A complete sample of 92 radio sources with $S_{1.4} > 40 \mu Jy$ was detected using the VLA data alone and then imaged with the MERLIN+VLA combination. The combined images offer: i) higher angular resolution (synthesised beams of diameter 0.2–0.5 arcsec); ii) improved astrometric accuracy and iii) improved sensitivity compared with VLA-only data. The images are amongst the most sensitive yet made at 1.4 GHz, with rms noise levels of 3.3 μ Jy beam⁻¹ in the 0.2-arcsec images. Virtually all the sources are resolved, with angular sizes in the range 0.2 to 3 arcsec. The central 3-arcmin square was imaged separately to search for sources down to $27 \mu Jy$. No additional sources were detected, indicating that sources fainter than 40 μ Jy are heavily resolved with MERLIN and must have typical angular sizes >0.5 arcsec. Radio sources associated with compact galaxies have been used to align the HDF, the HFF and a larger CFHT optical field, to the radio-based International Celestial Reference Frame. The HST optical fields have been registered to < 50 mas in the HDF itself, and to <150 mas in the outer parts of the HFF. We find a statistical association of very faint ($\geq 2 \mu Jy$) radio sources with optically bright HDF galaxies down to ~ 23 mag. Of the 92 radio sources above 40 μ Jy, \sim 85 per cent are identified with galaxies brighter than I=25 mag; the remaining 15 per cent are associated with optically faint systems close to or beyond the HFF (or even the HDF) limit. The high astrometric accuracy and the ability of radio waves to penetrate obscuring dust has led to the correct identification of several very red, optically faint systems including the the strongest sub-mm source in the HDF, HDF850.1. On the basis of their radio structures and spectra 72 per cent (66 sources) can be classified as starburst or AGN-type systems; the remainder are unclassified. The proportion of starburst systems increases with decreasing flux density; below 100 $\mu Jy > 70$ per cent of the sources are starburst-type systems associated with major disc galaxies in the redshift range 0.3 – 1.3. Chandra detections are associated with 55 of the 92 radio sources but their X-ray flux densities do not appear to be correlated with the radio flux densities or morphologies. The most recent sub-mm results on the HDF and HFF do not provide any unambiguous identifications with these latest radio data, except for HDF850.1, but suggest at least three strong candidates.

Key words: galaxies: evolution – galaxies: active – galaxies: starburst – cosmology: observations – radio continuum: galaxies

1 INTRODUCTION

2

Radio observations allow us to probe the nuclear regions of galaxies which are obscured by gas and dust in other wavebands. In addition, radio observations with high angular resolution can distinguish, on morphological grounds, between emission that is driven by star-formation and that which is driven by Active Galactic Nuclei (AGN). While sub-mm wavelengths provide one means of detecting starformation in the early Universe, through redshifted infrared radiation from dusty star-forming regions, current submm instruments do not have sufficient angular resolution to avoid source blending in deep sub-mm fields, or the astrometric capability to avoid confusion in crowded optical/NIR fields. Sensitive, high angular-resolution radio observations are currently the best way to uniquely identify the optical counterparts to this population. Furthermore, because of the negative K-correction, dusty galaxies observed at sub-mm wavelengths preferentially lie at high redshifts whereas radio observations are sensitive to a wide range of redshifts and to a mix of starburst and AGN activity and hence provide complementary information on the population of distant galaxies.

The Hubble Space Telescope (HST) has been used to image a window on the distant universe to very high sensitivity. The central Hubble Deep Field (HDF) and surrounding Hubble Flanking Fields (HFF) are complete to R magnitudes of 29 and 25 respectively (Williams et al. 1996). The HDF region was selected to avoid known bright galaxies in any observable waveband.

We report here the results from our high-resolution, high-sensitivity 1.4-GHz MERLIN+VLA study of the $\mu \rm Jy$ sources found in a 10-arcmin field enclosing both the HDF and HFF, together with a more sensitive search for radio sources in a 3-arcmin square field enclosing the HDF itself. These represent amongst the most sensitive 1.4-GHz observations yet made and together with their high angular resolution (0.2 arcsec) and astrometric positional accuracy (tens of mas) these data allow, for the first time, detailed imaging and accurate identification of $\mu \rm Jy$ radio sources.

This work represents a major extension to the original 1.4-GHz VLA results reported in Richards et al. (1999) and Richards (2000) providing better astrometry, more sensitive maps, and higher angular resolution. It also complements and adds to the work at 8.4 GHz reported by Fomalont et al. (2002) and Richards et al. (1998).

In Sections 2 and 3, we summarize the VLA and MER-LIN observations and the procedures adopted to make the radio images. In Section 4 we describe in some detail the process of alignment of the optical and radio fields in order to achieve a registration accuracy of <50 mas (HDF) to <150 mas (HFF/outer 10-arcmin field). In Section 5 we discuss the individual radio/optical objects in the 10-arcmin field. In Section 6 we outline the different procedure adopted to image the 3-arcmin field and discuss the statistical association of very weak radio sources with optical objects down to R=25 mag. In Section 7 we discuss the structural properties of the μ Jy radio sources, their optical identifications and redshifts, their luminosities and inferred star-formation rates. In Section 8 we make comparisons with other observations in radio, sub-mm, infra-red, and X-ray wavebands; whilst in Section 9 we discuss the optically faint systems.

We look forward to the possibilities opened up by the next generation of telescopes in Section 10 and our overall conclusions from this deep radio study are presented in Section 11.

2 THE RADIO OBSERVATIONS AND DATA REDUCTION

2.1 The VLA observations

The detailed description of the VLA observations and calibration are given in Richards (2000) and we merely summarize the work here for completeness. We observed an area centred on the Hubble Deep Field and located at R.A. $12^{\rm h}$ $36^{\rm m}$ $49^{\rm s}.4$ Dec. $+62^{\circ}$ 12' 58''.00 (J2000) with the VLA in A-array for a total of 50 hours at 1.4 GHz. In order to minimise chromatic aberration, we observed in 'pseudocontinuum mode' with 7×3.125 MHz channels centred on intermediate frequencies 1365 MHz and 1435 MHz, frequency windows previously established to be relatively free of radio frequency interference.

After time-averaging the data to 13 seconds and significant tapering in the spatial frequency plane, preliminary 10-arcsec resolution maps were made covering the field out to the first side-lobe of the primary beam – about 0° .8 from the field centre. These were then searched for bright, confusing sources with flux densities whose side-lobes might contaminate the noise characteristics of the inner portion of the field.

Each confusing source above 0.5 mJy was imaged and heavily CLEANed using the full resolution data set. Because of changes in the primary beam response across our 44-MHz bandpass it was necessary to deconvolve each of the confusing sources in spectral-line mode separately from each frequency channel. Furthermore, the confusing sources were independently deconvolved for each hand of circular polarization; this was to account for the beam-squint of the VLA antennas which produces small but significant differences for each hand of polarization for sources on the edge of the primary beam. The CLEAN components were then Fourier transformed and subtracted from the visibility data which were then used to image the inner few arcmin of the field. Following this procedure, the rms noise was found to be about 50 per cent higher than expected from receiver noise alone. In particular, a few side-lobes from particularly strong confusing sources (S > 10 mJy) located near the half-power point of the primary beam were still apparent.

By examining the images made from 30 minute segments of data, we isolated a few time intervals where the visibility data appeared to be corrupted, possibly due to incomplete confusing source subtraction associated with telescope pointing errors, or perhaps low level interference. We deleted all data segments where the rms noise exceeded the mean value by greater than 50 per cent. This amounted to about 7 hours of data and, in all, about 42 hours of high quality data were used to construct the final images. In the final VLA images we achieved an rms noise of 7.5 μ Jy beam⁻¹, compared with a theoretical value closer to 5 μ Jy beam⁻¹. 92 sources with flux densities >40 μ Jy (5.3 σ) were reliably detected in the 10-arcmin × 10-arcmin field.

2.2 The MERLIN observations

We observed the same position with the Multi-Element Radio Linked Interferometer Network (MERLIN) at 1.4 GHz in February 1996 and April 1997 for a total of 18.23 days. These observations included the 76-metre diameter Lovell Telescope which increases the array sensitivity by a factor ~ 2.4 compared with identical observations excluding the Lovell Telescope. Observations with a single intermediate frequency, were centred on 1420.0 MHz with 32×0.5 -MHz channels to allow imaging over a wide field 10 arcmin on a side (comparable with the primary beam of the Lovell Telescope HPBW=12.4 arcmin). Data from the correlator were recorded every 4 seconds. As with the VLA data, correlator limitations resulted in only parallel hands of circular polarization being correlated, thus no linear polarization information is available.

The interferometric phases were calibrated by observing the nearby 0.4 Jy phase calibration source J124129+622041 with a duty cycle of 8:2 minutes (source:calibrator). The visibility amplitudes were calibrated against 3C286 and B1803+784 with assumed flux densities of 14.774 Jy and 1.914 Jy respectively (Baars et al. 1977). Bandpass calibration was performed using B1803+784. Visibilities corrupted by instrumental phase errors, telescope errors, or external interference were flagged and discarded. Finally, the visibilities were re-weighted to reflect the differing sensitivities of the various telescopes involved in the MERLIN array. Due to the high angular resolution of MERLIN, its lack of short interferometer spacings, and the effect of the primary beam of the Lovell Telescope, no significant problems with confusing sources outside the 10-arcmin field were encountered. However, the four strongest sources within the 10-arcmin field were mapped and their CLEAN components subtracted from the MERLIN data, prior to the MERLIN+VLA imaging of the remaining 88 weaker sources detected by the VLA. In addition, the 'subtracted data' set was used for the imaging of the 3-arcmin field. The frequency channels at the extreme ends of the passband are subject to a loss of sensitivity due to bandwidth limitations on the microwave radio links. The lowest rms noise value was found when excluding the lowest three and the highest channel, resulting in a final bandwidth of 14 MHz. The rms noise achieved in naturally-weighted images from the MERLIN data alone was 5.9 μ Jy beam⁻¹ which is within 10 per cent of the theoretical value.

3 THE RADIO IMAGES

3.1 Data and image combination

Since the correlators used for the observations of the HDF and HFF were optimally configured for the two separate arrays, the MERLIN and VLA visibility datasets are fundamentally different in structure, containing differing numbers of intermediate frequencies, frequency channels, and channel bandwidths. For this reason, combining the visibility datasets in the AIPS software package proved wholly impracticable, not least due to the size of the visibility datasets which, in combination, proved far too large for the software package as implemented to handle. The data were therefore combined in the sky-plane rather than the uv plane.

For all the 92 radio sources detected by the VLA in the

10-arcmin field, individual 'postage-stamp' maps were made centred on each source from both the VLA and MERLIN datasets separately. No deconvolution was performed prior to any image combination; thus the 'dirty maps' and 'dirty beams' were made from each naturally-weighted dataset separately. In order to retain optimum Fourier Transform gridding for each dataset, a different cell-size was selected for each array (MERLIN 0.05 arcsec, VLA 0.4 arcsec). The VLA 'dirty maps' and 'beams' were then re-gridded to the cellsize of the MERLIN images and then averaged with them to produce combination 'dirty maps' and a combination 'dirty beam'. We gave equal statistical weight to each input image since the MERLIN and VLA images were of comparable sensitivity. This process is equivalent to combining the data sets prior to Fourier transformation into the sky plane. The central quarters of these combination images were then deconvolved with a conventional CLEAN algorithm (Högbom, 1974) resulting in deconvolved images 25.6 arcsec on a side.

To demonstrate the equivalence of sky plane and visibility plane combination, we have performed a test with one $307-\mu Jy$ source, J123649+620738, which lies 320 arcsec almost due south from the field centre, just outside the 10-arcmin field. The MERLIN and VLA datasets were separately phase rotated to the position of this test source and then averaged in time and to a single frequency channel. Averaging restricts the field of view to a small region around the test source, but simplifies and compresses the datasets by a considerable amount allowing data combination prior to Fourier transformation. From the averaged datasets, a 'dirty map' and 'dirty beam' were then made and the map cleaned using the sky-plane combination method described above. Separately, the averaged data were then combined in the visibility plane and a second 'dirty map' and 'dirty beam' were then made and CLEANed. The two CLEANed images are shown in Fig. 1; two compact components are embedded within a region of emission extending over ~ 1.5 arcsec. The two images are essentially identical; the difference between them is noise-like with a peak difference of under 4 μ Jy beam⁻¹ in the contoured area.

We also constructed a mini-mosaic of the inner 3 arcmin \times 3 arcmin field (see Section 6) using the sky-plane combination technique in order to search for additional sources below the VLA-alone 40- μ Jy detection threshold. In this case, however, 72 contiguous images were made in an 8×9 grid centred on the HDF, using a pixel size of 0.0625 arcsec. We spaced the grid so that the central 410 – 412 pixels (within a CLEANed area of 512 \times 512 pixels) of the images abutted one against another so as to cover the field completely allowing for sky curvature. We stress that these images are not centred on existing VLA-only detections as is the case with the images derived for the 10-arcmin field. The image coverage of the 3- and 10-arcmin fields is illustrated in Fig. 2.

Primary beam corrections for combination images within the the 10-arcminute field are small since they are dominated by the 25-m antennas of the VLA and MERLIN which have a half-power beam width (HPBW) of ~ 35 arcmin at 1.4 GHz. The Lovell telescope has an HPBW of 12 arcmin but on a baseline to a 25-m antenna the combined HPBW is ~ 20 arcmin (see Strom (2004) for the derivation). With respect to a source at the field centre, the flux of a source 5 arcmin distant is only depressed by 1 per cent and 12 per cent for 25-m–25-m and 25-m–Lovell

Figure 1. A comparison of CLEANed images using MERLIN+VLA combination in the visibility (left) and image (right) planes. The contour interval is linear with a lowest contour value of 10 μ Jy beam⁻¹.

baselines respectively. We compared the images from VLA-only and MERLIN+VLA combinations and estimated that, in the combination images, the measured fluxes 5 arcmin from the field centre are depressed by only ~ 6 per cent and for the majority of sources in the 10-arcmin field the effect is significantly less. The position uncertainties given in Table A1 take into account the local increase in noise due to the various aberrations and the quoted flux densities listed in Table A2 have been corrected for primary beam effects. No correction has been made to the contoured combination images shown in Appendix B.

