Abstract: In this work, we focused on Electro Spray (ES) and Ultrasonic Spray Coating (USC) as two promising and innovative fabrication techniques for the optimisation of carbon electrode surfaces to be employed in Bio-Electrochemical Systems. We performed, on commercial carbon paper electrodes, controlled depositions of a nanostructured layer containing PEO and PEDOT:PSS. We then employed electron microscopy and Raman spectroscopy to characterise the morphology and superficial uniformity of the so-obtained electrodes. Together with electrochemical characterisations and experiments in bio-electrochemical devices, we demonstrated how ES and USC represent promising techniques for the optimisation of carbon electrodes' surfaces, obtained with the deposition of a conductive nanostructured layer.

Keywords: microbial fuel cells; microbial electrolysis cells; surface decoration; electro spray; ultrasonic spray coating

1. Introduction

Nowadays, bio-electrochemical systems such as Microbial Fuel Cells (MFCs) and Microbial Electrolysis Cells (MECs) draw increasing attention for their potential applications in sustainable energy production. In both MFCs and MECs systems, the anode electrode plays a crucial role in improving the overall devices' performances, and numerous studies have been aimed at increasing the electrode's surface hydrophilicity, porosity and electrical conductivity [1]. To this end, promising results were obtained by electrode surface optimisation with both Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and Polyethylene oxide (PEO) [1,2]. Indeed, PEDOT:PSS is a well-known conductive polymer and has already found applications in many sectors, among which are energy conversion and storage. In addition, other works have demonstrated how surface decoration with PEO increased electrodes' surface hydrophilicity and, in MFCs, promoted the proliferation of the biofilm that is crucial for the proper functioning of such devices [2]. In this work, we focus on Electro spray and Ultrasonic Spray Coating as two promising and innovative fabrication techniques for the deposition of PEO and PEDOT:PSS solutions on commercial carbon paper. Both techniques are scalable and offer fine control over the deposition of nanostructured layers. While previous works already processed PEDOT:PSS with electrochemical methods [1], this is the first time that such material has been deposited on MFC electrodes with ES or USC techniques.

Employing both ES and USC, we fabricated samples on which we then characterised the morphology and the electrochemical properties provided by the nanostructured layer.

In addition, we investigated the use of Raman spectroscopy to quantitatively validate and map the spatial uniformity of such layers. Finally, we assessed performance improvements and stability in laboratory MFC devices.

2. Materials and Methods

2.1. Materials and Electrodes Fabrication

We fabricated all electrodes, starting from as-purchased commercial Carbon Paper (AvCarb, Lowell, MA, USA). To realise the nanostructured coating, we prepared spraying solutions containing Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, 1.3 wt.% water dispersion, purchased from Sigma Aldrich), Polyethylene oxide (PEO, 600 kDa average molecular weight, purchased from Sigma Aldrich Darmstadt, Germany), and de-ionised water (Merck Millipore, Darmstadt, Germany).

Electrolyte solutions for electrochemical characterisation contained sodium acetate, ammonium chloride, potassium chloride and sodium dihydrogen phosphate, all purchased from Sigma Aldrich.

2.1.1. Anode Fabrication via Ultrasonic Spray Coating (USC)

We employed a Nadetech Ultrasonic Spray Coater (Nadetech Innovations, Navarra, Spain) to deposit the PEDOT:PSS nanostructured layer on bare carbon paper. The sprayed solution consisted of a commercial PEDOT:PSS aqueous dispersion (0.5 wt.% PEDOT, 0.8 wt.% PSS), diluted in de-ionised water (2/8 volume ratio). As a result, the final solution contained 1 mg/mL of PEDOT and 1.6 mg/mL of PSS, providing us with a finer control over the deposited material amount with respect to pure commercial solution. Instead, in order to deposit both PEO and PEDOT:PSS, we prepared a spraying solution suitable for USC, starting from the same PEDOT:PSS commercial aqueous dispersion, adding PEO (1 wt.%) and then diluting in deionised water (1/9 volume ratio). Prior to use, we stirred the solution overnight to ensure uniform mixing.

