## Abstra
t

Experimental orrelation between the rms nu
leus harge radius and the neutron-proton asymmetry is discussed. Simple attempt of explanation of this correlation using a semi-empirical liquid drop model which takes into account nuclear compressibility, nuclear deformation and neutron skin ters is presented. It seems that such provided to determine the such as tool for determination of the nu
lear equation of state.

The nuclear equation of state (EOS) and the nuclear reaction kinetics determine stellar structure and evolution. In particular, the EOS allows to estimate the critical parameters at which the collapse process is halted and the shock wave in a core collapse supernova becomes formed  $[1, 2]$  $[1, 2]$  $[1, 2]$  $[1, 2]$ . But the equation of state is not only relevant in astrophysical aspe
ts. Knowledge of EOS is a way to better understand the nu
lear heavy-ion rea
tions [\[3](#page-9-2), [4](#page-9-3)] and some fundamental properties of heavy nuclei, like for instance binding energy or stability of neutron-rich nuclei [\[5](#page-9-4)].

The equation of state for infinite, asymmetric nuclear matter usually represents the relation between the energy density per nu
leon (baryon) e and densities rea
hed by neutrons and protons in the nu
lear matter. In this relation the Coulomb energy is not taken into account. Many theoretical approaches [\[6](#page-9-5)] have shown that the properties of infinite asymmetri nu
lear matter, at relatively low temperature, an be des
ribed by an approximate form of EOS:

<span id="page-1-0"></span>
$$
e(\rho, \delta) = e(\rho, \delta = 0) + \delta^2 e_{sym}(\rho)
$$
\n(1)

where the baryon density  $\rho$  is a sum of neutron  $\rho_n$  and proton  $\rho_p$  density. Isospin asymmetry  $\delta$ , is defined as

$$
\delta = \frac{\rho_n - \rho_p}{\rho_n + \rho_p} = \frac{\rho_n - \rho_p}{\rho}.
$$
\n(2)

First term in the eq. [\(1\)](#page-1-0) represents energy density per baryon associated to symmetric nuclear matter  $(\delta = 0)$ . This energy can be expanded around normal nuclear matter density  $\rho_0$  as

$$
e(\rho, 0) = e(\rho_0, 0) + \frac{K_{\delta=0}}{18} \left(\frac{\rho - \rho_0}{\rho_0}\right)^2 + \dots
$$
 (3)

In the formula above  $K_{\delta=0}$  is the nuclear compressibility for symmetric matter, defined as

$$
K_{\delta=0} = 9\rho_0^2 \frac{\partial^2 e(\rho, 0)}{\partial \rho^2} \big|_{\rho=\rho_0} \,. \tag{4}
$$

<span id="page-1-1"></span>Second term in eq. [\(1\)](#page-1-0) stands for the symmetry energy and can be also expanded around  $\rho_0$  as

$$
e_{sym}(\rho) = e_{sym}(\rho_0) + \frac{L}{3} \left( \frac{\rho - \rho_0}{\rho_0} \right) + \frac{K_{sym}}{18} \left( \frac{\rho - \rho_0}{\rho_0} \right)^2 + \dots
$$
 (5)

where variables  $L$  (slope) and  $K_{sym}$  (curvature) characterizing the density dependence of the nu
lear symmetry energy are given by

$$
L = 3\rho_0 \frac{\partial e_{sym}(\rho)}{\partial \rho} \big|_{\rho = \rho_0} \tag{6}
$$

and

$$
K_{sym} = 9\rho_0^2 \frac{\partial^2 e_{sym}(\rho)}{\partial \rho^2} \mid_{\rho = \rho_0} \tag{7}
$$

The coefficients  $\rho_0$ ,  $e(\rho_0, 0)$ ,  $e_{sym}(\rho_0)$ ,  $K_{\delta=0}$ , L,  $K_{sym}$  allow us to determine the EOS around the normal nuclear density. Unfortunately, values of the slope  $L$  and the curvature  $K_{sym}$  are neither well determined experimentally nor accurately estimated theoretically [6]. Data from the giant monopole resonances suggest that  $K_{sym}$  varies from -566  $\pm 1350$  MeV to 34  $\pm$ 159 MeV [\[7](#page-9-6)]. So far, experimental predictions for the L value are rather scarce. In the recent paper  $|8|$  the isospin transport calculations compared with the MSU diffusion data suggest  $L \approx 60$ . In theoretical models L varies from -50 up to 200 MeV [9]. Moreover, theoretical estimates for  $K_{sym}$  are model-dependent and vary from about -700 to +466 MeV  $[10]$  $[10]$ .

