Abstract—Cloud Computing has emerged as a new paradigm for IT industry. By leveraging the pay-as-you-go model, cloud computing enables to deliver the resources dynamically for customers. However, the high energy consumption of data centers contributes to high operational costs and carbon emission to the environment. Therefore, the Green cloud computing is required to be promoted to reduce the energy consumption of data centers. Many energy-efficient algorithms have been proposed to reduce the energy of cloud computing environment, however, most of them are not compared under same environment scenario, and the their performance are not evaluated with same experiment settings. In this paper, we choose several state-of-the-art energy efficient algorithms for comparison. We compare these algorithms comprehensively from multiple perspectives, including ideas, modelling, metric. We also evaluate these algorithms with same experimental settings in CloudSim. The experimental results show the performance comparison of these algorithms. Finally, the detailed discussions of these algorithms are provided.

Index Terms—Cloud Computing, Data Centers, Energy Efficient Algorithms, QoS, CloudSim

I. INTRODUCTION

Cloud Computing develops rapidly and has been widely utilized by enterprises. Cloud Computing has been regarded as a new paradigm for IT industry, and the paradigm has grown into one of the backbones of modern economy. Cloud service providers are offering a variety of cloud services for customers with on-demand access to resources. Cloud Computing also enables new business to be established within short time, facilitates the expansion of enterprise globally, accelerates the

progress of scientific research, and promotes the creation of various models and applications [CSUR].

The infrastructure of Cloud Computing is cloud data centers. Currently, the majority of data centers spread of 300-4500 square meters containing hundreds to thousands physical machines. The fast growth data centers also consume huge energy consumption.

A typical data center can consume up to 25,000 KWh per day. It is estimated that US data centers can consume kWh, which equals to 50 coal-based power plants. It is also analyzed that the carbon footprint will reach []. To relieve the huge energy consumption and carbon emission, energy efficient algorithms have been proposed

Virtualization technology is an important part of green cloud data centers to support energy efficiency via Virtual Machine (VMs) consolidation, where a VM is the software implementation of a computer that running with operating system and applications. Virtual machine (VMs) consolidation is one of the dominant energy efficient solutions to reduce the energy consumption of cloud data centers. VMs are packed on fewer physical machines via consolidation, thus the idle physical machine can be switched to the low-power mode.

The proposed algorithms should be evaluated under real test-bed. However, due to the uncontrolled traffic, it is hard to conduct experiments under large-scale environment and reproduce the results. Therefore, running experiments with simulation toolkit is an acceptable and convenient way. Simulation toolkits can be easily applied to construct large-scale environment. During the existing simulators, CloudSim is one

of the most widely used one. CloudSim is an open-source toolkit for modelling cloud resource scheduling data centers, which has attracted users from hundreds of universities and research institutes.

In this paper, we select several VM-based energy efficient algorithm and implement them in CloudSim. The evaluated algorithms are picked from prominent journals and have showed good performance in energy efficiency. We compare them from multiple perspectives. The key contributions are as follows:

The main motivation of this work are: To compare performance of different energy efficient algorithms for cloud data centers; To discuss the best suitable scenarios of different energy-efficient algorithms.

The motivation for this article was to clearly analyze the problem of rising energy consumption by providing a comparison of some state-of-the-art energy efficient algorithms in cloud data centers. VM consolidation based energy efficient algorithms have been proposed in many research papers. The article offers a cross-sectional view of the investigated VM consolidation-based algorithms, which are published in prominent journals. An exhaustive comparison of the investigated algorithm was conducted, and the algorithms were evaluated using different metrics while under same configurations. This article was particularly motivated from the following facts:

- The need and demand for understanding existing VM-based energy efficient algorithms for cloud data centers
- The proposed algorithms were evaluated in different scenarios and configurations, thus their advantage and disadvantage are not carefully examined.
- The need for selecting the best suitable algorithm based on different priorities.

In this study, we provide an overview on VM consolidation based energy efficient algorithm for cloud computing in Section 2. The investigated algorithms are described in Section 3. Section 4 discusses the modelling of the investigated algorithms, and the adopted metrics in the investigated algorithms are summarized in Section 5. Section 6 shows the performance comparison of the investigated algorithms. Finally, the conclusions and future directions are given.

