SECTION 4J. METAL PHOTOCHEMISTRY

J1. NaOH (sodium hydroxide)

Back to Index

$NaOH + h\nu$	$\rightarrow Na(^2S) + OH$	345.6 kJ mol^{-1}	346 nm	(1)
	$\rightarrow NaO + H$	518.8 kJ mol^{-1}	230 nm	(2)
	$\rightarrow Na(^2P) + OH$	548.1 kJ mol^{-1}	218 nm	(3)

(Recommendation: 10-6, Note: 10-6, Evaluated: 10-6)

Absorption Cross Sections: The spectrum of NaOH, sodium hydroxide, has been reported by Rowland and Makide[2] (200–400 nm) and Self and Plane[3] (193–395 nm). Rowland and Makide inferred absorption cross section values and the average solar photodissociation rate from the flame measurements of Daidoji.[1] Self and Plane[3] used laser photofragment spectroscopy to measure absorption cross sections at 200 and 300 K from the production of Na atoms. The reported cross sections at the lower temperature are systematically smaller at all wavelengths, but fall within the limits of the measurement precision for the room temperature values. The results from the Rowland and Makide[2] and Self and Plane[3] studies are in reasonable agreement. The recommended cross sections in Table 4J-1 are taken from Self and Plane.[3]

Photolysis Quantum Yield and Product Studies: The quantum yield for photodissociation at wavelengths <346 nm is expected to be unity.

Table 4J-1. Recommended Absorption Cross Sections of NaOH at 298 K

λ (nm)	10^{20} σ (cm^2)
193.4	551
205.7	867
205.9	563
210.3	185
216.3	489
218.7	696
225.2	1430
230.6	1820
234.0	1680
248.4	173
254.8	115
265.9	48
268.3	41.8
277.0	19.1
285.0	7.1

J2. NaCl (sodium chloride)

Back to Index

$NaCl + h\nu \rightarrow Na + Cl$ 410 kJ mol^{-1} 292 nm (1)

(Recommendation: 87-41; Note: 10-6; Evaluated: 10-6)

Absorption Cross Sections: There are several studies of the UV absorption spectra of NaCl, sodium chloride, vapor. For a review of work prior to 1982, which was carried out at high temperatures, see Rowland and Rogers.[2] The study of Davidovits and Brodhead[1] is particularly noteworthy. They report a NaCl absorption spectrum over the wavelength range 200–300 nm for temperatures between 1123–1223 K with a cross section of $(3.5 \pm 0.3) \times 10^{-17}$ cm^2 molecule^{-1} at 238 nm. The recommended cross sections in Table 4J-2 are taken from the work of Silver et al.,[3] who measured a spectrum of gas-phase NaCl at room temperature over the wavelength range 189–360 nm by directly monitoring Na atoms produced in the photolysis of NaCl.

Photolysis Quantum Yield and Product Studies: The photolysis quantum yield for NaCl is expected to be unity for absorption above the dissociation threshold.

Table 4J-2. Recommended Absorption Cross Sections of NaCl at 300 K

λ (nm)	$10^{20}\ \sigma$ (cm^2)

J3. NaO (sodium oxide)

Back to Index

$NaO + h\nu \rightarrow Na + O$ 266.5 kJ mol^{-1} 449 nm (1)

(Recommendation: 10-6, Note: 10-6, Evaluated: 10-6)

Absorption Cross Sections: The UV absorption spectrum of NaO, sodium oxide, has been reported by Self and Plane[1] at 200 and 300 K at wavelengths between 193 and 423 nm. Absorption cross sections were determined using pulsed laser photolysis of NaO combined with detection of Na atoms using laser induced fluorescence. A systematic decrease in absorption cross section at lower temperature was reported for all wavelengths included in their study. The recommended absorption cross sections in Table 4J-3 are taken from Self and Plane,[1] which is the only study available.

Photolysis Quantum Yield and Product Studies: The photolysis quantum yield for NaO is expected to be unity for absorption above the dissociation threshold.

