## Abstract

X-ray absorption spectroscopy (XAS) on the O 1s threshold was applied to Bi-based, single crystalline high temperature superconductors (HT<sub>c</sub>'s), whose hole densities in the CuO<sub>2</sub> planes was varied by different methods. XAS gives the intensity of the so-called pre-peak of the O 1s line due to the unoccupied part of the Zhang-Rice (ZR) singlet state. The effects of variation of the number  $n$  of CuO<sub>2</sub> - planes per unit cell ( $n = 1,2,3$ ) and the effect of La-substitution for Sr for the  $n = 1$  and  $n = 2$  phase were studied systematically. Furthermore the symmetry of the states could be probed by the polarization of the impinging radiation.

In the cuprates the electronic states near the Fermi energy  $E_F$ , which are involved in the low lying excitations leading to superconductivity, are mainly due to holes in the  $\text{CuO}_2$  planes. Over the last years, soft x-ray-absorption spectroscopy (XAS) has been utilized to obtain information about unoccupied states at both the O and Cu sites. In particular, polarization-dependent x-ray absorption measurements provided detailed information of their symmetry and orbital character [1]. Most of the previous doping and angular dependent XAS-studies were done on the p-type compounds  $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$  [2],  $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$  [3] and  $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$  [4]. Here we report the current status of our investigations on the electronic structure of the bismuth-based cuprates by x-ray absorption spectroscopy. The aim of the investigations is twofold: First, the Bi-system with varying number of  $\text{CuO}_2$  planes offers the opportunity to study 3D coupling effects. Even though the electronic structure in all these compounds is highly two-dimensional, there is an enormous difference in the transition temperature depending on the number of  $\text{CuO}_2$  layers. Second, we are interested in the influences of doping on the number of holes and the electronic structure of the Bi-based cuprates. Unlike to other studies where the hole density was varied by the oxygen stoichiometry or by replacing the Ca atoms in between the  $\text{CuO}_2$  planes, we obtained the doping by replacing trivalent Sr by divalent La, i.e. leaving Ca in between the  $\text{CuO}_2$  planes unchanged. The single crystals were grown out of the stoichiometric melt. The details of the growth of the crystals and characterization will be described elsewhere [5]. We prepared several series: Optimal doped crystals of the BSCCO-family with one to three  $\text{CuO}_2$  planes per unit cell with  $T_C$  of 29 K, 90 K, 110 K, resp., (see [6,7]) and doped single crystals of  $n = 1$  and  $n = 2$  where part of the  $\text{Sr}^{2+}$  is replaced by  $\text{La}^{3+}$ . The x-ray absorption measurements have been carried out in the fluorescence mode at the VLS-PGM beamline at BESSY. The overall energy resolution at the O 1s absorption edge was 0.3 eV; the sample temperature was 300 K. The fluorescence light was detected at an angle of  $0^\circ$  ( $E||a$ ) and  $85^\circ$  ( $E||c$ ) with respect to the photon beam using a Ge detector. The vacuum in the chamber was better than  $10^{-9}$  mbar during the measurements.

**Fig. 1** O 1s prepeak of  $\text{Bi}_2\text{Sr}_{2-x}\text{La}_x\text{CuO}_{6+\delta}$  at optimal doping ( $x = 0.38$ ) compared to Bi-2212 and Bi-2223 for two polarization geometries. The spectra are normalized at 600 eV photon energy. Left panel: polarization in the  $\text{CuO}_2$  plane, right panel: polarization perpendicular to the  $\text{CuO}_2$  plane.