In the present paper we will show a way to put some constraints for possible values of these parameters. In order to do it, we ompare the experimentally measured orrelation between root mean square radii of nuclei and isospin asymmetry, to the similar correlation resulting from a modified liquid-drop model (LDM).

One of the most elementary properties of a nucleus is the spatial nucleon density distribution. Unfortunately, this distribution annot be obtained experimentally in a straightforward way. In the ase of protons, knowledge of the Coulomb intera
tion allows to measure with a high precision the momenta of the charge distribution. From experimental data one usually fixes the root-mean-square (rms) radius  $\langle r_n^2 \rangle$ p  $\sum_{k=1}^{1/2}$ . In this paper we will use a part of the set of 799 ground state nuclear charge radii presented in [\[11](#page-9-10)]. This experimental data were obtained from the elastic electron scattering, muonic atom X-rays,  $K_{\alpha}$  isotope shift, and opti
al isotope shift. Errors asso
iated with the data are usually mu
h lower than 1%. For neutrons, the differences between neutron and proton density distributions at large nuclear radii in stable nuclei may be determined e.g. from antyprotonic atoms [\[16](#page-9-11)]

In the first column of Fig. [1](#page-8-0) we plot a correlation between the experimentaly measured

 $\langle r^2_p$ p  $\sum_{i=1}^{N-1/2} \sqrt[i]{A}$  and isospin asymmetry  $I = (N-Z)/(N+Z),$  where  $N$  and  $Z$  denote neutron and proton numbers, respectively. In Fig. [1a](#page-8-0) we plot these correlations for all available nuclei with masses  $A = N + Z > 100$ . We can notice here some branches which are roughly mutually parallel. These branches are much better visible on the next drawings in this column (Fig. 1c, e, g) showing the correlations for nuclei with selected mass intervals.

Let us try to explain the nature of the observed correlations. We consider here the influence of three effects: nuclear deformation, dependence of nucleon density on isospin. and neutron skin.

At the beginning we will study the influence of nucleus deformation on the proton rms radius. In our analysis we neglect the diffuseness of the surface and we assume only groundstate quadrupole deformation described by " $\beta$  parametrization" (a spherical harmonic expansion) [12]. Such an aproach should be sufficient for rather small ground state deformations. Now we an write the proton mean-square radius in the form

<span id="page-3-0"></span>
$$
\left\langle r_p^2 \right\rangle = \frac{3}{5} R_0^2 \left( 1 + \frac{5}{8\pi} \beta^2 \left( A, I \right) \right) \tag{8}
$$

where  $R_0$  is the average radius. Parameters  $\beta(A, I)$  for considered set of nuclei are taken from model calculations used in [12]. Obtained correlations between deformation  $\beta^2$  and isospin I are presented in the right column in Fig. [1.](#page-8-0) As we can see from the upper graph (Fig. [1b](#page-8-0)) for almost all masses  $\beta^2$  is less than 0.1. Formula [\(8\)](#page-3-0) suggests that for a given  $R_0$ , nuclear deformation does not modify the  $\left\langle r_{p}^{2}\right\rangle$ p  $\sum_{k=1}^{1/2}$  value more than 1%, however (see Figs [1d](#page-8-0),f,h) it an enhan
e or suppress the observed orrelations depending on the sele
ted mass range. Even more importantly, it can also change the correlation sign (see e.g. Fig [1e](#page-8-0) and Fig  $1f$ ).

One can suspect, that such a strong correlation observed in the first column could be asso
iated with the form of the nu
lear equation of state. To examine this possibility we assume that the considered correlation can be a result of differences in the density of nuclear matter in the central region of nuclei due to different values of the surface tension and Coulomb interaction.

Saturation of the nuclear matter density in the central region of nuclei provides a base for des
ription of the nu
lear binding energy in the liquid-drop model. This model was formulated by Weizsä
ker (1935), Bethe (1936), and Bohr (1936). Up to now various modifications were introduced in this model and some of them consider also compressibility of nuclear matter [13].

The liquid-drop model in its simplest version describes the nuclear binding energy B as a sum of the volume, surfa
e and Coulomb terms.