Table 4J-3. Recommended Absorption Cross Sections of NaO at 200 and 300 K

λ (nm)	10^{20} σ (cm^2) 300 K	10^{20} σ (cm^2) 200 K
193.4	501	–
216.3	1490	515
225.2	1100	–

J4. NaO_2 (sodium superoxide)

Back to Index

NaO_2 + hν	→ Na + $O_2(^3\Sigma)$	155 kJ mol^{-1}	771 nm	(1)
	→ Na + $O_2(^1\Delta)$	249.4 kJ mol^{-1}	480 nm	(2)
	→ NaO + O	387.4 kJ mol^{-1}	309 nm	(3)

(Recommendation: 10-6, Note: 10-6, Evaluated: 10-6)

Absorption Cross Sections: The UV absorption spectrum of NaO_2, sodium superoxide, has been reported by Rajasekhar et al.[1] at 193, 248, and 308 nm (230 K) and Self and Plane[2] at wavelengths between 193 and 423 nm (200, 230, and 300 K). Absorption cross sections were determined using pulsed laser photolysis of NaO_2 combined with detection of Na atoms using laser induced fluorescence. The results from these studies are in good agreement. At most wavelengths, the temperature dependence of the NaO_2 absorption cross sections falls within the estimated measurement uncertainty. The recommended absorption cross sections in Table 4J-4 are taken from Self and Plane.[2]

Photolysis Quantum Yield and Product Studies: The photolysis quantum yield for NaO_2 is expected to be unity for absorption above the dissociation threshold.

Table 4J-4. Recommended Absorption Cross Sections of NaO_2 at 300 K

λ (nm)	10^{20} σ (cm^2)
193.4	383
205.9	146

J6. $NaHCO_3$ (sodium bicarbonate)

Back to Index

$NaHCO_3 + h\nu \rightarrow$ Products (1)

(Recommendation: 10-6, Note: 10-6, Evaluated: 10-6)

Absorption Cross Sections: The UV absorption spectrum of $NaHCO_3$, sodium bicarbonate, at 200 and 300 K has been reported by Self and Plane[1] for wavelengths between 193 and 277 nm. Absorption cross sections were determined using pulsed laser photolysis of $NaHCO_3$ combined with detection of Na atoms using laser induced fluorescence. No significant difference in absorption cross section with temperature was reported. The recommended absorption cross sections in Table 4J-6 are taken from Self and Plane,[1] which is the only study available.

Photolysis Quantum Yield and Product Studies: The photolysis quantum yield for $NaHCO_3$ is expected to be unity for absorption above the dissociation threshold.

Table 4J-6. Recommended Absorption Cross Sections of $NaHCO_3$ at 200 and 300 K

λ (nm)	$10^{20}\ \sigma$ (cm^2) 300 K	$10^{20}\ \sigma$ (cm^2) 200 K

SECTION 5. HETEROGENEOUS PROCESSES

Table of Contents

5.1 Introduction

Historically this section has presented evaluated and tabulated published information on stratospheric heterogeneous processes. However, in recent evaluations, its scope has been expanded to include tropospheric processes, initially due to community interest in tropospheric processes that affect the fluxes of reactive species into the stratosphere, as well as heterogeneous contrail and cloud processing of exhaust species from aircraft. In addition, to support NASA's expanded interest in the climate impact of tropospheric heterogeneous processes that influence greenhouse gas concentrations and the formation and chemical evolution of tropospheric fine aerosol particles, we have included kinetic data for selected heterogeneous interactions relevant to modeling cloud droplet and aqueous aerosol chemistry in the free troposphere. For instance, recent evaluations have built on reviews[1,2] of relevant inorganic and volatile organic species (VOCs) uptake on water ice surfaces relevant to aircraft contrails and cirrus clouds.

It should be noted, however, that both stratospheric and tropospheric heterogeneous chemistry are relatively new and evolving fields, and future results can be expected to change our quantitative and even our qualitative understanding on a regular basis. Their complexity is compounded by the difficulty of characterizing the chemical and physical properties of atmospheric heterogeneous surfaces and then reproducing suitable simulations in the laboratory.[3,4]

In this section, evaluations of heterogeneous uptake processes focused on the kinetics of several highly reactive gaseous atmospheric species including: OH on ice and liquid water; O_3 on aqueous bromide solutions; N_2O_5 on liquid water, aqueous nitrate and halide solutions and mineral dust; and HO_2 on aqueous salt solutions, mineral dust and organic surfaces. In the case of N_2O_5, uptake coefficients measured in laboratories were compared with those occurring on ambient particles during field measurements. A number of new or revised values for aqueous Henry's Law constants have been added. Finally, a new evaluation area has been added to this section: the review and evaluation of aerosol optical properties for atmospherically relevant ambient aerosol components. Initial activity evaluated the complex refractive index of ammonium sulfate over wavelengths from the far infrared to the near ultraviolet.