3.2 Positional comparisons with previously published 1.4 GHz images

Within each of the 'postage-stamp' images, the sky is treated as flat. However, the image offset from the interferometer pointing centre is corrected for sky curvature so as to avoid image distortion at large offsets. Richards (2000) imaged the entire 40-arcmin VLA primary beam using 16 facets of size $14 \text{ arcmin} \times 14 \text{ arcmin}$. There is measurable sky distortion near the edges of these facets which introduce positional offsets of up to 0.2 arcsec for individual sources. However, after correction for these known effects, we find that the MER-LIN and VLA positions agree to within 15 mas. The MER-LIN+VLA combination images are of significantly greater angular resolution than the VLA-only images of Richards (2000). Furthermore, at MERLIN resolutions the vast majority of these weak radio sources are resolved. The positions quoted in Table A1 are for the brightest features in the combination images, and for the reasons just given, differ from those quoted in Richards (2000). A full analysis of the astrometric alignment of this multiple small-image technique is given in Section 4.1 where we find that the quoted positions for the MERLIN+VLA combination images in Table A1 lie on the International Celestial Reference Frame (ICRF) to within 15 mas.

4 THE OPTICAL IDENTIFICATIONS OF THE RADIO SOURCES

Williams et al. (1996) describe the WFPC2 observations and data reduction procedure and present a complete catalogue of objects detected within the HDF. In the 4.7 arcmin² region of the HDF, objects as faint as $U=27.6,\ B=28.1,\ V=28.7,\$ and I=28.0 (AB magnitudes) are detected at the 10 σ level. In addition to the HDF, eight HST exposures of one orbit were taken in I-band (F814) in flanking fields (HFF) immediately adjacent to the HDF (Williams et al. 1996). The point source sensitivity for each of these frames is about R=25 mag.

In the process of aligning the optical and radio fields, we also used a deep CFHT I-band frame taken by Barger et al. (1999). This field is 9 arcmin on a side and encloses both the HDF and HFF frames. The CFHT field also enabled additional optical identifications outside the HDF and HFF to be made. This field has a resolution of about 1.5 arcsec and its limiting magnitude is $R\sim 26$.

4.1 Radio/optical astrometric alignment

In order to make reliable optical identifications of the radio sources, it is important to align the HST images with the radio images which are closely tied to the ICRF (see below). Although the fine guidance system of the HST is accurate to a few mas, intrinsic uncertainties in the HST Guide Star Catalog positions on the order of 1–2 arcsec are the limiting

Figure 2. Schematic of the image coverage in the 3- and 10-arcmin fields. Only a few of the 92 'postage-stamp' images are indicated for simplicity.

source of error in tying the HST astrometric grid to the ICRF.

4.1.1 Radio astrometry

The position grid of the VLA HDF radio images is tied to the radio source J121711+583526 with an assumed position of R.A. $12^{\rm h}$ $17^{\rm m}$ $11^{\rm s}.0202$ and Dec. $+58^{\circ}$ 35' 26''.228 (J2000) (Patnaik et al. 1992). This source has quoted positional errors of 13 mas with respect to the ICRF. Subsequently, the position of the compact core of this source has been established at higher radio frequencies to an accuracy of order 1 mas with respect to the ICRF (Beasley et al. 2001). However, the object shows significant jet emission, especially at 1.4 GHz, and positional blending between core and jet components result in an overall radio positional uncertainty of ~ 10 mas. The accuracy of transferring the position of J121711+58585 to the position of the VLA HDF images is much better than 50 mas, derived from an estimate of typical long-term systematic phase errors and the angular separation in the sky between J121711+58585 and the Hubble fields.

The position of the compact MERLIN phase calibration source, which lies less than 40 arcmin from the HDF field centre (J124129+622041, R. A. 12^h 41^m 29^s.589115 Dec. +60° 20′ 41″.32402 (J2000), has been established to lie on the ICRF to better than 1 mas (Beasley et al 2001). The error in transferring the position of J124129+622041 to the position of the MERLIN images is less than 5 mas, again

derived from typical systematic phase performance and the calibration source to HDF separation.

As an internal consistency test, we compared the independently derived MERLIN and VLA radio positions for the compact flat-spectrum AGN source J123714+620823 (which lies some 5 arcmin from the HDF field centre towards the edge of the 10-arcmin field); they agree to better than 12 and 10 mas in Right Ascension and Declination respectively. This is consistent with the quoted phase calibrator position errors in Patnaik et al. (1992). We are therefore confident that the radio positions for the MERLIN+VLA combination images presented in this paper lie on the ICRF to within 15 mas.

4.1.2 Optical – radio alignment of the CFHT field

Each HST WFPC2 frame typically contains too few radio detections to align the radio and optical images directly. An intermediate stage is thus required. We have therefore aligned the ground-based CFHT deep I-band image covering a 9-arcmin field centred on the HDF (Barger et al. 1999) under the radio detections. The CFHT image has, to first order, already been corrected for geometrical distortion. However, a further correction was made in order to optimise the alignment of this frame with respect to the radio source positions and hence the ICRF. This was achieved by fitting the positions of 36 galaxies identified with brighter radio sources in the 10-arcmin radio field. Both 4- and 6-parameter fits were performed. The 4-parameter solution fits for an x and y shift, a rotation, and a stretch term. The 6-parameter fit allows for non-perpendicular x-y axes with a further stretch term. The 6-parameter solution was found to be no better than the 4 parameter solution since the two axes were found to be perpendicular to better than 0.01 degrees. We adopted the 4-parameter solution and applied these to positions derived from the CFHT frame.

The fitting residuals in the outer parts of the CFHT frame (typically outside the area of both the HDF and HFF) show that there are small but significant departures from the model. The fitting residuals are shown in Fig. 3. Where it was felt that the residuals showed a consistent offset over a region in the outer parts of the CFHT frame, a further empirical positional shift correction was made. These final corrections are also marked in Fig. 3.

4.1.3 Alignment of CFHT and HDF/HFF WFPC2 frames

After applying positional shifts from the 4 parameter solution (derived from the whole of the CFHT frame), the rms of the fitted residuals in the central part of the image, which overlies the 3 HDF frames, was found to be 66 mas. For this sub-region only, a small modification was made to the CFHT shift parameters in order to optimise the optical to radio alignment within the HDF itself resulting in a reduction of the rms fitted residuals to 41 mas. The rms of the fitted residuals for the inner flanking fields (within 2.5 arcmin of the HDF pointing centre) was found to be 118 mas. For the outer flanking fields the rms of the residuals was found to be 143 mas.

Optically compact galaxies in each WFPC2 frame were then registered over the same galaxy in the positionally corrected CFHT image. By this means, the WFPC2 frames

Table 1. Astrometric alignment errors in the 10-arcmin field.

Registration Error	Su l HDF	Sub-Region of the 10-Arcmin Fiel HDF Inner HFF Outer HFF Beyon							
$\begin{array}{c} \text{Radio} \Leftrightarrow \text{ICRF} \\ (\text{MERLIN} \Leftrightarrow \text{VLA} \Leftrightarrow \text{ICRF}) \end{array}$	<15mas	<15mas	<15mas	<15mas					
$\begin{array}{c} \text{Optical} \Leftrightarrow \text{ICRF} \\ (\text{MERLIN+VLA} \Leftrightarrow \text{CFHT} \Leftrightarrow \textit{HST}) \end{array}$	<50mas	50-100mas	100-150mas	150-250mas					

Figure 3. Fitting residuals for the CFHT frame (Barger et al. 1999); the HDF and HFF WFPC2 frames are shown as solid lines. Circles and bars mark the residual offsets from the 4-parameter fitted solution for a number of radio sources with compact nuclear components associated with compact optical galaxies. Arrows at grid intersections mark the derived distortion terms used to correct galaxy positions in the outer part of the CFHT frame after applying the 4-parameter solutions. A 1000 mas scale for the bars and arrows is shown at bottom right.

were aligned with the radio frame and therefore the ICRF. The optical to radio registration errors are still the dominant source of errors in this procedure. Within the HDF itself, the residual optical registration error is less than 50 mas, rising to approximately 120 mas in the inner parts of the HFF, and to approximately 150 mas at the edge of the HFF. At the edge of the CFHT frame the registration error is ~ 250 mas. These astrometric errors are summarised in Table 1.

5 THE 10-ARCMINUTE FIELD

In this section we present and discuss the detailed radio structures found for the complete sample of 92 weak radio sources stronger than 40 μ Jy (5.3 σ) detected in the VLAonly dataset and lying within the 10-arcmin field centred on the HDF. To repeat, for each source combination MER-LIN+VLA 'postage-stamp' images were made with a deconvolved area 25.6×25.6 arcsec² around the VLA position. Three sizes of restoring beam were employed: the formal fitted beam of 0.204×0.193 arcsec² with major axis position angle -6°, and larger circular beams of 0.3 arcsec, and 0.5 arcsec. The complete list of source details is given in Tables A1 and A2, and the radio structures at the angular resolution shown in column 5 of Table A1 are displayed in Fig. C1, overlaid on the astrometrically-aligned optical images. The optical images are either WFPC2 HDF/HFF frames or, for those regions outside the HFF, the CFHT frame. The additional source information found in the central 3-arcmin field is presented in Table 2 and discussed in Section 6. The high resolution of the HDF/HFF observations allows us to concentrate on characterising the phenomena responsible for radio emission; these may coexist with other processes in the same host galaxy.

5.1 Classifying the radio structures

Although few of these μ Jy radio sources are appreciably resolved by the 2-arcsec beam of the VLA A-array image, virtually all are resolved by the MERLIN+VLA combination showing that they have angular sizes in the range 0.2 to 3 arcsec, typically smaller than the sizes of the optical galaxy images. Fig. 4 shows the observed distribution of angular sizes. The structural description scheme adopted in Table A2 is as follows:

FRI: Fanaroff & Riley (1974) Type I 'classical' double structure.

WAT: Wide-Angled-Tail 'classical' double structure.

C: Compact component at 0.2-arcsec resolution.

C1E: Compact component + one-sided extended emission.

CE: Compact component + two-sided extended emission.

E: Extended emission with no compact component. Note that most of the E sources have sub-galactic dimensions.

+ : Low surface-brightness emission lies beyond that re-

Table 2. 1.4-GHz radio sources detected at $\geq 7\sigma$ with 0.5-arcsec resolution in the 3-arcmin field. All sources were also detected by the VLA alone at 1.4 GHz (see Tables A1 and A2).

I – radio contours overlap the 3σ position box of an ISO detection

Figure 4. Distribution of largest angular sizes for 91 of the 92 radio sources studied in the 10-arcmin field and listed in Table A2. The remaining source, J123644+621133, has a largest angular size of 12 arcsec.

gion shown in the MERLIN/VLA image (detected by the VLA alone).

There are very few radio structures typical of high luminosity sources (i.e. twin lobes on either side of the parent galaxy) and those that are found are associated with the relatively stronger, mJy, sources. The vast majority of μ Jy sources in the 10-arcmin field have radio structures with sub-galactic sizes.

We have compared our 1.4-GHz flux densities with those measured by the VLA at 8.4 GHz (Richards et al. 1998) to derive radio spectral indices for our sample (see column 5 in Table A2 and table 5 in Richards 2000).

The classification scheme adopted for the radio sources is as follows:

AGN/AGN Candidate: We classify a source as an 'AGN' if it has a a flat or inverted radio spectrum accompanied by a compact core and one or two-sided extended structure¹. Sources with only some of these characteristics are classified as 'AGN candidates'.

Starburst/Starburst Candidate: We classify a source as a 'Starburst' if it has a steep radio spectrum, is extended on sub-galactic scales (often aligned with the galaxy major axis) and is also detected by the Infrared Space Observatory (ISO) (Goldschmidt et al. 1997; Aussel et al. 1999). The correlation between radio and IR luminosity is so close (Carilli & Yun 1999; Garrett 2002) that an ISO detection, especially at 15 μ m, is a strongly statistically significant indicator that at least the proportional fraction of the radio emission is also of starburst origin. Sources with only some of these characteristics are classified as 'Starburst Candidates'. Three high-redshift (z > 2) starburst systems which show evidence for an additional embedded AGN component, such as a compact core or hard X-ray emission (see Table A2), are designated as S*. Alexander et al. (2002) discuss the likelihood of 15- μ m sources with hard X-ray emission harbouring AGN.

Unclassified: Sources with complex radio structures which could be associated with either AGN or starburst activity are listed as 'unclassified', for example if the radio emission is more extended than optical emission and there is a dearth of other evidence.

Appendix B gives a source-by-source summary of detections in the 10-arcmin field.

 $^{^1\,}$ J123725+621128 has a steep spectrum at VLA resolution but the MERLIN+VLA images show that it is unmistakably an AGN with large radio lobes

Figure 5. (Upper) radio brightness at 1.4 GHz smoothed to 1-arcsec resolution at the position of known galaxies, plotted as black + signs against the WFPC2 galaxy I magnitude, in 1-magnitude bins. The control data are displayed as grey \times signs and incorporate a random 7-arcsec shift applied to the radio positions in both R.A. and Dec.. (Lower) data for the known galaxies shown unbinned.

6 THE THREE-ARCMINUTE FIELD

6.1 Mapping and analysis

The innermost 3.41×3.84 arcmin² of the radio field was examined in more detail, and is referred to as the '3-arcmin field'. A grid of 8×9 maps was made from the calibrated MERLIN and VLA data sets as described in Section 3.1. We also restored the CLEAN components for the four bright sources in this region which had already been subtracted as described in Section 2.2.

The noise fluctuations at low brightness levels are higher than expected for a pure Gaussian distribution. A number of factors are likely to contribute to this excess, as discussed in Section 2.1. These include pointing fluctuations, residual ripples due to sources in the outer parts of the primary beam and residual side-lobes of the brighter sources in the field. Since such effects are likely to produce as many negative deviations as positive, we have adopted a pragmatic approach to establishing real source thresholds.

Initially each of the 72 maps was examined for regions with brightness above 25 μ Jy beam⁻¹; 42 of them had no such peaks. The brightness distribution in these 'source-free' maps was statistically analysed. The rms noise level with a 0.5-arcsec restoring beam is 3.9 μ Jy beam⁻¹ with no positive or negative peaks above $\pm 7\sigma_{\rm rms}$. The noise level with the smallest 0.2-arcsec restoring beam is 3.3 μ Jy beam⁻¹ with no peaks above $\pm 8\sigma_{\rm rms}$. In the other 30 images, positive regions above these levels (27 and 25 μ Jy beam⁻¹ at 0.5- and 0.2-arcsec resolutions respectively) are therefore considered reliable detections.