<span id="page-4-1"></span>
$$
B = B_v + B_s + B_C,\t\t(9)
$$

where  $B_v$  is the dominant volume ingredient usually written as,

<span id="page-4-2"></span>
$$
B_v = a_v (1 - k_v I^2) A,
$$
\n(10)

and  $a_v$  and  $k_v$  are coefficients. The term  $k_v I^2$  takes into account the lowering of the binding energy caused by different number of protons and neutrons in the nucleus.

<span id="page-4-0"></span>Next term is  $(9)$  takes into account lower binding energy for nucleons located on the nu
lear surfa
e, and an be expressed as

$$
B_s = a_s (1 - k_s I^2) A^{2/3} f = \left[ a_s (1 - k_s I^2) A^{-1/3} \right] A f, \tag{11}
$$

where  $a_s$  and  $k_s$  are coefficients. Factor  $f = (1 + \frac{2}{5}\beta^2 - \frac{4}{105}\beta^3)$  takes into account the nuclear deformation (see  $[14]$ ). We can notice that the surface correction per one nucleon (square bracket in  $(11)$  vanishes with the increasing A

Coulomb interaction between protons appears in the next correction, which is proportional to  $Z^2$  and inversely proportional to the radius of the nucleus. This term can be written as

<span id="page-4-3"></span>
$$
B_c = a_c \frac{Z^2}{A^{1/3}} g = \left[ a_c \frac{Z^2}{A^{4/3}} \right] g A \tag{12}
$$

where  $a_c$  is a parameter, and  $g = (1 - \frac{1}{5})$  $\frac{1}{5}\beta^2 - \frac{4}{105}\beta^3)$  similarly like  $f$  in [\(11\)](#page-4-0) describes possible influence of the nuclear deformation. Comparison of  $(9)$  to the experimental data (e.g. [15] allows to determine coefficients presented in formulas  $(10)$ - $(12)$  as:

<span id="page-4-4"></span>
$$
a_v = -15.677 \text{ MeV}, a_s = 18.560 \text{ MeV}, a_c = 0.717 \text{ MeV}
$$
  

$$
k_v = k_s = 1.79 \text{ MeV}.
$$
 (13)

It should be stressed, that LDM is dedicated to a finite drop of nuclear matter with a constant density. From the analysis of experimental data we can deduce that apart from nuclear surface the nucleus density is roughly constant and for mass  $A > 40$  it has a Fermilike shape distribution. The central region density itself somewhat varies for different nuclei.

The form of the volume part of the binding energy [\(10\)](#page-4-2) is in fa
t related to the EOS at the ground state density. For  $a_v = e(\rho_0, 0)$ ,  $a_v k_v = e_{sym}(\rho_0)$ ,  $\rho = \rho_0$ , and  $\delta^2 = I^2$  the energy obtained from EOS [\(1\)](#page-1-0) is equivalent to the volume energy per nu
leon in the LDM [\(10\)](#page-4-2). For our onsideration we reformulate the liquid-drop model in a way that allows to determine the entral region density for a given nu
leus. We want to obtain the entral region density as a function of coefficients  $\rho_0$ ,  $e(\rho_0, 0)$ ,  $e_{sym}(\rho_0)$ ,  $K_{\delta=0}$ , L,  $K_{sym}$ , and  $\delta=I$ , determining the nuclear EOS. In principle neutron and proton density distributions may have different radii,  $R_n$ ,  $R_p$ , what gives the so called skin effect. Lets assume for the beginning  $R_n = R_p$ .

Modifying the LDM we assume that density in the central region is a function of global values N and Z (i.e. there is no local dependence). According to the idea of the LDM, we can say that the central region density  $\rho$  results mainly from nuclear interaction present in infinite nuclear matter, further being modified by the surface tension and Coulomb repulsion. Therefore, reformulating the liquid-drop model, we write the binding energy per nu
leon  $b(\rho, I, A)$  in a form similar to [\(9\)](#page-4-1):

$$
b(\rho, I, A) = b_v(\rho, I) + b_s(\rho, I, A) + b_c(\rho, I, A).
$$
\n(14)

<span id="page-5-1"></span>In the above formula the volume part of the binding energy is defined by  $EOS(1)$  $EOS(1)$ .

$$
b_v(\rho, I) = e(\rho, \delta).
$$
\n(15)

Let  $b_{v0} = e(\rho_0, \delta)$ . Now, the correction for the surface effect we can rewrite in a new, density dependent form

<span id="page-5-0"></span>
$$
b_s(\rho, I, A) = a'_s (1 - k'_s I^2) \frac{b_v(\rho, I)}{b_{v0}} \left(\frac{\rho_0}{\rho}\right)^{2/3} A^{-1/3} f
$$
  

$$
= \frac{a'_s}{a'_v} b_v(\rho, I) \left(\frac{\rho_0}{\rho}\right)^{2/3} A^{-1/3} f.
$$
 (16)

Factor (<sup>po</sup> ρ  $\int_{0}^{2/3}$  in [\(16\)](#page-5-0) is responsible for the surface change due to the change in the core density. The corresponding coefficients are marked by prime to distinguish from parameters of the standard LDM. In principle their values can slightly differ from the original ones.