II. RELATED WORK

we pick up representative algorithm in each category for comparison. The growth energy efficiency problem has been increasing ever since advancements in the computing industry have been made and consequent high energy demand has been noticed.

VM consolidation is the process of consolidating VMs to another physical machine without interrupting the running status of applications. Virtualized cloud data centers can minimize the number of active physical machines through VM consolidation techniques. The VM consolidation can be trigger when physical machine is overloaded or under-utilized, thus the energy efficiency can be improved. Also, VM consolidation facilitate workload balancing among all machines and prevent usage of specific machines. Cloud computing can perform VM

consolidation depending upon the current resource demand of VMs. This can also enhance fault tolerance by consolidating VMs from failure-sensitive machine to steady machine transparently for users.

III. OVERVIEW OF THE INVESTIGATED ALGORITHMS

A. MBFD

Beloglazov et al.[1] proposed an energy-aware allocation algorithm of data center resources that focuses on VM scheduling. Their objective is reducing the energy consumption of data centers while ensuring SLA. They solve the first part of the allocation, the initial VM placement which is regarded as a bin packing problem, with an algorithm called Modified Best Fit Decreasing(MBFD). MBFD aims to assign the VMs to the hosts that produce the minimum increase of energy consumption. In the second part, the algorithm optimizes the VM allocation via consolidation for better energy efficiency. Due to the uncertainty of task lifecycles, some VMs are likely to host a over-provisioned of applications while others run with low resource utilization. Unbalanced workloads in cloud data center result in a severe waste of resources and performance degradation. Therefore, a better VM migration policy is needed for the optimization of the current VM allocation. The minimization of migrations(MM) policy set two utilization thresholds, lower and higher. Every scheduling cycle, VM manager will check the status of each VM. If the resource utilization (i.g. CPU utilization) of a VM exceeds the higher threshold, MM will be applied to migrate minimum VMs from an over-utilized host to adjust the resource utilization to be lower than the upper utilization threshold. Otherwise, all VMs, the resource utilization of which is below the lower utilization threshold, should be migrated from their original hosts, which will be switched off to reduce energy consumption after the migration.

Experiment results in this paper prove the efficiency of their algorithms and also find that the interval between lower and higher utilization threshold is an important parameter to balance the energy consumption and SLA violation.

B. EcoCloud

EcoCloud [] is a energy efficient scheduling policy based on probabilistic procedures. VM assignment and VM migration are the two phases in the algorithm. In the VM assignment phase, different from the MDBF introduced in the previous section, the VM manager sends an invitation to a subset of all active hosts to obtain a list of hosts that accept the incoming VM. After receiving the invitation, the host performs a Bernoulli trial, which computes the value of overall assignment function to decide whether to accept a VM or not. The assignment function consider the resource utilization and utilization threshold, the calculate the probability to accept the incoming VM. If the trial succeeds, the host sends back a message to the manager. The manager collects all messages and selects one available host to allocate the incoming VM. The second part of EcoCloud is VM migration, which utilizes two Bernoulli trial based functions to handle the over-utilized

and under-utilized situations separately. If the trial of under-utilized situation is successful, a randomly selected VM will be migrated. On the other hand, migrations with over-utilized will migrate the VM that decreases resource utilization to be lower than overload-utilized threshold. The target host to accept the VM is decided by another assignment function with slight modification of a parameter.

The main advantage of EcoCloud is that the approach can reduce downtime duration and transmission bandwidth. Furthermore, hosts can make migration decisions by themselves, thus the pressure of VM manager is relieved.

C. GRANITE

GRANITE is a holistic virtual machine scheduling algorithm capable of minimizing total data center energy consumption, including computing energy and cooling energy. This work considers Computer Room Air Conditioner (CRAC) as the only cooling devices and constructed their models. Based on server models and cooling models, GRANITE utilizes greedy algorithm to conduct the VM initial placement and dynamic migration. In the proposed algorithm, there are two stages: initial VM placement and dynamic VM consolidation. They assume that the users' resource demand can be predicted. In the initial placement stage, the greedy algorithm is applied in GRANITE for all VMs to select the host with least increase of total energy after the placement. The CRAC will be adjusted if the CPU temperature is above the threshold. In the dynamic VM consolidation stage, the algorithm aims to balance the workloads and cooling energy consumption. The GRANITE defines a dynamic temperature threshold and checks host status. If the host temperature is above the temperature threshold, a set of VMs will be migrated to other hosts. The target host for migration is similar to the greedy algorithm in the initial placement stage. With experiments in CloudSim, the results show that GRANITE can outperform the baselines in total energy consumption. The advantage of this work is that it combines the server status and data center thermal control to form the fine-grained energy efficient scheduling. However, the task performance is not considered in this work.