5.1.1 Surface Types—Acid/Water, Liquids and Solids

To a first approximation there are three major types of water containing surfaces believed to be present at significant levels in the stratosphere. They are: (1) Type I polar stratospheric clouds (PSCs), nominally composed of nitric acid trihydrate (NAT, $HNO_3 \bullet 3H_2O$); (2) crystals of relatively pure water ice, designated as Type II PSCs because they form at lower temperatures than Type I and are believed to be nucleated by Type I (similar surfaces may form as contrails behind high-altitude aircraft under some stratospheric conditions); and (3) sulfuric acid aerosol, which is nominally a liquid phase surface generally composed of 60–80 weight percent H_2SO_4 and, concomitantly, 40–20 weight percent H_2O. While PSCs, as their name suggests, are formed primarily in the cold winter stratosphere at high latitudes, sulfuric acid aerosol is present year round at all latitudes and may influence stratospheric chemistry on a global basis, particularly after large injections of volcanic sulfur episodically increase their abundance and surface area. There is also evidence that ternary $H_2SO_4/HNO_3/H_2O$ liquid solutions may play a significant role in PSC formation.

In addition to the major stratospheric surface types noted above, several other types of heterogeneous surfaces are found in the stratosphere and may play a significant role in some stratospheric processes. For instance, laboratory work has indicated that nitric acid dihydrate (NAD) may play an important role in the nucleation of Type I PSCs (Worsnop et al.,[7] Fox et al.[1]) and that mixtures of solid nitric acid hydrates and sulfuric acid tetrahydrate (SAT) (Molina et al.,[4] Zhang et al.[8]) and/or a more complex sulfuric acid/nitric acid hydrate (Fox et al.[1]) may also be key to understanding Type I PSC nucleation and evolution. Analyses of the range of atmospheric conditions possible in the polar stratosphere have also led to interest in solid SAT surfaces and possibly other forms of frozen sulfuric acid aerosols (Toon et al.,[5] Middlebrook et al.[3]), as well as liquid sulfuric acid aerosols significantly more dilute than the 60–80 weight percent normally present at lower latitudes (Wolff and Mulvaney,[6] Hofmann and Oltmans,[2] Toon et al.[5]).

In the free troposphere the heterogeneous surfaces of interest include liquid or solid water (cloud droplets and crystals, contrails), and sulfate particles. Uptake data are compiled for liquid water for several reasons. First this surface is one asymptote of the aqueous acid aerosol continuum; second, the interactions of some trace species with liquid water and water ice (Type II PSC) surfaces are often similar, and third, the uptake of some trace species by liquid water surfaces in the troposphere can play a key role in understanding their tropospheric chemical lifetimes and thus, the fraction that may be transported into the stratosphere. The nature of the sulfate-bearing aerosol is complex. Field measurements by single-particle mass spectrometry show that the particles contain organic species to some degree. The chemical nature of the organics has not been quantified, although it is likely that they are highly oxidized having had long residence times in the atmosphere. Similarly, the inorganic composition is not clear. Most particles of continental origin are neutralized with ammonium, and there is some evidence from the free troposphere that this remains true far above the ground. However, in regions away from ammonia sources, there is the potential for the aerosol to be acidic. The phase of the particles may be either solid, or supercooled liquid. Low relative humidities and full neutralization with ammonia promotes crystallization, whereas higher relative humidities and acidic content are more frequently associated with liquid particles. The phase of the organics is not known but is unlikely to be crystalline and more likely to be an amorphous liquid or solid.