Figure 1a,b describes the process condition and parameters. Fabricated samples, here named *USC PEDOT 50/100/200* or *USC PEO-PEDOT 200*, are described in Figure 1c alongside details on the deposited material amount.

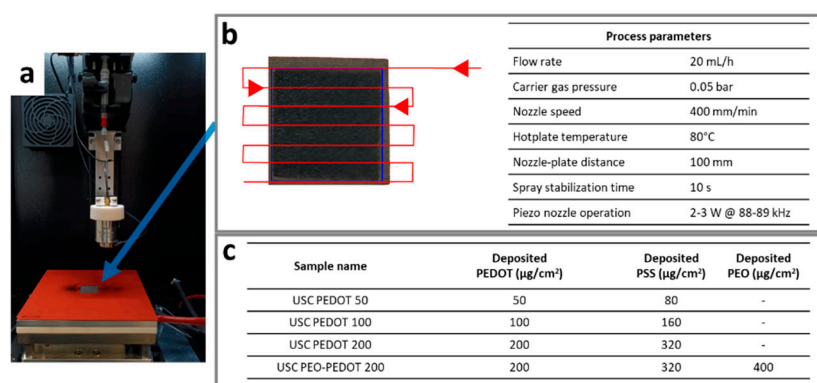

Figure 1. (a) Detail of the USC equipment; (b) pattern and process parameters employed to perform PEDOT:PSS and PEO depositions. (c) Overview of anode electrodes fabricated with USC.

We obtained each electrode sample from a 30×30 mm carbon paper square, held in place on the heated deposition plate by vacuum suction and a silicone mask. The deposition duration ranged within 2–6 min, with the spray nozzle following a pattern that aimed at maximising the surface uniformity of deposited material (Figure 1b).

2.1.2. Anode Fabrication via Electropray (ES)

We employed a NANON 01A electropray device (MECC Co. Ltd., Fukuoka, Japan) to deposit PEO and PEDOT:PSS on carbon paper. The spraying solution consisted of pure commercial PEDOT:PSS commercial aqueous dispersion, with the addition of PEO (1 wt.%).

Prior to use, we stirred the solution overnight to ensure uniform mixing. As a result, the final solution contained 5 mg/mL of PEDOT, 8 mg/mL of PSS and 10 mg/mL of PEO, and it was properly loaded into a syringe. The ES process was obtained by applying a voltage value of 30 kV, thus guaranteeing the direct deposition of nanodrops onto carbon paper used as a collector substrate. The deposition lasted about 40 min, with a flow rate of 1 mL/h and a nozzle-plate distance of 90 mm. The fabricated electrodes, here called *ES PEO-PEDOT 200*, contained 200 $\mu\text{g}/\text{cm}^2$ of PEDOT, 320 $\mu\text{g}/\text{cm}^2$ of PSS and 400 $\mu\text{g}/\text{cm}^2$ of PEO. Thus, samples *USC PEO-PEDOT 200* and *ES PEO-PEDOT 200* allowed us to compare ES and USC as fabrication techniques, being equal the deposited material amount.

2.2. Characterisation Techniques

2.2.1. Morphological and Physical-Chemical Characterisations

To analyse the surface morphology of anode electrodes, we employed a Field Emission Scanning Electron Microscope (FESEM, ZEISS Supra 40, Carl Zeiss AG, Oberkochen, Germany), also featuring a detector for energy-dispersive x-ray (EDX) spectroscopy.

We examined the surface of fabricated anodes using Raman spectroscopy to highlight the presence of PEDOT:PSS by observing its fingerprint peaks. In this work, we also tried to assess how Raman spectroscopy could provide information on the uniformity of the deposited PEDOT:PSS layer. To this end, we analysed our as-fabricated samples, employing a Renishaw inVia™ Qontor Raman Microscope (532 nm laser excitation wavelength). Over the whole samples' surface, we acquired multiple single-point spectra and a $300 \times 250 \mu\text{m}^2$ map (31×17 pixels).