In Fig. 1 the O 1s absorption spectrum of optimally doped  $n = 1-3$  phase [8] is shown for two polarization geometries. For  $\mathbf{E}||\mathbf{a}$  (normal incidence) the electrical field vector of the synchrotron radiation lies within the sample plane aligned parallel to the crystallographic  $a$  axis and for  $\mathbf{E}||\mathbf{c}$  (grazing incidence)  $\mathbf{E}$  is about 85% parallel to the surface normal. A single pre-peak at 528.7 eV can be seen in the normal incidence spectra of all three systems, corresponding to O 1s  $\rightarrow$  O 2p transitions. Neglecting excitonic effects, one can conclude that oxygen-derived 2p final states are located at the Fermi level. They have the well-known  $x,y$ -symmetry due to the polarization dependence shown in Fig. 1 and have been viewed as empty states in a heavily p-doped O 2p-like valence band [1-4]. The main onset in the absorption at 530 eV photon energy corresponds to antibonding O 2p states. The intensities of the pre-peaks increase within experimental uncertainty linearly with  $n$ , the number of Cu-O layers per unit cell. Thus it is found that  $T_C$  is not proportional to the height or intensity of the pre-peak since the  $T_{C,\max}$  of the phases is 29 K, 91 K, 108 K for  $n = 1, 2$ , and 3, respectively. Furthermore it is interesting to note that the  $n = 3$ -phase has a stronger contribution perpendicular to the  $\text{CuO}_2$  planes.

**Fig. 2** X-ray absorption spectra (XAS) of the O 1s prepeak of  $n = 2$   $\text{Bi}_2\text{Sr}_{2-x}\text{La}_x\text{CaCu}_2\text{O}_{8+\delta}$  (left panel) for various doping levels ( $x = 0.03, 0.12, 0.34, 0.46$ ) and XAS spectra of  $n = 1$   $\text{Bi}_2\text{Sr}_{2-x}\text{La}_x\text{CuO}_{6+\delta}$  (right panel) for various doping levels ( $x = 0.38, 0.45, 0.60, 0.72$ ). The  $T_C$  of the  $n = 2$  samples scales from 90 K ( $x = 0.03$ ) down to 6 K ( $x = 0.43$ ). The  $T_C$  of the  $n = 1$  samples scales from 29 K ( $x = 0.38$ ) to 5 K ( $x = 0.72$ ). The spectra are taken for  $\mathbf{E}||\mathbf{a}$  and normalized at 600 eV photon energy.

In Fig. 2 we present first results of a La doped  $n = 2$  system  $\text{Bi}_2\text{Sr}_{2-x}\text{La}_x\text{CaCu}_2\text{O}_{8+\delta}$  (left panel) and La doped  $n=1$   $\text{Bi}_2\text{Sr}_{2-x}\text{La}_x\text{CuO}_{6+\delta}$  system (right panel). For  $n = 2$  the intensity of the pre-peak is highest for very low La doping ( $x = 0.03$ ,  $T_C = 90$  K). With increasing La content both, the height of the pre-peak and the transition temperature decrease. In the case of  $n=1$  lanthanum-free samples ( $x = 0$ ) are found to be strongly hole overdoped, with a  $T_C$  of about 7 K. In order to reach optimal  $T_C$ , part of the  $\text{Sr}^{2+}$  must be replaced by  $\text{La}^{3+}$  which reduces the hole concentration in the  $\text{CuO}_2$  plane. Fig 2 (right panel) shows the evolution of the pre-peak when going from optimally ( $x = 0.38$ ) to the hole-underdoped compound ( $x = 0.72$ ). These experimental findings principally confirm the established view that the intensity of the pre-peak should dependent on the density of

doped holes in the  $\text{CuO}_2$  planes [1]. Nevertheless, the behaviour of overdoped Bi-2201 is much more intriguing and will be studied in a forthcoming publication [9].

In summary, we found the intensity of the XAS pre-peak to scale with the number of  $\text{CuO}_2$  layers per unit cell of the Bi-based cuprates, but not with  $T_{C,\text{max}}$  of the respective samples. The hole density for the  $n = 3$  phase showed a stronger out of plane-component. By La-substitution the density of doped holes could be varied continuously over a wide doping range for the  $n = 1$  and  $n = 2$  phase, giving an alternative to doping by Ca-substitution in between the  $\text{CuO}_2$  layers.