5.1.2 Surface Types—Soot and Alumina

Aircraft at cruise altitudes and rocket exhausts contribute small but measurable amounts of carbonaceous "soot" (Pueschel et al.[14]) and aluminized solid propellant rocket exhausts and spacecraft debris produce increasing levels of alumina (Al_2O_3) and similar metal oxide particles (Zolensky et al.[17]) in the stratosphere and upper troposphere. Soot lofted above from surface combustion sources may also be present in the upper troposphere, and to a lesser extent in the lower stratosphere. Alumina from rocket exhausts is generally emitted as liquid droplets from the rocket nozzle and crystalizes as the alpha or metastable gamma phases as it solidifies in the exhaust plume. "Soot" refers to a material that is a combination of elemental and organic carbon, with proportions varying depending on the source material and the combustion conditions. In studies of soot directed to understanding the interaction with atmospheric gases, two types of soot have been used: carbon blacks having relatively small hydrogen and oxygen contents (e.g. Degussa FW2, Cabot Monarch 1000, ground charcoal and spark-generated soot) and organic combustion soots having higher hydrogen, oxygen and nitrogen content (e.g. soot from the combustion of n-hexane, methane, propane, decane, ethylene, acetylene, toluene and stearic candles). In the case of organic combustion soot, even different fuels used to generate the soot have been reported to affect the chemistry; for example, the yields of HONO from the reaction of NO_2 with acetylene, toluene, ethylene and decane soot were observed to vary with the fuel used.[4,10]

Polycyclic aromatic hydrocarbons (PAH) and oxygenated polycyclic aromatic compounds (O-PAC) are major constituents of soot formed from the combustion of liquid fuels.[1-3,5,9,11,15] The bulk composition of soot can have varying amounts of C, H, and O. For example, Chughtai et al. [6] report that the composition (in weight %) of *n*-hexane soot varies from 87 to 92 % C, 1.2 to 1.6 % H, and 11 to 6% oxygen. Stadler and Rossi[16] showed that the elemental composition of the soot as well as its surface area depended on whether the flame was rich or lean; in the case of the rich flame giving a grey-colored soot, the composition (weight %) was 97.3% C, 0.83% H, 1.65% O, and 0.20% N while the lean flame produced a black soot comprised of 96.4% C, 0.19% H, 3.2% O, and 0.27% N.

The functional groups on the soot surface are expected to be important in terms of the uptake and reaction of gases on the surface. X-ray photoelectron spectroscopy (XPS) studies of *n*-hexane soot show surface carbon and oxygen, although the specific nature of the bonding could not be determined (Akhter et al.[3]). The surface functional groups on soot vary, depending on the fuel composition, method of generation and the post-treatment of the soot. For example, Degussa FW2 carbon black, which has been used in a number of studies of uptake and reactions of gases on soot, is post-treated with NO_2 by the manufacturer and Cabot Monarch 1000 is post-treated with aqueous HNO_3. There may be sufficient NO and NO_2 concentrations generated under some conditions during the formation of soot by spark generators that these may also have been reacted with these gases prior to collection and uptake studies. Studies of a number of gases interacting with soot surfaces suggest there are at least two and likely more, types of reactive surface sites; one type reacts very rapidly, e.g. with O_3, while others react more slowly. The first type may be most relevant to the reactions of soot particles in exhaust plumes from combustion sources, while the latter is most relevant to soot diluted in air.

Fourier transform infrared (FTIR), Raman and electron paramagnetic resonance (EPR) spectroscopic studies of n-hexane soot show C–O functionalities assigned to anhydrides and aryl ethers, alkyl ketones; they also detected -C=C–H, highly substituted aromatics and conjugated carbonyl-aromatic groups.[2,15] Kirchner et al.[13] measured the FTIR spectra of soot from the combustion of diesel fuel and *n*-hexane (described as “flame deposited”) and soot collected from a commercial spark generator in Ar, and from the emissions of a diesel automobile as well as Degussa FW2 soot (described as “filter deposited”). In all cases, absorption peaks characteristic of --C–C–, –C=C–, –C–O, aromatic –C=O, and carboxylic –C=O groups (both aromatic and aliphatic) were observed. However, the flame-deposited soot showed bands due to substituted aromatics while the filter-collected samples did not. The filter-deposited samples had bands due to aliphatic –C–H groups that were not observed for the flame-deposited soot. Only the spark-generated soot showed bands due to both –C=C–H and to –O–H.