Eleven positions have peaks above 27 μ Jy beam⁻¹ (see Table 2). All these sources coincide with VLA 1.4-GHz

detections with flux densities $> 40 \mu Jy$ (total); they can all be regarded as secure and thus the sample is complete to this limit. The positions and sizes of these eleven sources were found by fitting Gaussian components in the image plane. Nine sources are significantly resolved, and one (J123656+621207) is too weak for its size to be measured reliably. One object in Table A1 (J123646+621445), which also lies in the 3-arcmin field, is so spatially resolved as to fall below the 27 μ Jy beam⁻¹ detection threshold and thus does not appear in Table 2. This imaging exercise therefore revealed no new sources in the 3-arcmin field in the brightness range 27-40 μ Jy beam⁻¹. Note however that at the same time as reducing the detection threshold from 40 (VLA-only) to 27 μ Jy beam⁻¹, we also increased the angular resolution from 2 arcsec (VLA-only) to 0.5 arcsec. The slope of the integral source counts around 40 μ Jy is -1.4 (Richards 2000) and one would therefore expect to find ~ 8 additional sources within the 3-arcmin field in the flux density range 27–40 μ Jy, including one compact AGN. Since we do not detect any new sources, we infer that most objects weaker than 40 μ Jy are heavily resolved with a 0.5-arcsec beam, do not contain compact radio components $> 27 \mu Jy$ and must have angular sizes > 1 arcsec. We ascribe the failure to detect an additional compact AGN source to chance. The planned extension of the investigation to the complete mapping of the 10-arcmin field (see Section 10) will provide additional constraints on this interpretation.

6.2 Statistical comparison with HDF galaxies

For the part of the 3-arcmin field which overlies the central HDF area itself, the MERLIN+VLA images were smoothed

to 1-arcsec resolution, after excluding all 11 significant individual source detections (points above $+27~\mu\mathrm{Jy}$ beam⁻¹). The radio brightness was then measured at the positions of all catalogued HDF galaxies (Williams et al. 1996). The results are shown in Fig. 5, binned by *I*-band magnitude. The figure shows that sources over an order of magnitude weaker than our detection threshold (40 $\mu\mathrm{Jy}$), are statistically associated with galaxies brighter than $I\sim23$ mag. A control sample which incorporates a random 7-arcsec shift applied to the radio measurement positions, in both R.A. and Dec. with respect to the optical galaxies shows no excess of detected brightness. Thus the source population down to a few $\mu\mathrm{Jy}$ shares similar properties with the 10-arcmin field sample, being identified statistically with the brighter HDF galaxies.

7 PROPERTIES OF THE RADIO SOURCES

7.1 Source sizes

As summarised in Fig. 4, the great majority of the μ Jy source population have radio angular sizes in the range 0.2 arcsec to 3 arcsec. Only one source in the sample of 92 objects is unresolved (J123714+620823). Only two sources (J123644+621133 and J123725+621128) show classical radio structures usually associated with high luminosity AGN, and both of these are representative of the tail of the mJy source population rather than that of the μ Jy sources. One other AGN system, (J123652+621444), shows evidence from WSRT observations of a possible one-sided low surface-brightness jet structure extending for some 30 arcsec with an implied size of around 100 kpc.

Notwith standing that perhaps a total of 10 per cent of low-surface brightness extended sources have been missed by the original VLA-only survey (see Section 8.1), the great majority of objects in the 10-arcmin field have radio structures extended predominantly on galactic and sub-galactic scales. Their radio structures have been defined and discussed in Section 5.1 and Appendix B respectively. The typical source angular scale appears similar down to 27 $\mu\rm Jy$ and even beyond (see Section 6).

The fact that the typical angular size of μJy sources is ~ 1 arcsec may have implications for future deep surveys with the Square Kilometre Array (SKA) which could encounter a natural confusion limit. If the slope of the source counts at 1.4 GHz remains as steep as -1.4 then surveys, with limiting flux densities 100 times fainter than the present one, will reach surface densities >500 sources arcmin⁻² (similar to the surface density of optical galaxies in the HDF). If the typical source size remains ~ 1 arcsec then the proportion of sky covered with radio sources, C, will be >0.14. If C > 0.05 significant blending of sources begins to occur (Fomalont et al. 2002) and obviously if C > 0.14 a large amount of source blending would result, regardless of the size of the synthesized observing beam. This simple inference depends, however, on two large extrapolations (source counts and sizes). The optical HDF is not significantly confused and it could be, for example, that the fainter radio sources are smaller, being associated with the fainter, smaller, irregular galaxies; this could reduce C to below the natural confusion limit.

7.2 Optical identifications and redshifts

Sixty-one of the 92 sources (65 per cent) in the 10-arcmin field have measured spectroscopic or estimated photometric redshifts (at the time of performing this analysis). Fig. 6 shows the redshift distribution for each of the three classifications. Note that the highest redshift source, J123642+621331, appears to contain a compact AGN. It is clear that it is only the starburst systems which extend to redshifts in excess of 2. For those systems with redshifts less than 2, we have compared the redshift distributions for each classification.

The AGN and unclassified systems have median redshifts of 0.91 and 0.85 respectively, and a Kolmogorov-Smirnov goodness of fit test shows that there is a 79 per cent probability that they are drawn from the same population. Conversely, the starburst systems have a significantly lower median redshift of 0.56 and there is only a 7 per cent probability that they are drawn from the same population as the AGN systems. Thus it appears that majority of the starburst systems are associated with galaxies at a lower redshift than the AGN sources. On this basis, the majority of the unclassified sources are most likely to be AGN dominated systems with some starbursts included. It is worth noting, however, that nearly half the starburst systems appear in two adjacent histogram bins covering $0.3 \le z < 0.7$. The excess of sources in these bins is correlated with the redshifts of two major clusters found by Cohen et al. (2000) in their Caltech Faint Galaxy Redshift Survey of the HDF.

The histogram of starburst galaxies and starburst candidates also shows evidence for a tail extending to redshifts in excess of 4 (although the highest redshift candidate may also contain an AGN). Fig. 9 shows that many of these high redshift starburst systems have been identified as sub-mm sources (Chapman et al. 2004a, Chapman et al. 2004c submitted). In addition, two are optically faint and extremely red, suggesting that they are dust-enshrouded. Of the thirteen optically faint radio sources in the 10-arcmin field, only two are classified as AGN or AGN candidates. Thus, although the majority of starburst systems are associated with galaxies brighter than I = 25 and at redshifts less than two, it appears that we are beginning to sample an additional population of high redshift systems. In addition, some of these high redshift systems may be complex, containing both dustshrouded starbursts and embedded AGN (see Appendix B and Section 9).

7.3 Structural classification and source flux density

Fig. 7 summarises the classification of the 92 sources in the 10-arcmin field in each of three flux density ranges (40–55 $\mu\mathrm{Jy},$ 56–105 $\mu\mathrm{Jy},$ and 106–6000 $\mu\mathrm{Jy});$ these contain approximately equal numbers of sources: 30, 30, and 32 respectively. It is immediately apparent that the proportion of starburst and starburst candidate systems rapidly increases with decreasing flux density below 100 $\mu\mathrm{Jy}$. In the highest flux density range, there are only around 20 per cent starburst systems with around 40 per cent AGN and 40 per cent unclassified sources. In the lowest flux density range, the proportion of starburst systems has risen above 70 per cent while the proportion of AGN systems has dropped to less than 5 per

Figure 6. Redshift distribution for those sources in the 10-arcmin field with measured spectroscopic redshifts (black) and estimated photometric redshifts (white).

Figure 7. Distribution of source classifications for the objects in the 10-arcmin field in each of three flux ranges (40–55 μ Jy, 56–105 μ Jy, & 106–6000 μ Jy) containing 30, 30, & 32 sources respectively.

cent. Fomalont et al. (2002) note that in their sample of radio sources at 8.4 GHz, the average radio spectrum for those sources identified with optical counterparts becomes steeper for fainter sources ($S_{8.4} < 35~\mu \rm{Jy}$). These authors also state that objects fainter than $I=25.5~\rm{mag}$ predominantly have steep radio spectra. Thus it is clear that at flux densities below around 50 $\mu \rm{Jy}$ at centimetric wavelengths, a popu-

lation of steep radio spectrum starburst systems begins to dominate.

There is, however, a selection effect which could reduce the numbers of AGN identified at low flux levels. AGN systems are easily identified if they have flat or inverted radio spectra. Radio spectral information is derived from the present 1.4-GHz observations and those at 8.4 GHz

Figure 8. 1.4-GHz monochromatic luminosity for AGN and AGN candidate sources with redshifts in the 10-arcmin field. Filled symbols are spectroscopic redshifts, open symbols are photometric redshifts. Asterisks show named sources. The plotted line marks the detection threshold of 40 μ Jy for sources assuming a spectral index of 0 ($\Omega_{\rm V}=0.7,\Omega_{\rm M}=0.3,$ and H $_0=65~{\rm km~s^{-1}~Mpc^{-1}}).$

(Richards et al. 1998). The 8.4-GHz image is extremely sensitive (rms noise = $2.78~\mu\mathrm{Jy}$ beam⁻¹); however the small primary beam of the VLA antennas (HPBW = $5.2~\mathrm{arcmin}$) restricts the region of source detection to a field of around 8 arcmin in diameter. Weak sources close to the edge of the 10-arcmin field will not be detected at 8.4 GHz, and this is likely to prevent the correct identification of weak AGNs. Such systems are likely then to be designated as 'unclassified'. However, since less than 20 per cent of the unclassified sources are found in the lowest flux range shown in Fig. 7, it is thought that few if any AGN have been mis-identified at low flux levels. Moreover the K-correction works in favour of detecting AGN in comparison with starbursts at high z, as noted in Section 8.2.

7.4 Source luminosities and star-formation rates

Figs. 8 and 9 show the rest-frame 1.4-GHz monochromatic luminosities for the AGN, and starburst/starburst candidate sources in the 10-arcmin field with measured or estimated redshifts respectively, together with a number of well-known lower redshift radio sources of each type. The detection threshold for 40 μ Jy is plotted as a line assuming a radio spectral index of 0 for the AGNs and 0.7 for the starburst systems.

All the AGN candidates are well above the detection threshold which simply reflects the fact that they have flux densities well above 40 μ Jy. Their luminosities are similar to those of low luminosity, low redshift FRI type radio galaxies like M84, Virgo A, and 3C449 (Fanaroff & Riley, 1974); but significantly lower than those of FRII type sources and powerful quasars like 3C273 (see Fig. 8 where the source 3C465 has a rest-frame luminosity intermediate between FRI and FRII type systems). However, apart from two sources (J123644+621133 and J123725+621128) which show 'classi-

Figure 9. 1.4-GHz monochromatic luminosity for starburst and starburst candidate sources with redshifts in the 10-arcmin field. Filled symbols are spectroscopic redshifts, open symbols are photometric redshifts. Five-pointed stars mark sub-mm systems. Triangles mark two high redshift systems with possible embedded AGN, (J123642+621331, & J123651+621221). The sub-mm system with a possible embedded AGN (J123635+621424) is shown in grey. Asterisks show named sources. The plotted line marks the detection threshold of 40 $\mu\rm Jy$ for sources assuming a spectral index of 0.7 ($\Omega_{\rm V}=0.7,\,\Omega_{\rm M}=0.3,$ and $H_0=65~\rm km~s^{-1}~Mpc^{-1}).$

cal' double radio structures, all the remaining AGN systems are small core-jet systems extended on sub-galactic scales.

The starburst candidates lie closer to the detection threshold since they represent the majority of the weaker radio sources in the 10-arcmin field. All the systems are substantially more powerful than M82 and about half are more luminous than Arp 220. The sources at z > 2 (marked as stars and triangles in Fig. 9) have particularly high luminosities exceeding that of Arp 220 by an order of magnitude. The object at the highest redshift (J123642+621331) which is more than 3 orders of magnitude more luminous than Arp 220, may be a hybrid system containing both a dust-shrouded starburst and an embedded AGN (see discussion in Appendix B). The other two starburst sources which appear to contain compact AGN are not noticeably superluminous. Star-formation rates for starburst and starburst candidate systems with measured redshifts are shown in Table 3. These are derived from the rest-frame monochromatic 1.4-GHz luminosity via the relationship derived by Condon & Yin (1990) and Condon (1992). Star-formation rates for stellar masses $> 5 M_{\odot}$ were calculated using the relationships given by Cram et al. (1998) and then multiplied by 5.5 to give the total star-formation rate for stellar masses between 0.1 M_{\odot} and 100 M_{\odot} using a Salpeter IMF.

8 COMPARISON WITH OTHER CATALOGUES

8.1 The WSRT catalogue

After our data had been taken and analysed, it has become clear that a number of extended, low surface-brightness radio

Table 3. Rest-frame monochromatic 1.4-GHz Luminosities and star-formation rates (assuming Salpeter IMF, see Section 7.4) for starburst systems with measured or estimated redshifts. Star-formation rates marked with an * may be overestimates as these galaxies are thought to contain an embedded AGN.

sources may have been missed by the initial VLA-only finding survey. Using the WSRT interferometer, which has much lower angular resolution (15 arcsec) and is thus more sensitive to extended objects than the VLA A-array (2-arcsec resolution), Garrett et al. (2000) detect additional radio sources in the region of the 10-arcmin field. Furthermore, they identify at least two (J123720+621247 and J123636+621132) with nearby, extended star-forming galaxies. Since these objects were not detected by the VLA, it implies they are extended on the 5-20 arcsec angular scale and do not contain compact radio structure. However, the crowded nature of the optical field makes identification for most of these new detec-

tions very uncertain. In addition, Garrett et al. (2000) state that further analysis of the full field is required to distinguish how many of the WSRT-only detections are real and associated with discrete, extended radio sources, and how many are blends of closely-separated, faint radio sources.

The WSRT source catalogue given by Garrett et al. (2000) lists 85 objects above a 5σ limit of $\sim 50~\mu \rm Jy$ within the 10-arcmin field. Of these 63 are also detected by the VLA hence 22 are WSRT-only detections. The VLA-only flux densities listed in Table A2 include 78 sources above 50 $\mu \rm Jy$ (6.7 σ) of which 15 are VLA-only detections. One possible explanation is that these sources have varied between

the epochs of the VLA and WSRT observations. However, many of the VLA-only detections show extended radio structures in the MERLIN+VLA combination images and have steep radio spectra – indeed, in Section 7, we argue that the majority of weakest radio sources in the 10-arcmin field are extended starburst systems. These objects are very unlikely to be variable radio sources. The implication is that the WSRT catalogue is unreliable at this level, and that of the 22 WSRT-only detections, perhaps only between 8 and 10 are real extended low-surface brightness radio sources lying within the 10-arcmin field which have been missed by the VLA. It is still likely, therefore, that the VLA-based source list in Table A2 is incomplete and is missing $\sim\!\!10$ per cent of the $\mu\rm Jy$ radio source population.