The main idea of the algorithm is similar to MBFD algorithm, but it considers cooling power, which leads to a more accurate and holistic scheduling results.

D. LOAD

LOAD [] is an algorithm based on learning automata for energy and SLA efficient consolidation of VMs in cloud data centers. The proposed algorithm considers user demanded resource to predict overloaded hosts. By preventing overloaded hosts and shutting down idle hosts, the proposed algorithm aims to save energy consumption of data centers. The learning automata-based overload detection enhances the VM consolidation by predicting CPU usage of hosts upon resource usage history. Each VM is equipped with one automata including 3 actions, increasing CPU utilization, reducing CPU utilization and no changing of CPU utilization. At the beginning, the 3

actions are with equal probability. After the beginning stage, the reward and penalty of learning automata will be updated based on environment. The automata selects one of the three actions in each iteration based on the probability. And in the next iteration, if the automata's decision is right, the action will be rewarded, otherwise, the action will be penalized. The learning automata is applied to estimate usage of VMs on host. If the estimation shows that the host may be overloaded, the VMs will be migrated and other VMs will be prevented to be migrated to the current host. The migrated destination is based on the BFD algorithm. The simulation results show that leveraging learning-based prediction can reduce energy consumption of data centers.

This work advances the existing work by considering the dynamically prediction for resource usage. This work predicts the overloaded situations and does not handle the under-utilized situations.

E. PPVMP

PPVMP [] is power-aware and performance-guaranteed VM placement approach. Its objective is balancing the trade-offs between saving energy and guaranteeing VM performance. In this approach, the authors constructed VM performance models to present the VM degradation trend. The authors addressed that if two VMs with CPU-intensive requirements are placed on the same host, the resource utilization of host may be unbalanced. PPVMP applies Ant Colony Optimization (ACO) based method to minimize host energy consumption and VMs performance degradation simultaneously. To leverage ACO, the necessary entities in ACO, including pheromone updating rules and probabilistic decision rules are defined. If one solution has more pheromone trails, the VM has larger probability to be placed on host. PPVMP also has two updating rules for local and global pheromone, which are applied in each iteration. In iterations, each ant receives and sorts all VMs randomly and allocated non-allocated VMs. The local pheromone is updated by ant when they perform a movement. After all ant construct their solutions locally, the global pheromone update is conducted, and only dominated solutions will be kept. The process is repeated until it reaches the maximum iteration number. The results based on simulation and real testbed show that the proposed algorithm can reduce energy consumption and guarantee VM performance. However, the experiments are not evaluated under heterogeneous environment.

F. PRS

PRS is an approach exploits proactive and reactive methods to schedule real-time tasks. Its objective is improving resource utilization and reducing energy consumption by considering the uncertainty of cloud computing environment. Uncertainty (e.g. overloading, variation of VM performance, arrival of urgent tasks) can lead to the pre-computed baseline schedule is not satisfied with in real execution. They model the uncertainty features and propose policies to control uncertainties by scaling up or down resources according to workloads. PRS manages two task queues, one is waiting queue and the

other is urgent task queue, where non-urgent and urgent tasks will be added into the two queues separately. When the non-urgent tasks turn into the urgent ones, they will be moved to the urgent queue. The urgent tasks will be executed on VMs immediately. In the algorithm, the proactive scheduling is used to build baseline schedules based on tasks' finish time and their deadlines. The reactive scheduling is triggered dynamically to generate proactive baseline schedule in order to handle disruptions, e.g. system becomes overloaded, new urgent task comes into system or a task is finished. When system workloads become light and some VMs are with long idle time. The idle VMs will be turned off and VMs or consolidated to a minimal number of hosts. The target host is computed based on BFD algorithm. Simulations with CloudSim show that PRS can reduce energy consumption while guaranteeing real-time tasks deadline compared with baselines.

The advantage of the proposed work is that it can enhance cloud computing environment to handle uncertainty.