For soot formed from the combustion of liquid fuels, the location in the flame at which the soot is collected also changes the surface enough to alter its reactions. For example, Akhter et al. [2] showed that the functional groups as well as particle size depend on the height of collection of soot from the base of the flame. Such changes appear to also alter the reactions of soot; for example, Gerecke et al.[10] measured HONO and NO yields from the reaction of NO_2 with ethylene soot and found that the HONO yield decreased with distance from the bottom of the flame that the soot was collected from, while the yield of NO increased. Kirchner et al.[13] reported much stronger infrared absorption bands due to substituted aromatics in soot samples collected from the combustion of *n*-hexane near the bottom of the flame compared to the top; in addition, absorption bands due to the –O–H group were only observed in samples collected at the bottom of the flame.

Not only can the surface groups directly affect its interaction with gases, but they determine the hygroscopic properties of the soot surface. Chughtai et al.[7,8] have shown that the hydration of soot surfaces depends on the fuel composition (particularly sulfur and trace metal content) and combustion conditions, as well as the extent of surface oxidation. A highly hygroscopic surface holding significant amounts of water may behave differently than a “dry” surface with respect to the interaction with gases; for example, black carbon suspended in aqueous solutions with ozone and irradiated to generate OH has been shown to help assist in the initiation of bulk solution phase OH chemistry.[12] There are also free radical sites on soot surfaces whose EPR signals are strongly affected by the adsorption of paramagnetic species such as NO_2 (e.g. see Chughtai et al.[6]). These unpaired electrons in soot may contribute to the surface reactivity.

The *International Steering Committee for Black Carbon Reference Materials* (http: //www.du.edu/~dwismith/bcsteer.html) has issued preliminary recommendations for representative black carbon reference materials. They recommend that soot formed from the combustion of saturated hydrocarbons, preferably *n*-hexane, be used for soot black carbon. For aerosol black carbon, they recommend the use of Urban Dust Reference Material (SRM) 1649a, which is a sample collected in Washington, D.C. in a baghouse in 1976–1977. However, for studies of the uptake and reactions of gases in the atmosphere with combustion-generated soots, organic combustion generated soots, particularly *n*-hexane soot, appear to be the most reasonable surrogate.

5.1.3 Surface Types—Solid Alkali Halide Salts and Aqueous Salt Solutions

Some modeling studies also suggest that certain types of major volcanic eruptions transport significant levels of sodium chloride and associated alkali halide salts into the stratosphere (Michelangeli et al.^{2}), so studies of stratospheric trace species interacting with solid NaCl or similar alkali halide salts, as well as salt solutions, have also been included. Sea salt aerosols are, of course, much more abundant in the troposphere, and have their largest influence on the chemistry of the marine boundary layer.

The heterogeneous chemistry of salt surfaces is very complex. For example; the uptake and reaction of gases with NaCl and NaBr have been shown to be very sensitive to the presence of small amounts of strongly adsorbed water (SAW) on the salt surface. Because water is not taken up on the 100 crystal surface of NaCl at room temperature, the SAW is thought to be concentrated at steps and edges where one water molecule can interact with two ions, resulting in a larger enthalpy of adsorption. This means that powders of salt, which have a larger surface-to-volume than single crystals, also have more SAW because of the relatively larger numbers of steps and edges. In addition, the amount of SAW on sprayed films is affected by the solvent used, with more SAW when water is used as the solvent. This SAW plays a key role in facilitating the reorganization of the surface during the reaction; thus, it appears to mobilize the product ions and allow them to recrystallize into 3-D microcrystallites of product on the surface, exposing fresh salt and allowing the reaction to continue well beyond the point that the surface would normally passivate. While the overall features of this process are reasonably well understood, the exact nature of the SAW and the molecular level interactions and processes are not. The overall effect, however, is time-dependent trace gas uptake coefficients.

Salt particles may also exist as aqueous solutions, if the relative humidities are sufficiently high. Chemistry may then occur both on the surface of the liquid droplets and in the bulk. The surface composition is not necessarily the same as the bulk. In particular, it is believed that the more polarizable anions (such as bromide and iodide) partition to the surface of such particles, perhaps affecting their reactivity. When salt aerosols freeze, the resulting particle will be composed of ice and the vast majority of the solutes will be excluded into a brine that will exist on the surface of the particles and at any grain boundaries and crystal-crystal interfaces that exist. At sufficiently low temperatures, the sodium chloride component will crystallize but other components, such as bromide, are expected to remain in an increasingly concentrated brine.[1] It is also likely that marine organics are mixed with sea-salt inorganics, via the bubble bursting mechanism occurring at the sea surface when an organic microlayer exists on the sea surface. These organics may affect the surface reactivity of salt particles.