8.2 ISO

Aussel et al. (1999) detected 100 sources at 6.7 or 15 μm or both within the HDF/HFF. The ISO beams were 3 and 6 arcsec within ~ 3.5 and ~ 5 arcmin fields of view at the shorter and longer wavelengths respectively; 28 radio sources lie within the maximum ISO field of view. Of these, 15 have IR counterparts within 3 arcsec. In addition the core of the FRI J123644+621133 is just over 3 arcsec from a 6.7- μ m source, found only by the ISO detection method described by Goldschmidt et al. (1997). Two more (J123646+621445 and J123656+621301) are at separations of 3-6 arcsec; in the case of J123646+621445 the IR source appears to be associated with a separate nearby galaxy (see Appendix B). Note that in the column in Table A2 labelled ISO, '-' signifies that the source is outside the ISO field and 'No' signifies a non-detection within the field at the local flux-density limit, see Aussel et al. (1999) for details of how this varies with position and frequency. Twelve of the radio sources with IR counterparts are classified as starburst galaxies using the criteria in Section 5.1 (of which 3 have embedded AGN), two are AGN and two are unclassified. The majority of radio sources (7) within the ISO field of view which do not have IR counterparts are also starburst candidates, 3 are unclassified and 2 are AGN/AGN candidates.

Starbursts typically have a steep spectrum in both the IR and the radio whilst AGN have a flatter radio spectrum. Hence the K-correction implies that, at the same luminosity, AGN should be detectable at greater distances than starbursts and the proportion of the latter may be underestimated. Elbaz et al. (2002) showed that 80-90 per cent of the extragalactic 15 μ m background is of starburst origin and 3/4 of ISOCAM galaxies are ULIRGs (Ultra-Luminous IR Galaxies). The proportions are consistent in other deep surveys such as of the Lockman Hole as well as in the HDF.

Garrett (2002) demonstrated that the 1.4-GHz and 15- $\mu{\rm m}$ rest-frame luminosities of HDF sources detected by both WSRT and ISO are closely correlated out to at least $z\sim1.3$, suggesting a common emission environment. This correlation is based on using a starburst-model spectral index in the IR and the vast majority of the radio sources with associated IR emission are independently classified as starburst candidates. A third of the radio sources in the sample identified by Garrett (2002) are among the non-detections seemingly resolved-out in the MERLIN+VLA data (Section 8.1). One may be a misidentification and 10 out of the 12 remaining

sources have extended emission and other starburst characteristics.

73 ISO sources lie within the 3-arcmin field. In order to investigate statistical associations with the ISO sources, the mean MERLIN+VLA flux density from within concentric circles centred on the ISO positions was measured, together with equivalent flux densities of a control sample incorporating a 10-arcsec random position offset from the radio position. The most significant correlation with the radio brightness is obtained with circles of 2.5 arcsec diameter. The results are shown in Fig. 10 and we note that radio flux densities $> 10~\mu\mathrm{Jy}$ were found at the positions of 30 ISO detections, about half of which are probably significant statistically. Although this is only a $\sim \! 2\sigma$ result it indicates that deeper surveys and more accurate IR positions, as will be obtained with the Spitzer satellite, are likely lead to many more radio-IR associations.

8.3 Chandra

43 of the 92 sources in the 10-arcmin field sample (47 per cent) were detected in X-rays by *Chandra* using a 1 Ms exposure (Hornschemeier et al. 2001). A further 12 counterparts with full-band counts < 65 were found in the full 2 Ms *Chandra* exposure recently catalogued by Alexander et al. (2003). These are all listed in Table A2. Note that in the column labelled *Chandra*, 'No' signifies a non-detection within the field at the local flux-density limit, see Alexander et al. (2003) for details of how this varies with position and energy. The *Chandra* field of view at high sensitivity is slightly larger than the 10-arcmin radio field.

We note that the X-ray detection rate appears to be uncorrelated with the radio source flux density since in each of the three flux ranges shown in Fig. 7, 16/30, 20/30, and 19/32 radio sources are detected by *Chandra* respectively. In addition, Fomalont et al. (2002) state that the seven X-ray identifications (from the 1 Ms observation) in the HDF itself show no trends in radio spectral index or optical counterpart and are identified with galaxies of various spectral types. There is no obvious correlation between X-ray and radio flux densities or classification. Since Fig. 7 shows that source classification is a strong function of radio flux density, this implies that the X-ray emission from the μ Jy radio source population is not a good predictor of AGN activity in the HDF unless this arises from a separate mechanism within the same galaxy.

A long series of papers have appeared analysing the *Chandra* results using multi-wavelength comparisons. However thus far most considerations of radio data have used the 1 Ms X-ray catalogue and the VLA-only radio data. In the next paper we intend to use Virtual Observatory tools to compare the new more sensitive samples which, for the first time, contain enough sources in common to allow comparisons based on selection by specific properties such as spectral index or redshift.

8.4 SCUBA sub-mm sources

Identifying the optical/NIR counterparts to sub-mm sources has proved difficult due to the poor spatial resolution and astrometric capability of current sub-mm telescopes. However, high resolution radio images offer new possibilities for

Figure 10. Histogram showing the MERLIN+VLA 1.4-GHz brightness at the positions of *ISO* detections within the 3' field, compared with the off-source brightness. The 'on source' histogram is shifted to the right of the 'off source' one indicating a weak statistical association of radio emission with *ISO* sources.

locating sub-mm sources and for the determination of their properties. For starburst systems, it is well established that the radio continuum flux (due to synchrotron emission from SNR and violent turbulence associated with intense starformation) and the FIR/sub-mm flux (due to dust from stellar winds) are tightly correlated as a result of their both being linearly related to the massive star-formation rate (e.g. Helou et al. 1985, Helou & Bicay, 1993). If the FIR-radio correlation extends to high redshift then in principle, sensitive radio observations can be used to pinpoint distant sub-mm sources.

From radio-far-infrared SED-based redshift arguments Smail et al. (2000) have suggested that the median redshift for the bright SCUBA galaxy population is ~ 3 , with the substantial majority of SCUBA sources lying at redshifts > 2. Dunlop et al. (2004) argue that since SCUBA sources in other fields have been identified with relative ease compared with HDF850.1 (see below), the majority probably lie at redshifts < 4. This is in agreement with Hughes et al. (1998) who have assumed a redshift range of 2 < z < 4 for calculating the contribution made by sub-mm sources to starformation density. Ivison et al. (2002) have investigated the SCUBA source population in the Lockman Hole and ELAIS N2 regions with deep multi-band imaging. With good radio positional information, they identify radio counterparts for 18 of 30 sub-mm sources. Of these, they find that at least 60 per cent of the host galaxies appear to be morphologically distorted, suggesting that the radio and sub-mm emission arises from extended starbursts and that interactions are common.

With all this in mind, and armed with our accurate radio-optical astrometry, we have revisited the issue of sub-mm source identifications in the HDF and HFF. We have used the results of Serjeant et al. (2003) who have re-measured the positions for the eight brightest sub-mm sources in a field centred on the HDF (Hughes et al. 1998). Following discussion with S. Serjeant on the sub-mm position errors, we have drawn error circles with a radius of 2σ where $\sigma = \sqrt{1^2 + \theta_{\rm SNR}^2}$ arcsec. In this quadratic combination the first term is an estimate of the positional error due to confusion and the second is the standard random error due to finite signal-to-noise ratio ($\theta_{\rm SNR} = 0.5 \times {\rm FWHM/SNR}$).

FWHM is the size of the imaging beam. Fig C2 shows these error circles overlaid on the astrometrically aligned optical fields. The combined MERLIN/VLA radio images at the position of each sub-mm source at 0.6-arcsec resolution are shown as contours. Following the assessment by Serjeant et al. of the sub-mm signal-to-noise ratio of HDF850.3, we are not convinced by its reality and therefore we do not include it

We now discuss the individual sub-mm sources in, or close to the edge of, the HDF as presented by Serjeant et al. (2003). Our discussion draws extensively on that of Serjeant et al.; however in a number of cases we come to different conclusions as a result of the improved radio information that we have at our disposal.

8.4.1 HDF850.1

The suggested association of Serjeant et al. for this source is the elliptical galaxy 3-586.0 (Williams et al. 1998), although they do allow the possibility that HDF850.1 is optically faint. The astrometric alignment of the optical field to the ICRF (derived from radio observations presented here), together with observations by IRAM (again with respect to the ICRF) has now allowed Dunlop et al. (2004) unambiguously to identify this brightest sub-mm source. Dunlop et al. have shown that, in a Subaru K' band image, from which a smoothed version of WFPC2 I-band frame has been subtracted, there is an extremely red object (ERO) with I-K> 5.2 at the position of a very weak (16 μ Jy) radio source which lies ~ 1 arcsec to the SW of the elliptical galaxy 3-586.0. The radio source/ERO is within the 3σ positional errors as measured by the IRAM interferometer (Downes et al. 1999) on the ICRF system. The SED determined by Dunlop et al. suggests the ERO is a starburst system at a redshift of 4.1±0.5. The inferred star formation rate is very high ($\sim 2000 \ \mathrm{M}_{\odot} \ \mathrm{yr}^{-1}$), although this may be reduced by a factor close to 3 after correction for gravitational lens boosting by the intervening elliptical galaxy ~ 1 arcsec to the NE.

8.4.2 HDF850.2

The SCUBA source lies just outside the HDF and hence we reproduce the CFHT optical field; there is no optical candidate down to I \sim 25 mag within the error circle. The nearest optical galaxy is 36564+1209 (I \sim 23 mag, Barger et al. 1999) which lies 5.6 arcsec to the north of the SCUBA position. The extended, steep-spectrum radio source J123656+621207 (46 μ Jy, α >1.32) lies 4.2 arcsec to the north of the SCUBA position, outside the error circle. The radio source and the optical galaxy are certainly not coincident. It remains possible, although in our view unlikely, that the radio source J123656+621207 is associated with the sub-mm source. Whether the SCUBA source is associated with J123656+621207 or not, it is clearly associated with an optically faint system, below the limit of the CFHT or WFPC2 images of this HFF field.

8.4.3 HDF850.4

HDF850.4 and HDF850.5 are a possible blended detection. Borys et al. (2003) in a reworking of the sub-mm data list

this as a single detection (SMJ123650+621318). After consultation with S. Serjeant we have treated HDF850.4 and HDF850.5 as separate sub-mm detections but for completeness we have also plotted an error circle derived for the blended source position from Borvs et al. (see above).

Serjeant et al. (2003) suggest that HDF850.4 may be associated with the z=0.851 (Cowie et al., 2004) galaxy 2-339.0 which lies within 0.8 arcsec of the sub-mm source position and close to the centre of the field as reproduced. However, Carilli & Yun (1999) argue that this is hard to reconcile with the lack of any detected radio emission with an Arp 220-like SED since at this redshift they would expect $S_{1.4} \sim 280~\mu\text{Jy}$. There is a 3σ radio detection of $14~\mu\text{Jy}$ close to the nuclear region of 2-339.0. However, this radio flux density is still less than 1/20 of that predicted by Carilli & Yun (1999) for an Arp 220-type SED at z=0.9. We note that this galaxy lies within the error circle associated with SMMJ123650+621318 (Borys et al. 2003).

Another possible identification is with the bright I=21.1 mag galaxy 2-264.1 (z=0.475) coincident with the high signal-to-noise ratio radio source J123649+621313 ($S_{1.4}=49~\mu{\rm Jy}$) which is listed as a starburst system in Table A2. This galaxy lies 5.3 arcsec to the SW and within the error circle.

For completeness one should also consider the I=22.7 mag (z=1.238) galaxy which lies just outside the error circle ~ 6 arcsec to the west of the sub-mm position as a candidate identification. This galaxy also contains a radio source ($S_{1.4}\sim 27~\mu{\rm Jy}$). In addition, another candidate radio identification lies close to the southern edge of the error circle. The $S_{1.4}\sim 19~\mu{\rm Jy}$ possible radio detection is not associated with any optical object to the limit of the CFHT image.

The identification of this sub-mm source remains unclear.

8.4.4 HDF850.5

Serjeant et al. (2003) state that the position of this source is likely to have been affected by the proximity of HDF850.4 (see also above). The most obvious optical candidate, galaxy 2-404.0 (z=0.199, Lanzetta et al. 1996), lies 6.6 arcsec to the west but is not a radio source.

Our deep radio image shows a possible radio counterpart on the eastern edge of the error circle at the 3σ level (14 μ Jy). There is no optical identification at this radio position to the limit of the HST WFPC2 image.

We concur with Serjeant et al. who conclude that there is no reliable identification for this object.

8.4.5 HDF850.6

This source lies outside the HDF and we reproduce both the WFPC2 and CFHT images of this region in the HFF. Serjeant et al. (2003) suggest that this object is most likely to be associated with the radio source J123701+621146 ($S_{1.4}=128~\mu\mathrm{Jy}$) which we classify as a starburst in Table A2. The radio source lies 2.9 arcsec from the sub-mm position but is within the error circle. Although the source is extended over ~ 3 arcsec in the VLA-only image, a high resolution image shows that the central 1.5 arcsec overlies

an ERO with I–K>5 (Alexander et al. 2001). This is not visible in the HST WFPC2 frame, but is just detectable in the lower resolution CFHT image which has a better surface brightness sensitivity. Cohen et al. (2000) derive a spectroscopic redshift of z=0.884 for the ERO on the basis of a single detected emission line (O II, λ_{3727}).

In agreement with Serjeant et al. we conclude that J123701+621146 is the most likely radio counterpart to HDF850.6 and is probably identified with the ERO and the SCUBA source. There is however one other possible radio detection (15 μ Jy) lying within the error circle, but this has no optical counterpart to the limits of either of the WFPC2 HFF or CFHT images. If this latter radio source is the correct association, the radio to sub-mm flux ratio would imply a redshift $z \ge 4$ (see discussion in Section 8.6).

8.4.6 HDF850.7

Serjeant et al. (2003) discuss a possible identification of this source with a z=1.219 (Barger et al. 1999) I=22.3 mag galaxy which lies ~ 5 arcsec from the sub-mm position just outside the error circle. This galaxy is identified with the steep-spectrum radio source J123634+621241 ($S_{1.4}=230~\mu$ Jy). Our high resolution image of this radio source confirms that it is an extended starburst system (Table A2). The galaxy is also detected in X-rays by *Chandra* and is identified with the *ISO* source HDF_PM3_3 (Aussel et al. 1999).