2.2.2. Electrochemical Characterisation and Operation in MFCs

We conducted all electrochemical characterisations using a PalmSens 4 (PalmSens BV, Municipality, The Netherlands) potentiostat. To assess the performance of fabricated electrodes in their intended environment of use, we performed both electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) in an electrolyte solution commonly used in microbial fuel cells. This solution contained sodium acetate ($\text{C}_2\text{H}_3\text{NaO}_2$, 1 g/L), ammonium chloride (NH_4Cl , 0.31 g/L), potassium chloride (KCl, 0.13 g/L) and sodium dihydrogen phosphate (NaH_2PO_4 , 2.450 g/L).

We performed EIS characterisations to investigate the interfaces arising at the anode electrode: the fabricated anodes were analysed in a three-electrode configuration, where they served as working electrodes in contact with the standard MFC electrolyte solution. A platinum wire acted as a counter electrode, while the reference was a Ag/AgCl electrode. For EIS, we applied a 0 V DC bias and an AC sinusoidal signal with a 10 mV amplitude and frequency ranging from 200 mHz to 150 kHz. Employing the same setup, we then conducted CV characterisations, applying potentials from -0.5 V to 0.9 V at 100 mV/s for 5 cycles.

Finally, to study the performances of fabricated electrodes as anodes in MFC devices, we employed a setup and procedures analogous to those described in [3].

3. Results and Discussion

3.1. Morphological and Physical-Chemical Characterisations

We analysed the morphology of the samples fabricated in comparison with bare commercial carbon paper (Figure 2a–f). As the amount of the deposited material increased, the PEDOT:PSS layer became more evenly distributed over the surface. Additionally, it was possible to observe a preferential accumulation of deposited material on the most superficial fibres. The samples containing both PEO and PEDOT:PSS confirmed a similar superficial uniformity.

Figure 2. (a–f) FESEM images of the fabricated anodes' surfaces. All images display a $75\times$ magnification, with the marker corresponding to $100\ \mu\text{m}$. (g) FESEM image of a detail on a *USC PEDOT 200* electrode and (h) map of the elemental composition (EDX spectroscopy $K\alpha_1$ peaks, represented elements: carbon, oxygen, sulphur).

Additionally, the EDX characterisation (Figure 2g,h) allowed the regions on the samples' surface where mainly carbon is present (uncovered carbon paper surface) to be distinguished from those also containing oxygen and sulphur (belonging to the deposited PEDOT:PSS).

Raman Characterisation

The Raman spectrum of carbon paper (Figure 3) presented the two peaks typical of carbon-based materials (a D band around $1347\ \text{cm}^{-1}$ related to the presence of defects, vacancies and bent sp^2 bonds in the graphitic structure, and a G band around $1573\ \text{cm}^{-1}$, which was related to the in-plane vibration of sp^2 hybridised C-C bonds). When analysing fabricated anodes, the main peaks located at 1256 , 1360 , and $1437\ \text{cm}^{-1}$ can be associated with the presence of PEDOT:PSS on top of the carbon paper substrate (respectively, with $\text{C}\alpha\text{--C}\alpha'$ inter-ring stretching, $\text{C}\beta\text{--C}\beta'$ stretching and $\text{C}\alpha=\text{C}\beta$ symmetric stretching vibrations [4,5]). The other, weaker intensity peaks observed were also in good agreement with those described in detail by Kong et al. [4].

Figure 3. (a) Raman spectra acquired at two different sites on a *USC PEDOT 200* sample, compared with those of bare carbon paper. (b) False-colour map representing the relative abundance of PEDOT:PSS on carbon paper.

As shown in Figure 3a, the two selected Raman spectra acquired at different sites on the sample featured different intensities of characteristic peaks, which hinted at a carbon-dominated (*Site 1*) or PEDOT:PSS-dominated (*Site 2*) response. Such macroscopic non-uniformity led us to further investigate potential inhomogeneities observable at the micro-scale. To this end, as previously described, we acquired a matrix of single-point measurements, producing a $300 \times 250 \mu\text{m}^2$ map. Then, by computing the ratio between the intensity of a PEDOT:PSS characteristic peak (1437 cm^{-1}) with respect to that of a carbon characteristic peak (1347 cm^{-1}), we obtained a false-colour image representing the relative abundance of PEDOT:PSS (Figure 3b).