5.1.4 Surface Composition and Morphology

The detailed composition and morphology of each surface type are uncertain and probably subject to a significant range of natural variability. Certain chemical and physical properties of these surfaces, such as their ability to absorb and/or solvate HCl and HNO_3, are known to be strongly dependent on their detailed chemical composition. Moreover, most heterogeneous processes studied under laboratory conditions (and in some cases proceeding under atmospheric conditions) can change the chemical composition of the surface in ways that significantly affect the kinetic or thermodynamic processes of interest. Thus, a careful analysis of the time-dependent nature of the active surface is required in the evaluation of measured uptake kinetics experiments. Experimental techniques which allow the measurement of mass accommodation or surface reaction kinetics with high time resolution and/or with low trace gas fluxes are often more credible in establishing that measured kinetic parameters are not seriously compromised by surface saturation or changing surface chemical composition.

The relevant kinetic uptake parameters: mass accommodation coefficients and surface reaction probabilities, are separately documented for relevant atmospheric trace gas species for the major and, where available, the minor stratospheric and upper tropospheric surfaces noted above. Since these parameters can vary significantly with surface composition (e.g., the H_2SO_4/H_2O ratio for sulfate aerosol or the HNO_3/H_2O ratio for Type I PSC) the dependence of these parameters on surface composition is reviewed where sufficient data are available. In addition, in the notes to Table 5.1, we summarize the thermodynamic information that is now available to describe the non-reactive partitioning of species to a variety of surfaces, especially ice. Due to its chemical and morphological complexity, uptake values for soot are documented in a separate table.

5.1.5 Surface Porosity

The experimental techniques utilized to measure mass accommodation, heterogeneous reaction, and other uptake coefficients generally require knowledge of the surface area under study. For solid surfaces, and most particularly for water and acid ice surfaces formed *in situ*, the determination of how the molecular scale ice surface differs from the geometrical surface of the supporting substrate is not easy. Keyser, Leu, and coworkers have investigated the structure of water and nitric acid ice films prepared under conditions similar to those used in their flow reactor for uptake studies.[6,7,9] They have demonstrated that ice films grown *in situ* from the vapor can have a considerably larger available surface than that represented by the geometry of the substrate; they have also developed a simple model to attempt to correct measured uptake rates for this effect.[8,9] This model predicts that correction factors are largest for small uptake coefficients and thick films. The application of the model to experimental uptake data remains controversial (Keyser et al.,[8] Hanson and Ravishakara,[4] Kolb et al.[10]). Some experimenters prefer to attempt growing ice surfaces as smooth as possible and to demonstrate that their measured uptake coefficients are only weakly dependent on surface thickness (Hanson and Ravishankara[5]). For the case of ice surfaces, it has been demonstrated that freezing thin films of liquid water leads to ice films that are smooth at the molecular level.[1]

Similar issues arise for uptake experiments performed on powered, fused and single crystal salt or oxide surfaces (Fenter et al.,[2] Hanning-Lee et al.[3]). There are two issues here. First, the molecular level Brunauer, Emmett, Teller (BET) surface area that is commonly measured by determining the mass of a gas such as N_2 adsorbed by a given sample mass is, for many atmospheric solids, larger than the geometric surface area. However, determining the BET surface area of porous materials does not necessarily reflect the available surface area for molecules larger than that used in the BET measurement. Second, many experimental studies have used samples consisting of multiple layers of particles in order to increase the amount of gas that is taken up and hence improve the accuracy of the measurement. However, there is considerable uncertainty in how to accurately assess the fraction of the total sample that is available for reaction. When recommendations are made for uptake coefficients on solid alkali salts in this assessment, the values have generally been obtained using at least two different sample types (e.g., powders, single crystals and spray-deposited films) and/or two different techniques (e.g., flow tubes and Knudsen cells).

The issue of surface area available for uptake is also important for interpreting uptake measurements on soot and soot surrogate surfaces. The degree to which measured uptake parameters must be corrected for porosity effects will remain in some doubt until a method is devised for accurately determining the effective surface area for the surfaces actually used in uptake studies.