Although the positional offset gives a relatively high probability of a chance coincidence with J123634+621241, Serjeant et al. argue that this source lies in a noisy area of the SCUBA image, and that the positional errors may have been underestimated. Our radio image shows only one other possible detection within the error circle $(3\sigma, 15~\mu\mathrm{Jy})$ for which there is no optical counterpart to the limit of the HST WFPC2 image. We conclude that the galaxy identified with J123634+621241 is the most likely optical counterpart to HDF850.7, but the positional offset makes this identification far from certain. By analogy with HDF850.1, the weak radio detection cannot be discounted.

8.4.7 HDF850.8

Serjeant et al. (2003) suggest that the galaxy 2-736.1, the eastern-most member of an interacting pair of galaxies \sim 2 arcsec from the sub-mm position, is the most likely identification for this source. Cohen et al. (2000) measure a spectroscopic redshift of z=1.355 for this galaxy.

Our radio image shows a weak ($\sim 15~\mu \rm{Jy}$) source associated with 2-736.1, although it is offset to the south-east by ~ 0.5 arcsec from the optical centroid. The radio to sub-mm flux ratio suggests a higher redshift (~ 2) than that measured, although the uncertainties are large. Although this remains the most plausible identification for HDF850.8, there are a number of other possible radio sources lying within the SCUBA error circle (including a 23- $\mu \rm{Jy}$ source on the western edge) which cannot be discounted. None, however, have optical counterparts to the limit of the HST WFPC2 image.

Table 4. Candidate radio source identifications above 4σ in the region of each sub-mm detection as listed by Serjeant et al. $(2003)^{\bullet}$, Chapman et al. $(2004b)^{\circ}$, and Borys et al. $(2003)^{\dagger}$. For Borys et al. (2003) we include only those sub-mm detections above 5σ not already listed by either Serjeant et al. (2003) or Chapman et al. (2004b). Furthermore, for Borys et al. (2003), since the nominal error circles are relatively large, we include only those radio candidates above 5σ . Sources marked with an * are possible bright $(S_{1.4}>40 \ \mu\text{Jy})$ radio counterparts which lie just outside the nominal sub-mm positional error circle as described in Section 8.4 and shown in Fig C2. The radio images were restored with a circular beam of 0.6 arcsec prior to cross-referencing with the sub-mm position. Redshift shown bracketed are uncertain due to significant radio/sub-mm position offsets.

8.5 Other sub-mm samples

Chapman et al. (2004c, submitted) have compiled a sample of sub-mm sources lying within a 7.5-arcmin diameter field centred on R. A. 12^h 36^m 48^s.0 Dec. +62° 15′ 40″.0 (J2000), which have S₈₅₀ >4 mJy and are detected at 1.4 GHz in the VLA A-array observations of this region with S_{1.4} >40 μ Jy (Richards 2000). This field centre lies 162 arcsec north and 10 arcsec east of the HDF and 10-arcmin field pointing centre. Ten objects are common to both the sub-mm sample and the 10-arcmin radio field.

In Table 4 we list all the candidate radio source/submm identifications for Serjeant et al. (2003) and Chapman et al. (2004b). For completeness we also note that Borys et al. (2003) have reworked a large amount of sub-mm data in a field which includes the HDF and parts of the HFF. From their list of detections we have selected those with a sub-mm signal-to-noise ratio >5 which are not included in Serjeant et al. (2003) and Chapman et al. (2004b). These are listed in Table 4 together with any radio detections with a radio signal-to-noise ratio > 5 falling within an error circle of radius 1σ obtained using figure 4 in Borys et al. (2003). These are the most plausible associations but the large submm positional errors listed by Borys et al. (2003) (typically $\sigma = 4 - 5$ arcsec) do not allow unambiguous identifications to be made.

8.6 The radio sub-mm connection

We have been able to combine the deepest 850-micron SCUBA images of the HDF and HFF and the deepest, high resolution, 1.4-GHz radio images, both with the best available astrometric accuracy. Despite this only one sub-mm source, HDF850.1, can be unambiguously paired-up with a radio source. The over-riding reason for this state-of-affairs remains the present-day sub-mm resolution and astrometric

accuracies (with the exception of HDF850.1, separately measured with the IRAM interferometer, Downes et al. 1999) which are inadequate for crowded fields. But this is not a complete explanation since in some cases there are no plausible radio candidates within conservative sub-mm error circles. Carilli & Yun (1999, 2000) and Barger et al. (2000) have shown that the SEDs of both local and high-redshift ULIRGs are similar, and that the ratio of the radio and submm flux densities can be used to construct a rough redshift indicator. The inverse K-correction ensures that the sub-mm flux density varies little with redshift, while the radio flux density falls off with the inverse square law. Barger et al. in their figure 8 show that a galaxy with a sub-mm flux density of 6 mJy will not be detected in the radio at 40 μ Jy for a redshift >4. Hence, it is likely that our failure to detect radio counterparts for some of the sub-mm detections in the HDF and HFF is simply due to their large redshift.

For the brighter sub-mm sources contained in the Chapman et al. (2004b) sample, the positional errors are lower than for those of Serjeant et al. (2003) which has allowed them to link them with radio sources in the 10-arcmin field. For the seven of their sub-mm sources listed in Table 4 with unambiguous identifications, we find that the measured redshifts lie in range 1 to 4 with a mean of 2.26.

9 OPTICALLY FAINT RADIO SOURCES

13 of the 92 sources (14 per cent) in the 10-arcmin field are not identified to the limit of the optical fields over which they lie. Richards et al. (1999) have suggested a number of possibilities regarding the nature of the optically faint, unidentified μ Jy radio source population:

- (i) They are FRI or FRII radio galaxies at moderate redshift. However, this would mean that optical counterparts would have absolute magnitudes 6 magnitudes fainter than typical FRI or FRII radio galaxies which have $I \sim \! 20$ mag. Furthermore, our new 0.2-arcsec resolution images do not have the appropriate radio morphology. We therefore reject this hypothesis.
- (ii) They are displaced lobes of asymmetric sources. However, other μ Jy radio sources consist of only a single component coincident with the optical counterpart, and the optically faint systems do not have radio structures which differ significantly. We therefore consider this hypothesis to be unlikely.
- (iii) The optical counterpart may be at such a high redshift, z > 7, that it is an *I*-band dropout due to the Gunn-Peterson effect.
- (iv) The optical counterpart may be obscured by dust see the previous section on the radio sub-mm connection.
 - (v) They represent a new population of objects.

The last three possibilities remain to be tested. We can, however, make some comments based on three individual objects.

As noted in Section 7.2, of the thirteen optically faint systems in the 10-arcmin field, only two are classified as AGN or AGN candidates. Six are classified as starbursts or starburst candidates with the remaining five listed as unclassified. Subsequent to the HDF WFPC2 imaging, deep IR studies of two of the starbursts (J123642+621331 and

J123651+621221) have revealed very red objects and are now identified as high-redshift dust-obscured starburst systems. In addition deep K' band imaging with the Suburu 8-m telescope has revealed an extremely red object associated with a weak 16- μ Jy MERLIN+VLA 1.4-GHz radio detection at the position of the brightest SCUBA sub-mm source HDF850.1 (see Section 8.4.1 for a detailed description).

Waddington et al. (1999) detect a very red object at the position of J123642+621331 with NICMOS in J- and H-band and with the KPNO 4-m at K-band. On the basis of a single Ly α emission line at 6595 Å and the observed spectral energy distribution, they infer a redshift of 4.424, and argue that it is a distant starburst disc galaxy with a weak embedded AGN. The radio structure consists of a compact component together with emission extended over 0.4 arcsec and is thus consistent with this interpretation. Garrett et al. (2001) detect the compact component with the EVN at an angular resolution of 20 mas; this may be the steep-spectrum AGN core.

Dickinson (2000) finds a very red NICMOS detection at the position of J123651+621221. The spectral energy distribution implies a dust-shrouded starburst at a redshift close to 2.7 (Alexander et al. 2001). The source is a hard *Chandra* X-ray detection which Hornschemeier et al. (2001) interpret as an obscured QSO. However, the extended steep-spectrum radio structure suggests a dust-obscured starburst system with no evidence for any compact radio core. If there is an obscured QSO in this object which is responsible for the X-ray emission, it is not a significant radio source.

The nature of the remaining optically faint sources remains unclear, but from the radio structures seen in the MERLIN+VLA combination images, it seems likely that those classified as starburst candidates are most likely to be high-redshift dusty systems. These represent the first few detections of a new population of objects. A variety of explanations are possible, for example activity around young black holes at z > 10, perhaps resulting from Population III star clusters. Following Haiman, Dijkstra & Mesinger (2004), such objects could be detectable at a level of tens of μ Jy at a high enough surface density to occur in these observations. Such possibilities underscore the vital role played by high resolution radio observations since they have high astrometric positional accuracy, show the detailed distribution of galactic radio activity, and do not suffer from dust obscuration. However, more sensitive observations, with higher angular resolution, in the IR and sub-millimetre bands are required to understand the true nature of these optically faint radio sources.

10 FUTURE DEVELOPMENTS

Using the same data and with the availability of enhanced computer power, we are extending the statistical study limited to the 3-arcmin field in this paper (see Section 6 and Fig. 5), to encompass the whole of the 10-arcmin field. This will form the basis of a future paper and will contain a statistical analysis of a mapped area over an order of magnitude larger than the 3-arcmin field. Very recently deeper HST ACS images have been released (Giavalisco et al 2004), which we will compare with the radio data. We do not wish to delay the present publication, since the new HST data

require astrometric alignment in order to have confidence in any further identifications of radio sources with faint optical galaxies.

With the development of e-MERLIN and the EVLA significantly more sensitive observations of the HDF and HFF will become feasible within a few years. When these broadband instruments come on line, imaging at 1.4 GHz will be a factor of five times more sensitive than now. Combination imaging with similar integration times to the present study will therefore yield rms noise levels $\sigma_{e-\text{MERLIN}+\text{EVLA}} \sim 0.6$ μ Jy beam⁻¹ in which radio sources like that associated with HDF 850.1, with a flux density of only 16 μ Jy, will be detected at the 20σ level. The slope of the integral source counts below 40 μ Jy implies an increase in the number of radio sources by a factor of six in a sample complete to 8 μJy (equivalent to the 40- μJy selection limit in the present 10-arcmin field). To this limit in the 10-arcmin field, we will be able to image in excess of 500 radio sources. Above 5 μJy (8 σ – equivalent to the 27- μJy limit in the 3-arcmin field) we will image around 1000 radio sources. Furthermore, the radio-optical statistical studies will be extended to radio sources with flux densities less than 1 μ Jv.

Compared with our current capabilities, at 5 GHz the imaging sensitivity will be increased by a factor of $\sim\!\!30$ within the inner 3-arcmin field (constrained by the Lovell telescope primary beam), and by a factor of $\sim\!\!15$ within a 9-arcmin field (constrained by the primary beams of the other antennas). This will result in noise levels of $\sigma_{e-\text{MERLIN}+\text{EVLA}}\sim\!\!0.15~\mu\text{Jy}$ beam $^{-1}$ in the inner region and 0.3 μJy beam $^{-1}$ in the outer combined with an angular resolution of $\sim\!\!50$ mas. Many of the starburst systems resolved for the first time in this work will thus be mapped with very high angular resolution, revealing the detailed areas of starformation for the first time and detecting any embedded AGN compact cores. Together with the 5-GHz astrometric precision of a few mas, detailed cross-waveband comparisons of conditions within each galaxy will thus be possible.

11 SUMMARY AND CONCLUSIONS

11.1 Observational Results

In a 10-arcmin field centred on the HDF, a complete sample of 92 sources with flux densities above 40 μ Jy have been detected with the VLA, and imaged with the MERLIN+VLA combination at resolutions of 0.2, 0.3 and 0.5 arcsec (Table A1). These are amongst the most sensitive 1.4-GHz images yet made, with rms noise levels of 3.3 μ Jy beam⁻¹ in the 0.2-arcsec resolution images. The images also combine high resolution (down to 0.2 arcsec) with high astrometric accuracy (< 50 mas in the HDF) and allow us to probe the association of radio source types with both the optical galaxy population and the sub-mm source population within the HDF and HFF. We note that a comparison of our catalogue with one from WSRT at lower angular resolution suggests that we may be missing ~ 10 per cent of the sources which have low radio surface brightness and angular sizes in the range 5-20 arcsec.

Positions derived from the independent MERLIN and VLA imaging agree to better than 15 mas over the entire 10-arcmin field. Radio sources associated with compact galaxies

have been used to align the WFPC2 and CFHT optical fields to the ICRF (Fig. 3 and Table 1). The optical field has been aligned to better than 50 mas in the Deep Field itself, and to ~ 150 mas in the outer parts of the Flanking Fields. The combined optical and radio images are reproduced in Fig. C1.

11.2 Interpretation

Radio source characteristics:

The available radio spectral and morphological data have enabled us to classify 72 per cent of the sources in the 10-arcmin field as either definite or candidate AGNs (20 per cent), or starburst systems (52 per cent). The radio source sizes are typically $\sim\!\!1$ arcsec (Fig. 4), somewhat smaller than the optical galaxy images. In addition to the imaging of 92 sources found with the VLA alone, the central 3 arcmin, which includes the HDF, has been separately imaged with the MERLIN+VLA combination at the full 3.3 $\mu\rm{Jy}$ beam $^{-1}$ sensitivity to search for sources down to 27 $\mu\rm{Jy}$. Although an additional $\sim\!\!8$ sources are expected to be present from number counts, no additional sources were found that were not previously detected by the VLA, indicating that such sources are heavily resolved with MERLIN and hence must have angular sizes $\gtrsim\!1$ arcsec.

The typical rest-frame luminosity of the AGN and AGN candidate sources is similar to FRI type systems, but is significantly less than that of powerful FRII type radio galaxies and radio-loud quasars. Only two AGN systems show 'classical' double radio structures; the vast majority being small core-jet structures extended on sub-galactic scales. All the starburst and starburst candidate sources are substantially more luminous than the nearby starburst galaxy M82, and about half are more luminous than the powerful ULIRG Arp 220. A number of starburst systems at redshifts in excess of 2 have been identified (Chapman et al. 2004a, 2004c submitted) as sub-mm sources with the aid of these radio data and are several orders of magnitude more luminous than Arp 220.

The proportion of starburst systems is found to increase with decreasing source strength (Fig. 7). At flux densities below 100 μ Jy more than 70 per cent of the μ Jy sources are starburst-type systems associated with major disc galaxies in the redshift range 0.3–1.3. Some 40 per cent of the brighter sources are found to be intermediate luminosity AGN systems identified with galaxies in a similar redshift range.