However, this technique could only provide relative abundance information, and was not sufficient to quantify the deposited material amount. Nonetheless, we believe that the Raman mapping technique deserves further investigation, as it might prove useful for comparing deposition uniformity, both at the mm- and μ -meter scale, across several repeated samples, or to compare different deposition techniques.

3.2. Electrochemical Characterisation and Operation in MFCs

The cyclic voltammetry characterisations demonstrated an electric double-layer capacitance (EDLC) behaviour for all samples (Figure 4a).

Figure 4. (a) EIS and (b) CV characteristics acquired on fabricated samples; (c) MFC device employed to study fabricated electrodes and (d) average performance recorded on MFC experiments.

In particular, electrodes fabricated via USC exhibited a direct correlation between the deposited PEDOT:PSS amount and the capacitive response. Compared to bare carbon paper, PEDOT:PSS-modified electrodes featured an increased electrical conductivity thanks to the presence of intrinsically conductive PEDOT. Additionally, the enhanced electric double-layer capacitance could be attributed to the hydrophilic PSS, which increased the surface's wettability and thus the electrically active area. Noticeably, samples containing both PEO and PEDOT:PSS presented a further deviation from the rectangular response of the EDLC. This could be attributed to an increase in interface resistance induced by the presence of PEO, as well as to the high scan rate employed [5].

Cyclic voltammograms were reproducible between scans, symmetric between forward and reverse scan, and presented no Faradic response. Such characteristics indicate that so-fabricated electrodes are inactive in electrolytes in microbial fuel cell electrolyte and represent good candidates to be employed in MFC.

The EIS characteristics (Figure 4b), which could be physically modelled with a Randles circuit, featured a distorted arc at high frequencies, while mass transfer impedances dominated at lower frequencies. The arc distortion was associated with the non-ideal capacitance characteristic of the complex electrode–electrolyte interface. For the *USC PEDOT* samples, these results confirmed both the direct correlation between EDLC and the deposited material amount, and that PEDOT:PSS deposition effectively reduced electrodes' impedances.

Finally, starting from these promising electrochemical results, we assessed the performances of fabricated electrodes as anodes in microbial fuel cell devices, as described in [3] (and represented in Figure 4c), assembling a triplet of devices for each deposition previously described. Figure 4d displays the output potential measured from MFCs, containing *USC PEDOT* anode electrodes, during the first 16 days of activity. Each curve represents the average potential of each triplet of MFCs, highlighting how devices containing PEDOT:PSS nanostructured anodes systematically provided a higher potential output compared to bare carbon paper electrodes.

4. Conclusions

In this work, we investigated the use of Electrospray (ES) and Ultrasonic Spray Coating (USC) as innovative fabrication techniques to obtain nanostructured layers for optimising carbon electrodes' surface. Starting with commercially available polymers, PEO and PEDOT:PSS, we obtained solutions that can be conveniently employed to deposit a nanostructured conductive layer on carbon paper using ES and USC techniques. Both techniques allowed us to finely control the deposited material amount, while requiring processing times ranging from less than one hour down to a few minutes. To the best of our knowledge, this is the first time that such techniques have been employed to deposit PEDOT:PSS on anodes for bio-electrochemical systems.

Employing electron microscopy, we analysed the morphology and uniformity of the nanostructured layer as a function of the material amount deposited with both ES and USC techniques. In addition, we investigated the potential of Raman spectroscopy as a tool to validate and map the relative spatial uniformity of PEDOT:PSS depositions, across both multiple samples and different fabrication techniques.

The electrochemical characterisations demonstrated the improvements given by electrode surface modification previously described, both in terms of reduced electrical impedances and of increased capacitive properties with respect to bare carbon paper.

Finally, experiments performed in MFC devices highlighted, since the early operative stages, the performance improvements provided by ES and USC optimised anodes.