The part describing the Coulomb interaction is modified only by factor  $(\frac{\rho_0}{\rho_0})$ ρ  $\int_0^{1/3}$  according to the radius change induced by core density changes  $(Z = Z(I, A))$ .

<span id="page-6-2"></span>
$$
b_c(\rho, I, A) = a_c' \frac{Z^2}{A^{4/3}} \left(\frac{\rho_0}{\rho}\right)^{1/3} g.
$$
 (17)

Here the binding energy is determined by the density  $\rho$  and a new set of coefficients  $a'_i$  $_{v}$ ,  $a'$  $\zeta_s$ ,  $a'_c$  $c_c',\rho_0,\,e(\rho_0,0),\,e_{sym}(\rho_0),\,K_{\delta=0},\,L,\,K_{sym}.$  The density  $\rho$  for a given nucleus is found from a condition  $\partial b(\rho, I, A)/\partial \rho \mid_{I, A=const}= 0$ . In this way  $\rho$  and binding energy values are uniquely determined by a selected set of coefficients. Here, as a first approximation, we are taking the value of coefficients with the sign prime equal to corresponding coefficients without prime which are given by [\(13\)](#page-4-4). Coefficients  $\rho_0$ ,  $e(\rho_0, 0)$ ,  $e_{sym}(\rho_0)$ , are rather well known. In Fig. [2](#page-8-1) we present the binding energy  $b(\rho, I, A)$ , as a function of density, for nuclei with  $A = 150$ and three different  $Z$  values equal to 50, 60 and 75 ( $I = 1/3$  ,  $I = 1/5$  and  $I = 0$ ). For these test calculations we take  $K_{\delta=0} = 240 \,\text{MeV}$  and we check energy density behavior for all possible combinations of  $L= \pm 100 \,\mathrm{MeV}$  and  $K_{sym} = \pm 500 \,\mathrm{MeV}$  what determine the symmetry energy [\(5\)](#page-1-1) .

The saturation of nuclear density in the central region is characteristic for heavier nuclei. For light nuclei we can say that almost all nucleons are located on their surface. In order to omit the problem of high ontribution oming from the surfa
e we shall test formula [\(14\)](#page-5-1) only for heavier nuclei,  $A > 100$ .

Assuming  $R_0 \sim \sqrt[3]{A/\rho}$  and using [\(8\)](#page-3-0) we can rewrite relation between  $r_{rms}$  and  $\rho$  in the form

<span id="page-6-0"></span>
$$
\frac{\left\langle r_p^2 \right\rangle^{1/2}}{\sqrt[3]{A}} = \alpha \frac{\sqrt{\left(1 + \frac{5}{8\pi}\beta^2\right)}}{\sqrt[3]{\rho}}
$$
\n(18)

where  $\alpha$  is a normalization constant. Formula [\(18\)](#page-6-0) neglects a neutron skin, which because of different radii of neutron and proton density distributions, surrounds the larger A nuclei. Lets define thickness of the neutron skin as

<span id="page-6-1"></span>
$$
d = R_n - R_p. \tag{19}
$$

where  $R_p = \sqrt{\frac{5}{3}}$  $\frac{5}{3}$  $\langle r_p^2$ p  $\bigg\}^{1/2}$ , and  $R_n = \sqrt{\frac{5}{3}}$  $\frac{5}{3}$   $\langle r_n^2$  $\binom{2}{n}$  $1/2$  is the effective proton and neutron radius, respe
tively. The entral region nu
leon density is now

<span id="page-7-0"></span>
$$
\rho = \rho_n + \rho_p = \frac{N}{\frac{4}{3}\pi R_n^3} + \frac{Z}{\frac{4}{3}\pi R_p^3}
$$
\n(20)

and instead of  $I=(N-Z)/(N+Z)$  one gets for the central region isospin  $\widetilde{I}$ 

$$
\widetilde{I} = \frac{N - Z(1 + d/R_p)^3}{N + Z(1 + d/R_p)^3} \simeq I \left(1 - \frac{3Zd}{r_0 \left(\frac{\rho_0}{\rho}\right)^{1/3} A^{4/3}}\right)
$$
\n(21)

For numerical calculations we use  $r_0 = 1.2049$  (see [\[14](#page-9-14)]).