$Optical\ identifications:$

We find a statistical association of very faint ($\geq 2~\mu \rm{Jy}$) radio sources with optically brighter HDF galaxies down to $\sim 23~\rm mag$ (Fig. 5). Of the 92 sources in the 10-arcmin field above 40 $\mu \rm{Jy}$, around 85 per cent are identified with galaxies brighter than $I=25~\rm mag$. The remaining 15 per cent are associated with optically faint systems close to or beyond the HFF limit (and for some objects, the HDF limit). As discussed in Section 8.3 many of these may be dust-shrouded starburst galaxies at high redshift (z>3). The high astrometric accuracy of the alignment and the ability of radio to see through obscuring dust have proved to be vital in making the correct optical identification of these very faint radio objects. In particular, this has led to the correct identification

of three optically faint, very red systems (J123642+621331, J123651+621221, and SCUBA HDF850.1). This underscores the vital role to be played by radio observations in probing the distant galaxy population.

X-ray identifications:

Over half of the radio sources in the 10-arcmin field are detected in X-rays by *Chandra*, however the X-ray detection rate appears to be uncorrelated with the radio source classification or flux density. This does not support the hypothesis that an X-ray detection is a direct diagnostic of AGN activity unless X-ray and radio emission mechanisms have different origins within the same galaxy. This will be investigated further in a later paper.

$Sub\text{-}mm\ identifications$:

We have combined our aligned radio and optical fields with the latest sub-mm results on the HDF and HFF. Currently radio observations can provide an important indicator of the correct identification of a high redshift galaxy (eg SCUBA HDF850.1, Dunlop et al. 2004). However, even with the aid of these ultra-sensitive radio observations and excellent radio-optical astrometry, reliable identifications of faint sub-mm sources in the HDF and HFF remain elusive. This will remain the case until sub-arcsecond astrometry in this wave-band becomes routinely available with the advent of ALMA.

ACKNOWLEDGEMENTS

This paper has made use of two radio arrays: MERLIN, a UK National Facility operated by the University of Manchester at Jodrell Bank Observatory on behalf of PPARC, and the VLA of the National Radio Astronomy Observatory a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. The optical data are based in part on observations made with the NASA/ESA Hubble Space Telescope, obtained at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555; and in part on observations made with the Canada-France-Hawaii Telescope by Barger et al. (1999). The cross-matching of the radio source list with the ISO (Aussel et al. 1999) and Chandra (Alexander et al. 2003) catalogues and other multi-wavelength comparisons made use of software tools developed by the Astronomical Virtual Observatory (www/euro-vo.org). We thank the anonymous referee for helpful suggestions.

Table A1. Radio Sources in the 10-arcmin Field: Astrometric Characteristics. The MERLIN+VLA peak position is given unless the source is a VLA-only detection (marked V); σ_{pos} is the error in the position in R. A. and Dec. Beam is the FWHM of the circular restoring beam used for the radio images in Fig. C1. 'Optical' refers to the telescope providing the optical image, either C for CFHT (Barger et al. 1999) or H for HST WFPC2 (Williams et al. 1996).

APPENDIX B: SOURCE DETAILS FOR THE 10-ARCMINUTE FIELD

In this section we give a brief description of the properties of each source detected and imaged in the 10-arcmin field. Where known, radio spectral indices are given $(S \propto \nu^{-\alpha})$. For weaker sources close to the edge of the 10-arcmin field, spectral index information is unavailable since they are on the edge of the VLA primary beam response at 8.4 GHz and are thus undetected by Richards et al. (1998). For stronger sources in this region, which still remain undetected at 8.4 GHz, lower limits to the radio spectral index are given. We note other detections and compare the radio and optical morphologies; however we cannot assume that the emission at different wavelengths comes from the same part of the galaxy or the same mechanism unless there is additional evidence for this, including the tight radio-far-IR correlation (see references in Section 8.2). Table A2 gives additional information (such as whether non-detections at other wavelengths are due to the limited fields of view of the relevant instruments). ISO data are taken from Aussel et al. (1999) and Chandra data are taken from Hornschemeier et al. (2001) and Alexander et al. (2003). We have not yet included the latest HST ACS data for reasons noted in Section 10.

J123606+620951 (Unclassified): is undetected at 8.4 GHz and thus has a radio spectrum with $\alpha>0.56$. It has a compact (<0.2 arcsec) component with weak extended emission. The radio source lies outside the CFHT image so no optical frame is shown in Fig. C1. However Cowie et al. (2004) catalogue an R=22.7 mag galaxy at the position of the radio source with a redshift of 0.6379. It is detected by *Chandra*.

J123606+621021 (Starburst Candidate): is separated from J123608+621035 by 17 arcsec but does not appear to be related to it. The radio structure is extended over 0.7 arcsec. It lies outside the area of the CFHT image so no optical frame is shown in Fig. C1. However Chapman et al. (2004b) catalogue an I=23.8 mag sub-mm galaxy ($S_{850}=11.6\pm3.5$ mJy) at the position of the radio source with a redshift of 2.33. There is a faint *Chandra* counterpart.

J123607+621328 (Starburst Candidate): is extended over 1.2 arcsec roughly NS. This source lies outside the CFHT image so no optical frame is shown in Fig. C1. However Cowie et al. (2004) catalogue an R=21.8 mag galaxy at the position of the radio source with a redshift of 0.4353.

J123608+621035 (AGN): has a relatively flat radio spectrum overall (α =0.36). It has a compact core and two-sided radio emission. The compact component lies at the nucleus of a 20.6 mag galaxy with a redshift of 0.681 (Cowie et al. 2004). It is detected by *Chandra*.

J123608+621553 (Starburst Candidate): Richards (2000) states that this source has an inverted radio spectrum ($\alpha=-0.24$). It is extended by approximately 0.5 arcsec. It is identified with a I=21 mag galaxy at the very edge of the CFHT frame with a redshift of 0.4593 (Cowie et al. 2004). No compact AGN core is seen, therefore it is most likely that the radio emission originates in an extended starburst with strong free-free absorption at 1.4 GHz to account for the spectral shape. It is detected by *Chandra*.

 $\bf J123608+621431$ (Starburst Candidate): is extended by ${\sim}1$ arcsec EW and is identified with a 23.7 mag galaxy of the CFHT frame.

J123610+620810 (Unclassified): has a relatively compact component with weak extended emission ~ 0.6 arcsec to the SW at 0.5-arcsec resolution (not shown). No optical information is available since it lies outside the area of the CFHT frame.

J123610+621651 (Unclassified): has extended radio emission (0.9 arcsec) on both sides of a relatively compact component at 0.2-arcsec resolution (not shown), which is coincident with the nuclear region of a I = 23.7 mag galaxy.

J123612+621138/J123612+621140 (Starburst Candidates): are separated by ~ 4 arcsec. J123612+621140 has a steep radio spectrum ($\alpha > 0.89$). J123612+621138 has no spectral index measurement although the radio sources are only partially separated by Richards (2000) who classifies the pair as a single object. Each one appears to be an extended starburst and is identified with a separate galaxy in a system which appears to be interacting. J123612+621138 is identified with an I=18.9 mag galaxy; J123612+621140 is identified with an I=19.4 mag galaxy. Cowie et al. (2004) measure the same redshift for each galaxy (z=0.275). J123612+621138 is detected by Chandra.

J123615+620946 (Starburst Candidate): is extended over ~ 0.8 arcsec and overlies the nuclear region of an I=22.0 mag galaxy with a redshift of 1.263 (Cowie et al. 2004).

J123616+621513 (Starburst Candidate): is extended over \sim 1 arcsec. The weak extended emission \sim 3 arcsec to the NW is only visible at low resolution and has no optical counterpart. It is not thought to be associated with J123616+621513 and falls below the 7σ detection threshold for the 10-arcmin field sample. J123616+621513 is identified with an I=22.9 mag galaxy. Chapman et al. (2004b) identify the system as a sub-mm galaxy (S₈₅₀ = 5.8 \pm 1.1 mJy) with a redshift of 3.61. It is detected by Chandra.

J123617+621011 (Unclassified): is extended over ~ 0.6 arcsec and contains a compact component at 0.2-arcsec resolution (not shown). The nature of the object is unclear since the radio structure could originate from AGN or starburst activity (or both). It is identified with a I=21.6 mag galaxy. Hornschemeier et al. (2001) find a single emission line at 6879.3 Å which they assign as [OII] at a redshift of 0.845. It is detected by *Chandra* with a X-ray luminosity strongly suggestive of AGN activity.

J123617+621540 (Unclassified): has a fairly steep radio spectrum ($\alpha > 0.55$). It contains a compact component with two-sided emission extended over 1.3 arcsec. It is identified with a faint galaxy (I = 23.9 mag) in a complex region on the CFHT frame.

J123618+621635 (AGN Candidate): contains two extended radio components separated by 2.5 arcsec. The radio component to the SE overlies the central region of an I=19.7 mag galaxy and shows no evidence for any compact core. The NW radio component appears to be associated with a second galaxy which may be part of an interacting system. Hornschemeier et al. (2001) find two emission lines from the SE component which they assign to be [OIII] at a redshift of 0.679. It is also detected by *Chandra*. On the basis of the X-ray luminosity and a weak [NeV] feature, Hornschemeier et al. (2001) suggest that this object is an AGN system.

J123618+621550 (Unclassified): exhibits a steep radio spectrum ($\alpha > 0.63$) compact component with one-sided

emission extended over 0.4 arcsec. It is unidentified at the limit of the CFHT frame. Chapman et al. (2004b) identify the system as a possible sub-mm galaxy ($S_{850}=7.3\pm1.1$ mJy) with a redshift of 1.87. However, this identification is uncertain since the measured redshift is for the optical object approximately 0.5 arcsec to the SW of the radio source; this is above the nominal astrometric alignment errors for the position of the radio source in the 10-arcmin field.

J123619+621252 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.8$) and has radio emission extended over 0.4 arcsec. It lies at the nucleus of an I = 19.9 mag galaxy at redshift = 0.473 (Cowie et al. 2004). The optical galaxy appears to have a companion and may be part of a merging system. It is detected by *Chandra*.

J123620+620844 (AGN): has a flat radio spectrum ($\alpha=0.01$) and shows a compact core with a one-sided (0.6 arcsec) extension to the east. The core component overlies the nucleus of an I=21.5 mag galaxy at a redshift of 1.0178 (Cowie et al. 2004).

J123621+621109 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.86$). The VLA-only image (not shown) reveals additional low surface brightness emission extending over 3 arcsec to the north-east. A brighter but still extended component is seen in the combination image and overlies the fainter, south-western member of an I=21.8 mag pair of merging galaxies at a redshift of 1.014 (Cohen et al. 2000). There is a *Chandra* counterpart.

J123621+621708 (Unclassified): has a steep radio spectrum ($\alpha > 0.56$) and contains a compact component with one-sided emission extending to the south-east. An extended radio component lies 2.5 arcsec to the north-west, close to the position of an I=23.4 mag galaxy on the CFHT frame. There is no optical object brighter than I=25 mag at the position of the compact radio component. Chapman et al. (2004b) identify the system as a possible sub-mm galaxy (S₈₅₀ = 7.8 ± 1.9 mJy) with a redshift of 1.99. However, this identification is uncertain since the measured redshift is for the galaxy to the NW of the radio source; this is well above the nominal astrometric alignment errors for the position of the radio source in the 10-arcmin field.

J123622+621544 (AGN Candidate): has a steep radio spectrum ($\alpha > 0.6$). The radio structure is extended and low surface-brightness emission seen in the VLA-only image (not shown) extends for nearly 3 arcsec to the north-west. A brighter region of emission region lies 0.75 arcsec to the south-east of the bright nucleus of an I=19.8 mag spiral galaxy in the HFF at a redshift of 0.6471 (Cowie et al. 2004). As the radio emission extends well beyond the optical galaxy the source is classified as an AGN candidate with an undetected core. There is a faint *Chandra* counterpart.

J123622+621629 (Starburst Candidate): is extended (1.3 arcsec) and is identified with an I=23.8 mag galaxy on the CFHT frame. Chapman et al. (2004b) identify the system as a sub-mm galaxy (S₈₅₀ = 7.7 ± 1.3 mJy) with a redshift of 2.40. There is a faint *Chandra* counterpart

J123622+620945 (Starburst Candidate): is extended over \sim 0.8 arcsec and shows evidence for double structure at position angle 110 degrees. There is no evidence of any compact radio structure at full resolution. The source overlies the nuclear region of an I=21.1 mag galaxy with a redshift of 0.7479 (Cowie et al. 2004).

J123623+621642 (AGN Candidate): has a steep radio spectrum ($\alpha=0.63$) and contains a compact component together with one-sided extended emission. It is identified with an I=23.9 mag galaxy in a complex region on the CFHT frame.

J123624+621017 (Unclassified): consists of two extended components separated by 2.1 arcsec at position angle 30°. Each component is \sim 0.5 arcsec in size and there is no evidence for any compact radio structure at 0.2-arcsec resolution. The source cannot be identified with any optical object brighter than I=25 mag in the HFF frame.

J123624+621743 (Unclassified): shows a compact feature in the 0.2 arcsec image (not shown) with additional emission extending over 0.9 arcsec. It is identified with a I = 22.9 mag galaxy and has a faint *Chandra* counterpart.

J123629+621045 (Unclassified): has a steep radio spectrum with $\alpha > 0.86$ and is extended east-west over 2.7 arcsec with no evidence of compact emission at the highest angular resolution. The eastern end of the radio source is coincident with the nucleus of an I = 22.2 mag galaxy at a redshift of 1.013 on the CFHT frame (Cohen et al. 2000) but the extension is not correlated with optical emission. Chapman et al. (2004b) identify this system as a sub-mm source ($S_{850} = 5.0 \pm 1.3$ mJy). It is detected by *Chandra*.

J123630+620923 (Starburst Candidate): is extended over 0.6 arcsec and overlies the nuclear region of an I=22.5 mag galaxy on the CFHT frame with an estimated photometric redshift of 0.953 (Bauer et al. 2002). It is detected by Chandra

J123630+620851 (Starburst Candidate): is extended over 3.3 arcsec. The extension is more clearly seen in the VLA-only image (not shown) and additional flux is seen with the Westerbork radio telescope indicating possible emission on the 10-arcsec scale. The radio structure roughly follows the optical isophotes of a complex galaxy system that appears to be interacting, the brightest member of which has I=22.6 mag.

J123631+620957 (Unclassified): has a steep radio spectrum ($\alpha > 0.99$) and a compact component with two-sided emission extending over 0.8 arcsec. There is no optical counterpart brighter than I=25 mag on the HFF frame but it has a faint *Chandra* counterpart.

