

We first compare the states of excitatory neurons on a multilayer perceptron (MLP, with 748-128-256-10 units) with and without the use of a forgetting layer in Fig. ??d. The results demonstrate that using the forgetting layer can substantially decrease **excitatory neurons' activation** and achieve a sparse representation. To quantify, referring to the metric of sparsity in biological neurons[?], we propose a metric to evaluate the sparsity in artificial neural networks. It is calculated by