As d seems to be much smaller than  $R_p$ , one gets from [\(19\)](#page-6-1) and [\(20\)](#page-7-0)

$$
R_p = \sqrt[3]{\frac{3A}{4\pi\rho}} \left( 1 - \frac{Nd}{r_0 \left(\frac{\rho_0}{\rho}\right)^{1/3} A^{4/3}} \right) \tag{22}
$$

The Coulomb energy is inversely proportional to the radius and consequently  $b_c$  in [\(17\)](#page-6-2) has to be written as:

$$
b_c(\rho, I, A) = a_c' \frac{Z^2}{A^{4/3}} \left(\frac{\rho_0}{\rho}\right)^{1/3} \left(1 + \frac{Nd}{r_0 \left(\frac{\rho_0}{\rho}\right)^{1/3} A^{4/3}}\right) g.
$$
 (23)

<span id="page-7-1"></span>As an alternative for eq. [\(18\)](#page-6-0) one should use now:

$$
\frac{\left\langle r_p^2 \right\rangle^{1/2}}{\sqrt[3]{A}} = \alpha \frac{\sqrt{\left(1 + \frac{5}{8\pi}\beta^2\right)}}{\sqrt[3]{\rho}} \left(1 - \frac{Nd}{r_0 \left(\frac{\rho_0}{\rho}\right)^{1/3} A^{4/3}}\right) \tag{24}
$$

Lets try to discuss the origin and slope of the observed correlation's as a function of different factors.

In Figs. [3](#page-8-2) and [4](#page-9-16) in columns marked "model 1", "model 2", and "model 3", we plot correlation's given by formula  $(24)$ , for different sets of the EOS parameters. For calculations named "model 1" we neglect the neutron skin and deformations of nuclei  $(\beta = d = 0$  in formula [\(24\)](#page-7-1)) whereas in "model 2" deformations are taken into account ( $\beta \neq 0, d = 0$ ). In "model 3" we are trying to estimate the influence of the neutron skin  $(\beta \neq 0, d \neq 0)$ . Calculations were performed for the soft  $(K_{\delta=0} = 120 \text{ MeV})$ , red points) and for the hard  $(K_{\delta=0} = 500 \text{ MeV}, \text{ blue points})$  EOS. In Fig. [3](#page-8-2)  $L = -150 \text{ MeV}$  and in Fig. [4](#page-9-16)  $L = 60 \text{ MeV}.$ As for nuclei  $\rho \approx \rho_0$  and in formula (5) the third term is a rather small correction, in both cases we take  $K_{sym} = 500 \,\text{MeV}.$ 

For "model 1" the  $\left\langle r_{p}^{2}\right\rangle$ p  $\sum_{i=1}^{1/2} \sqrt[i]{A}$  versus  $I$  correlation already contains a number of separated chains because of discrete values of the  $A$  and  $Z$  numbers. Nuclear deformations modify slightly slopes of the observed chains and may result in additional splitting (see "model  $2$ ",  $180 < A < 210$ ). As seen from the "model 3" calculations taking into account the neutron skin introdu
es quite important hanges.

## Con
lusions

An experimental correlation between the nucleus rms charge radius and the isospin of heavier nuclei has been observed. It seems to be related to interactions characteristic for the nuclear matter equation of state modified by confinement inside of an atomic nucleus. These interactions are responsible for nuclear deformations and creation of the neutron skin. We propose explanation of the observed correlation on the basis of a modified nuclear liquid drop model. Inspe
tion of studied orrelation's (Figs [3](#page-8-2) and [4\)](#page-9-16) suggests a possibility of evaluating the EOS parameters. A pre
ise determination of these values requires a more precise search and a more complex analysis which will be subject of a future work. Such investigation probably requires an extension of the LDM by additional terms taking into account such corrections as for example pairing, shell effects and diffuseness of the nucleus surface. Although  $b_s$  in formula [\(16\)](#page-5-0) decreases for large A values, it could be interesting to introdu
e here an additional orre
tion related to the lo
al isospin of the surfa
e.