J123632+621658 (Starburst Candidate): is extended over \sim 4 arcsec on the VLA-only image (not shown) and shows no sign of compact emission at higher resolution. The source is very heavily resolved with MERLIN and the position in Table A1 is taken from the VLA-only image at 2-arcsec resolution. The source is associated with an I=18.2 mag spiral galaxy with a redshift of 0.437 (Cowie et al. 2004).

J123632+620759 (Unclassified): has a steep radio spectrum ($\alpha > 0.58$) and is extended over some 2.6 arcsec on the VLA-only image (not shown). At higher resolution a compact component is found with two-sided extended emission, although the majority of the extended emission seen in the VLA-only image is resolved out. The radio source lies outside the CFHT frame so no optical image is shown in Fig. C1. However Cowie et al. (2004) catalogue an R = 24.0 mag galaxy at the position of the radio source with a redshift of 1.9939. It is detected by *Chandra*.

J123633+621005 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.98$) and is extended over approximately 1.2 arcsec. There is no evidence for any compact

emission at the highest angular resolution. It overlies a faceon I = 21.6 mag spiral galaxy at a redshift of 1.016 (Cowie et al. 2004) on the HFF frame. It is detected by *Chandra*.

J123634+621213 (Starburst): has a steep radio spectrum ($\alpha=0.74$). The extended radio emission is two-sided, surrounding a compact component. However EVN observations at 20 mas resolution do not detect this compact component (Garrett et al. 2001). The source is identified with a bright disc galaxy ($I=18.7~{\rm mag}$), at a redshift of 0.456 (Cowie et al. 2004). The HFF optical image shows evidence for a dust-lane or possible double nucleus which may indicate a recent merger. The brightest radio emission lies between the optical nuclei and the extensions follow the optical isophotal ridge-line. The galaxy is also detected by ISO with $S_{15\mu m}=448~\mu Jy$. X-ray emission is detected by Chandra.

J123634+621241 (Starburst): has a steep radio spectrum ($\alpha=0.74$). There is extended emission to the southwest of a compact component which is not detected by the EVN at 20 mas resolution (Garrett et al. 2001). The compact component overlies the nuclear region of an I=22.3 mag Scd galaxy at a redshift of 1.219 on the HFF WFPC2 frame (Cohen et al. 2000). It has an mid-IR flux density $S_{15\mu m}=363~\mu {\rm Jy}$ as detected by ISO, which implies a substantial star-formation rate. This source is the most likely radio counterpart to SCUBA HDF850.7 (see Section 8.4.1). There is a faint Chandra counterpart.

J123635+621424 (Starburst + AGN?): has a steep radio spectrum ($\alpha > 0.87$). It appears relatively compact, with an angular size of only <0.3 arcsec, in contrast to the earlier angular size estimate of 2.8 arcsec reported by Richards et al. (1998). The radio source overlies the bright optical nucleus of a face-on I = 22.6 mag spiral galaxy on the HFF frame. The spatial extent of the galaxy suggests that it is of low to moderate redshift. However, Bauer et al. (2002) list this object as having a spectroscopic redshift close to 2 and Dawson et al. (2002) assign a redshift of 2.011 from several detected emission lines. It is an ISO detection and Chapman et al. (2004b) identify the system as a submm galaxy ($S_{850} = 5.5 \pm 1.4$ mJy) at a a redshift of 2.01. It is detected by *Chandra*. Dawson et al. (2002) argue that the 15 μ m and X-ray detections are indicative of an AGN system. If this object is a compact nuclear starburst system, the implied star-formation rate from the radio and IR flux densities is very large ($\sim 1800 \text{ M}_{\odot} \text{ yr}^{-1}$).

J123636+621320 (Starburst Candidate): is extended over approximately 0.7 arcsec and shows no sign of compact emission. There is no optical counterpart brighter than I=25 mag at the radio source position on the HFF frame. There is a faint *Chandra* counterpart.

J123637+620852 (Starburst Candidate): has a steep radio spectrum ($\alpha>0.82$), is extended east-west over approximately 1.1 arcsec and shows no sign of a compact component. It is identified with an I=24.5 mag galaxy in a complex region on the CFHT frame.

J123640+621009 (AGN Candidate): consists of two components separated by 1.2 arcsec. The source as a whole has a radio spectrum of $\alpha=0.44$, which suggests the presence of a flat-spectrum component. The 8.4-GHz position (Richards et al. 1998) is close to the northerly component indicating that it has a flat spectrum and therefore may be associated with an AGN. Although no evidence for a compact feature can be found at 1.4 GHz, the radio image has

a low signal-to-noise ratio. The more northerly component overlies a faint compact $I=23.9~\mathrm{mag}$ galaxy on the HFF frame.

J123641+620948 (Unclassified): has a steep radio spectrum ($\alpha>0.56$) and contains a compact radio component with some extended emission with a total angular extent of approximately 0.6 arcsec. The compact component coincides with the nucleus of an I=20.2 mag disc galaxy at a redshift of 0.518 which may be part of a merging system (Cohen et al. 2000). The extended radio emission lies perpendicular to the major axis of the optical galaxy. There is a faint *Chandra* counterpart.

J123642+621331 (Starburst + AGN?): has a steep radio spectrum ($\alpha=0.94$). The radio structure consists of a compact component together with emission extended over 0.4 arcsec. Garrett et al. (2001) detect the dominant compact component with the EVN at an angular resolution of 20 mas; it may therefore be a steep-spectrum AGN core. There is no optical counterpart at the detection threshold in the HFF *I*-band image. Waddington et al. (1999) detect a very red object at the radio source position with NICMOS, in J and H-band, and with the KPNO 4-m in *K*-band. On the basis of a single Ly α emission line and the observed spectral energy distribution, they ascribe a redshift of 4.424 and argue that it is a distant starburst galaxy with a weak embedded AGN. This interpretation is consistent with the radio morphology. The source is detected by both *ISO* and *Chandra*.

J123642+621545 (Unclassified): has an intermediate radio spectrum ($\alpha=0.50$). The radio structure consists of a compact component and extended emission to the NE and SW with the latter reaching nearly 1.5 arcseconds from the core. The core component overlies the nucleus of an I=20.7 mag galaxy on the CFHT frame at a redshift of 0.857 (Hornschemeier et al. 2001). The source is detected by both ISO and Chandra; the compact component could be an AGN, but the nature of this object remains unclear.

J123644+621133 (AGN – FRI radio galaxy): has a bright core with a flat radio spectrum ($\alpha=0.1$, Richards et al. 1998) with steep spectrum emission oriented N–S and extending for about 15 arcsec in the VLA-only image (not shown). Overall the radio source exhibits a classical FRI structure. It is optically identified with an I=20.9 mag elliptical galaxy at a redshift of 1.050 (Cohen et al. 2000). This source is not catalogued by Aussel et al. (1999) but Goldschmidt et al. (1997) list a nearby ISO detection at 6.7 μ m only; Mann et al. (1997) identify this with the host of J123644+621133. There is a faint Chandra counterpart.

J123645+620754 (Unclassified): lies close to the edge of the 10-arcmin field. The source is extended east-west over some 3 arcsec, and there is no evidence for any compact emission. The position given in Table A1 is from the VLA-only image at 2-arcsec resolution. The radio source lies outside the CFHT frame so no optical image is shown in Fig. C1. However Cowie et al. (2004) catalogue an R=23.0 mag galaxy at the position of the radio source with a redshift of 1.433. There is a faint *Chandra* counterpart.

J123646+621448 (Unclassified): has a steep radio spectrum, ($\alpha > 0.84$) and contains a compact component with a one-sided 0.5 arcsec extension at a position angle of ≈ 160 degrees. It is not identified on the HFF frame to approximately I = 25 mag. However, on the lower resolution

CFHT frame it overlies a faint but distinct galaxy (I=25.5 mag). Chapman et al. (2004b) identify this system as a submm source ($S_{850}=10.3\pm2.2$ mJy). There is a faint *Chandra* counterpart.

J123646+621629 (Starburst Candidate): has a very steep radio spectrum ($\alpha > 1.62$). The radio structure consists of a compact central feature together with extended emission distributed symmetrically around it with a total angular extent of about 2.4 arcsec. The radio core is coincident with the nuclear region of an I=19.8 mag galaxy at a redshift of 0.502 (Cohen et al. 2000).

J123646+621404 (AGN): has an inverted radio spectrum (α =-0.04). The radio structure has a compact component and two-sided extended emission. The radio emission overlies the nucleus of a nearly face-on disc galaxy (I=20.7 mag) at a redshift of 0.961 (Cowie et al. 2004), which exhibits a broad emission line spectrum (Phillips et al. 1997). These observations combine to form strong evidence that this galaxy contains an AGN. This radio source was detected by ISO with $S_{7\mu m}=52~\mu Jy$ and it has a bright Chandra counterpart. Although Rowan-Robinson et al. (1997) interpret this source as a massive starburst, star-formation seems unlikely to be powering the bulk of the radio emission in this object.

J123646+620833 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.61$). The radio structure is extended over 0.8 arcsec and shows no sign of compact emission at 0.2-arcsec resolution. The radio emission overlies the nuclear region of an I=20.6 mag galaxy at a redshift of 0.9712 (Cowie et al. 2004). There is a faint *Chandra* counterpart.

J123646+621226 (Unclassified): has a steep radio spectrum ($\alpha > 1.14$) and is completely resolved-out at 0.2-arcsec resolution. The VLA-only image (as shown in Fig. C2) shows the source to be 3.2 arcsec in extent. No optical counterpart brighter than I=28 mag is found at the radio position. Deep near-infrared observations (Thompson et al. 1999) place magnitude limits of $I_{\rm AB} > 28.5$, $J_{110} > 29$, and $H_{160} > 29$ mag.

J123646+621445 (Unclassified): has a steep radio spectrum ($\alpha=0.98$) and is extended over 2.3 arcsec with the major axis roughly aligned with J123646+621448 which lies 6 arcsec to the north west. However, J123646+621445 overlies a fairly compact faint (I \sim 23.9 mag) galaxy. Since both sources overlie separate optical identifications, it is most likely that they are unrelated. The I=20.4 mag galaxy 2.5 arcsec to the NE of J123646+621445 has a measured redshift of 0.558 (Cohen et al. 2000), but does not seem to be related to the radio source. The ISO source at 4 arcsec separation in a similar direction cannot therefore be identified with the radio source with any confidence.

J123649+621313 (Starburst): has a steep radio spectrum ($\alpha=0.72$) with no evidence of any compact structure at 0.2-arcsec resolution. It is extended by approximately 1 arcsec along the major axis of an I=21.1 mag disc galaxy at a redshift of 0.475 (Cohen et al. 2000). The galaxy is in the ISO catalog of HDF sources with $S_{15\mu m}=320~\mu Jy$ and may be associated with SCUBA HDF850.4 (see Section 8.4.3). There is a faint Chandra counterpart. Low level radio emission below the formal detection threshold (and hence not in the catalogue) may also be seen from an I=22.7 mag disc galaxy located about 3 arcsec to the north which lies at a redshift of 1.238 (Cohen et al. 2000).

J123650+620801 (Starburst Candidate): is extended by approximately 0.7 arcsec and shows no sign of compact structure at 0.2-arcsec resolution. The radio source lies outside the CFHT image so no optical frame is shown in Fig. C1. However Cowie et al. (2004) catalogue an R=22.2 mag galaxy at the position of the radio source with a redshift of 0.559.

J123650+620844 (Starburst Candidate): has a steep spectrum ($\alpha > 0.80$). The radio structure shows a compact component together with extended emission of approximately 0.8 arcsec extent. The compact component overlies the nucleus of an I = 20.0 mag galaxy at a redshift of 0.434 (Cowie et al. 2004).

J123651+621030 (Starburst): has a steep-spectrum ($\alpha=0.74$). The radio source is extended over 1.2 arcsec and overlies the nuclear region of an I=19.9 mag disc galaxy at a redshift of 0.410 (Cohen et al. 2000). It is detected by ISO with $S_{15\mu m}=341~\mu Jy$. There is a faint Chandra counterpart.

J123651+621221 (Starburst + AGN?): has a steep spectrum ($\alpha > 0.71$). The MERLIN+VLA image shows a source extended over ~ 1.2 arcsec with no evidence for any compact component. Garrett et al. (2001) also find no evidence for any compact component with the EVN at an angular resolution of 20 mas. The radio structure thus favours a starburst rather than an AGN interpretation. The radio source is identified with very faint emission (I>28 mag) on the HDF frame. Dickinson et al. (2000) and Dickinson (2000) report a very red object $(I_{AB} = 27.8 \text{ mag}, J_{110} - H_{160} = 1.6)$ at the position of this source from NICMOS observations, implying a dust-obscured starburst system at a redshift approaching 3. The source is detected by ISO with $S_{15\mu m}=48$ μ Jy. Hornschemeier et al. (2001) find a hard X-ray detection with Chandra suggesting an obscured QSO at a redshift of 2.7.

The bright (I=21 mag) galaxy lying 1.5 arcsec to the south is at a redshift of 0.401 (Cohen et al. 2000), and is not thought to be related to the radio source.

J123652+621444 (AGN): has an inverted spectrum ($\alpha=-0.12$) (Richards et al. 1998) and is observed to vary in intensity on the time scale of months, suggesting the presence of an AGN (Richards 2000). The radio structure shows a compact core and one sided jet-like feature to the east ~ 1.3 arcsec in length. The low resolution WSRT image of this source (Garrett et al. 2000) shows evidence for low surface-brightness emission extending over ~ 30 arcsec to the east. If this is an extension to the core-jet structure seen in the high resolution MERLIN+VLA image, the jet has an overall extent of ~ 100 kpc. The core overlies the nucleus of an I=18.5 mag elliptical galaxy on the HDF frame at a redshift of 0.321 (Cowie et al. 2004). It is detected by *Chandra*.

J123653+621139 (Starburst): has a steep spectrum ($\alpha > 0.77$). The radio structure shows a compact component with a slight (~ 0.3 -arcsec) extension to the east. The compact component overlies the nucleus of an I=21.9 mag compact galaxy at a redshift of 1.275 (Cohen et al. 2000). It is also detected by ISO at 15 μ m with a flux density of 180 μ Jy. There is a faint Chandra counterpart.

J123654+621040 (Starburst Candidate): has a steep spectrum ($\alpha > 1.0$) and is extended over approximately 1.5 arcsec; it shows no signs of compact emission at 0.2-arcsec resolution. The source lies close to the edge of the

HFF frame but there is no optical identification at the radio source position brighter than I=25 mag.

J123655+620917 (Unclassified): has a radio spectrum with $\alpha > 0.55$. The source contains a compact component associated with the galaxy nucleus and emission extending over 0.6 arcsec. The compact component overlies the nucleus of an I = 20.4 mag galaxy at a redshift of 0.419 (Cowie et al. 2004)

 ${\bf J123655+620808}$ (Unclassified): has a steep radio spectrum ($\alpha>0.85$) and shows a compact component with emission extending over 0.7 arcsec. The radio source lies outside the CFHT image so no optical frame is shown in Fig. C1. However Cowie et al. (2004) catalogue an R=22.6 mag galaxy at the position of the radio source with a redshift of 0.792. There is a faint *Chandra* counterpart.

J123656+621207 (Starburst Candidate): has a steep spectrum ($\alpha>1.32$), is extended over ~ 1 arcsec and shows no sign of any compact emission at 0.2-arcsec resolution. It lies close to the edge of an HDF frame and at the radio position there is no optical object brighter than I=28 mag. Richards et al. (1999) report that NICMOS imaging shows no counterpart to the limits J>25 and H>25; Barger et al. (1999) find no counterpart at K>24. The radio source is located ~ 3 arcsec from the second brightest SCUBA source, HDF850.2 (Hughes et al. 1998), but the association is uncertain – see the detailed discussion in Section 8.4.2.

J123656+621301 (Starburst): has a steep radio spectrum ($\alpha > 1.22$), is extended over 1.2 arcsec and is identified with an I = 22.5 mag compact galaxy at a redshift of 0.474 (Bauer et al. 2002). It has an ISO counterpart and is detected by Chandra. The bright companion galaxy to the SE has a redshift of 0.475 (Cohen et al. 2000).

J123659+621449 (Starburst Candidate): is extended over 1.0 arcsec and shows no sign of compact emission at 0.2-arcsec resolution. The radio structure overlies a disturbed I=20.9 mag disc galaxy at a redshift of 0.761 (Cowie et al. 2004). The galaxy appears to show a dust-lane or double nucleus and may be undergoing a merger. The source is detected by ISO and has a faint Chandra counterpart.

J123700+620909 (AGN Candidate): has a steep radio spectrum ($\alpha=0.89$). There is a compact component with one-sided emission to the NE; the total angular size of the source being ~ 0.4 arcsec. The radio emission There is no optical counterpart at the radio position to the limit of I=25 mag in the CFHT frame.

J123701+621146 (Starburst): has a steep radio spectrum ($\alpha=0.67$) and is extended over 3 arcsec in the VLA-only image at 2-arcsec resolution (not shown). At 0.5-arcsec resolution some of the outer low surface brightness emission is resolved out, but the central 1.5 arcsec of emission is well imaged and shows no sign of any compact component. There is no optical detection at the radio position on the HFF frame brighter than I=25 mag. The source is detected by ISO. J123701+621146 is the most likely radio counterpart to SCUBA 850.6 (see Section 8.4.5). There is a faint Chandra counterpart.

J123702+621401 (Unclassified): has a steep radio spectrum ($\alpha > 0.79$) and is extended over 3.4 arcsec in the VLA-only image (not shown). At 0.5-arcsec resolution the source shows no sign of any compact component and some of the low surface brightness emission is resolved out. The SE end of the source overlies an I = 21.9 mag galaxy at a

redshift of 1.2463 (Cowie et al. 2004), with a significant fraction of the extended emission lying well outside the confines of the optical galaxy; the latter precludes a straightforward classification as a starburst candidate. It is detected by *ISO*.

J123704+620755 (Starburst Candidate): is extended over 1 arcsec and shows no sign of any compact component. It is outside the CFHT frame but it is detected by *Chandra*.

J123705+621153 (Starburst): has a steep spectrum $(\alpha > 1.27)$ and is extended over 1.5 arcsec with no evidence for any compact component at 0.2-arcsec resolution. The source is centred on the nuclear region of an I=20.6 mag face-on spiral galaxy at a redshift of 0.902 (Cowie et al. 2004). The source is detected by ISO and has a faint Chandra counterpart.

J123707+621408 (Starburst Candidate): has a relatively flat radio spectrum ($\alpha=0.29$). The source is extended over 0.9 arcsec and there is no evidence for any compact component. The radio morphology favours a starburst classification and the relatively flat spectrum may be attributed to low-frequency free-free absorption. There is no obvious optical identification on the HFF frame although there does appear to be a faint I=24.9 mag galaxy at the radio position on the CFHT frame. Chapman et al. (2004b) identify the system as a sub-mm galaxy (S₈₅₀ = 4.7 ± 1.5 mJy) with a redshift of 2.48. It is detected by Chandra.

J123707+621121 (Starburst Candidate): has a steep radio spectrum ($\alpha>0.82$). It is extended over 0.6 arcsec and there is no evidence for any compact component. There is a faint I=25 mag object at the radio source position on the CFHT frame.

J123708+621056 (Starburst Candidate): has a relatively flat radio spectrum ($\alpha=0.35$) but there is no evidence for any compact radio component at 0.2-arcsec resolution. The radio spectrum may therefore be due to substantial free-free absorption at 1.4 GHz. The source is extended over 0.7 arcsec and is displaced by \sim 0.5 arcsec from the central region of an I=19.8 mag edge-on disc galaxy at a redshift of 0.422 (Cowie et al. 2004). This separation is probably real since the registration errors, even towards the edge of the HFF, are substantially lower than 0.5 arcsec. There is a faint *Chandra* counterpart.

J123709 + 620837/J123709 + 620841(AGN and AGN Candidate): are separated by 4.5 arcsec. J123709+620837 has a flat radio spectrum ($\alpha = -0.35$). J123709+620841 is undetected at 8.4 GHz implying a steeper radio spectrum, although it is difficult to separate these sources in the 8.4-GHz image where the angular resolution is comparable with the source separation. They both have compact cores and faint extended emission. The compact component dominates the radio emission in J123709+620837, which is unambiguously identified as an AGN system with a compact flat-spectrum core. J123709+620841 may also be an AGN system, though this is less clear. Each radio source is identified with a separate galaxy (I = 20.4 and 21.4 mag with redshifts of 0.907 and 0.902 respectively (Cowie et al. 2004); in each case the compact radio component overlies the nucleus of the galaxy. Both sources have Chandra counterparts, J123709+620837 has the brighter X-ray emission.

J123711+621330 (AGN Candidate): has a steep radio spectrum ($\alpha=0.69$). The source contains a compact radio component with one-sided jet-like emission extending

 ~ 1.2 arcsec to the east. The compact component is coincident with the brightest part of an I=22.7 mag galaxy. The optical galaxy is asymmetric in the same sense as the radio structure. Bauer et al. (2002) estimate a photometric redshift of 1.112 for this galaxy. The classification as an AGN candidate is based on the registration of the compact component with the bright optical nucleus together with the asymmetry of the radio structure. The associated X-ray emission detected by Chandra is significantly offset by 0.9 arcsec to the east of the radio peak.

J123711+621325 (Starburst Candidate): has a steep radio spectrum ($\alpha > 1.16$) and extends over 0.8 arcsec and shows no sign of compact emission at 0.2-arcsec resolution. The source is identified with an I=25 mag galaxy on the CFHT frame. Chapman et al. (2004b) identify the system as a sub-mm galaxy (S₈₅₀ = 4.2 ± 1.3 mJy) with a redshift of 1.99. There is a faint *Chandra* counterpart.

J123713+621603 (Starburst Candidate): is extended over 0.9 arcsec with no evidence for any compact radio component at 0.2-arcsec resolution. It is identified with an I=22.8 mag galaxy on the CFHT frame; the source overlies the nuclear region.

J123714+621558 (Starburst Candidate): is extended over 1.5 arcsec with no sign of any compact component at 0.2-arcsec resolution. The source is identified with an I=20.8 mag galaxy on the CFHT frame at a redshift of 0.567 (Cohen et al. 2000).

J123714+620823 (AGN): has an inverted radio spectrum ($\alpha=-0.15$) and the radio structure is almost unresolved. The image shown in Fig. C1 and described in Tables A1 and A2 is from the MERLIN data only. It is identified with the nucleus of an I=22.0 mag galaxy on the CFHT frame.

J123716+621512 (AGN Candidate): has a relatively flat radio spectrum ($\alpha=0.41$). The source consists of a compact component and one-sided emission extending ~ 0.4 arcsec to the south-west. The source overlies the nucleus of an I=19.8 mag galaxy on the CFHT frame with a redshift of 0.230 (Cowie et al. 2004). There is a faint *Chandra* counterpart.

J123716+621643 (Starburst Candidate): is extended over 0.9 arcsec. The radio emission overlies what appears to be a pair of merging galaxies on the CFHT frame. The radio emission is offset from the brighter galaxy by ~ 1 arcsec. This is real since the registration errors in this region are <250 mas. The brighter galaxy has I=21.6 mag and a redshift of 0.557 (Cohen et al. 2000). There is a faint *Chandra* counterpart.

J123716+621733 (AGN Candidate): has a steep radio spectrum ($\alpha > 0.76$). The radio structure contains a compact component with a ~ 0.6 arcsec one-sided extension to the S-W. The compact component overlies the nucleus of an I=22.2 mag galaxy with a redshift of 1.146 (Cowie et al. 2004). It is detected by *Chandra*.

J123716+621007 (Starburst Candidate): has emission extending over ~ 0.7 arcsec. It overlies the nucleus of an I=19.9 mag galaxy at a redshift of 0.411 (Cohen et al. 2000). There is a faint *Chandra* counterpart.

J123717+620827 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.77$). The radio structure is extended N-S over 2.1 arcsec. At 0.5-arcsec resolution some of the low surface brightness emission is resolved out and there is no

evidence for any compact component. The brightest part of the radio structure overlies the nuclear region of an I=19.7 mag galaxy on the CFHT frame.

J123719+620902 (Starburst Candidate): is extended over ~ 0.7 arcsec and overlies the nuclear region of an I=22.1 mag galaxy on the CFHT frame. This source is not listed in Richards (2000).

J123721+621129 (AGN): has an inverted spectrum $(\alpha=-0.28)$ with a dominant compact radio component and one-sided emission extending ~0.8 arcsec to the north. This source is thus almost certainly an AGN system. There is no optical identification at the radio source position brighter than I=25 mag. There is a distorted disc galaxy to the NE with an estimated photometric redshift of 2.468 (Bauer et al. 2002), but the radio-optical offset of over 1 arcsec is far too high to be accounted for by astrometric errors. Richards et al. (1999) report that from deep I and K band imaging (Barger et al. 1999), this radio source is associated with a very red object with (I-K>5.2). There is a faint Chandra counterpart.

J123721+621346 (Starburst Candidate): has a steep radio spectrum ($\alpha > 0.66$). The radio structure is extended over 0.7 arcsec and shows no evidence for any compact component at 0.2-arcsec resolution. The source is identified with an I = 22.1 mag galaxy at a redshift of 1.019 (Cohen et al. 2000).

J123725+620856 (Unclassified): is extended over ~ 0.4 arcsec. It overlies the nuclear region of an asymmetrical I=22.1 mag galaxy, with an estimated photometric redshift of 0.984 (Bauer et al. 2002). It is detected by *Chandra*

J123725+621005 (Unclassified): is extended over \sim 3.8 arcsec aligned roughly E-W. There is no evidence for any compact component and at 0.2–0.5-arcsec angular resolution some of the low surface brightness emission has been resolved out. The position given in Table A1 is from the VLA-only image (not shown). The radio source overlies the nuclear region of an I=19.1 mag galaxy with an estimated photometric redshift of 0.360 (Bauer et al. 2002).

J123725+621128 (AGN – WAT radio galaxy): has a steep radio spectrum ($\alpha=1.35$). The radio lobes extend over ~ 3.8 arcsec and are oriented E-W. These lobes are characteristic of a classical wide-angled tail (WAT) radio structure. The compact radio core overlies the nucleus of a compact, I=22.9 mag galaxy and

J123730+621258 (Unclassified): has a steep spectrum $(\alpha > 0.79)$ and contains a compact radio component with extended emission over ~ 0.3 arcsec. The object lies outside the area of the CFHT frame.

J123732+621012 (Unclassified): is extended over $\sim\!\!1.9$ arcsec and contains no compact component. The object lies outside the area of the CFHT frame. The position given in Table A1 is from the VLA-only image (not shown).

J123734+620931 (Unclassified): is extended over \sim 2.8 arcsec and contains no compact component. The object lies outside the area of the CFHT frame. The position given in Table A1 is from the VLA-only image (not shown). There is a faint *Chandra* counterpart.

Figure C1. The radio structures of the sources in the 10-arcmin field. The radio images are shown contoured and overlaid on the astrometrically aligned optical fields which are displayed in false colour (CI = -1, 1, 2, 3, 4,.... $10 \times 10 \mu$ Jy beam⁻¹). All coordinates are in J2000 and the leading $12^{\rm h}$ and $+62^{\circ}$ have been omitted from the Right Ascension and Declination scales respectively. Where no optical field is shown, the region lies outside either the CFHT (Barger et al. 1999), or *HST* WFPC2 images (Williams et al. 1996). The angular resolution of the radio image (in arcsec) is indicated in Table A1 and in the figure together with a hatched beam area. The origin of the optical field shown for each source are given in Table A1.

Figure C2. The radio emission associated with the SCUBA 850 μ m sub-mm sources in the HDF. The combined MER-LIN+VLA radio images at the position of each SCUBA sub-mm source in the HDF and HFF (Serjeant et al. 2000) are shown contoured and overlaid on the astrometrically aligned optical field displayed in false colour (CI = 1, 1.5, 2, 2.5, 3, 3.5, 4 × 8.5 μ Jy beam⁻¹). All coordinates are in J2000 and the leading 12^h and +62° have been omitted from the Right Ascension and Declination scales respectively. The 3 σ SCUBA positional error circle is marked. For HDF850.1, 850.4, 850.5, 850.7, and 850.8 the optical field shown is from the HST WFPC2 (Williams et al. 1996). For HDF850.2 the optical field is from the lower angular resolution CFHT (Barger et al. 1999). For HDF850.6 the central pane is from the HST and the right centre pane is from the CFHT. Borys et al. (2003) list HDF850.4 and HDF850.5 as a single blended source SMMJ123650+621318. The 1 σ positional error circle for this is marked in blue over HDF850.4.

APPENDIX C: IMAGES OF RADIO AND SUB-MM SOURCES OVER OPTICAL FIELDS