Some studies evaluated in this review assume that the effective ice or salt surface area is the geometrical area, but more recent studies on solid surfaces generally attempt to assess the available surface area by employing BET measurements and porosity models. However, uncertainty in true reactive surface area for heterogeneous uptake on solids is often the dominate systematic error in reporting uptake coefficient values for these systems and makes evaluation of these data across laboratories and techniques difficult.

5.1.6 Temperature Dependences of Parameters

A number of laboratory studies have shown that mass accommodation coefficients and, to some extent, surface reaction probabilities can be temperature dependent. While these dependencies have not been characterized for many systems of interest, temperature effects on kinetic data are noted where available. More work that fully separates heterogeneous kinetic temperature effects from temperature-controlled surface composition is obviously needed.

5.1.7 Solubility Limitations

The uptake of certain trace gases by atmospherically relevant surfaces is often governed by solubility limitations rather than kinetic processes. In these cases properly analyzed data can yield measurements of trace gas solubility parameters relevant to stratospheric conditions. In general, such parameters can be strongly dependent on both condensed phase composition and temperature. Such parameters may be very important in stratospheric models, since they can govern the availability of a reactant for a bimolecular heterogeneous process (e.g., the concentration of HCl available for the HCl + $ClONO_2$ reaction on sulfuric acid aerosols) or the gas/condensed phase partitioning of a heterogeneous reaction product (e.g. the HNO_3 formed by the reaction of N_2O_5 on sulfuric acid aerosols). Surface saturation limitations have also been observed in experimental uptake studies on solid surfaces, including liquid water and water/acid ice surfaces.

5.1.8 Data Organization

Data for trace-gas heterogeneous interactions with relevant condensed-phase surfaces are tabulated in Tables 5-1 through 5-7. These are organized into:

Table 5–1 — Mass Accommodation Coefficients and Reversible Uptake Data for Surfaces Other than Soot
Table 5–2 — Surface Reaction Probabilities (γ) for Surfaces Other Than Soot
Table 5–3 — Soot-Surface Uptake Coefficients
Table 5–4 — Solubility Data for Pure Water
Table 5–5 — Ion Specific Schumpe Parameters
Table 5–6 — Solubility Data for Acids
Table 5–7 — Solubility Data for Sea Water
Data for aerosol optical properties are tabulated in Tables 5–8–1, 5–8–2, and 5–8–3.
Table 5–8–1 — Recommended Complex Refractive Indices for Ammonium Sulfate
Table 5–8–2 — Summary of Studies Having Measured the Complex Refractive Index of Ammonium Sulfate Across the Infrared Range
Table 5–8–3 — Results from Single Wavelength or Narrow Range Studies

5.1.9 Parameter Definitions

Mass accommodation coefficients (α), represent the probability of reversible uptake of a gaseous species colliding with the condensed surface of interest. For liquid surfaces this process is associated with interfacial (gas-to-liquid) transport and is generally followed by bulk liquid phase solvation. Examples include: simple surface absorption, absorption followed by ionic dissociation and solvation (e.g., $HCl + nH_2O \leftrightarrow H^+(aq) + Cl^-(aq)$), and absorption followed by a reversible chemical reaction with a condensed phase substituent (e.g., $SO_2 + H_2O \leftrightarrow H^+ + HSO_3^-$ or $CH_2O + H_2O \leftrightarrow CH_2(OH)_2$).

The term "sticking coefficient" is often used for mass accommodation on solid surfaces where physisorption or chemisorption takes the place of true interfacial mass transport.

Processes involving liquid surfaces are subject to Henry's law, which limits the fractional uptake of a gas phase species into a liquid. The distribution of a substance between the gas and liquid phase is controlled, at equilibrium, by the Henry's Law constant for that substance, which relates the concentration of the substance in solution to the partial pressure of the substance in the gas phase. In these tables, we present the Henry's Law constants as solubility values:

$$H = [\text{solution}]/P(\text{gas})$$

The units are molar (M) for solution concentration and atmosphere (atm) for the partial pressure in the gas phase. In many studies and other compilations, volatility values are presented, which are the inverse of solubility values. Often, other concentration units are used, sometimes the same unit for both phases. This leads to a dimensionless value, with no indication from the units if it pertains to solubility or to volatility.

Henry's Law is a limiting law, strictly valid only at the limit of zero concentration. For most gasses at concentrations of interest, deviations from this law are not significant. The value of the Henry's Law constant, H, depends strongly upon temperature. For a typical gas, it decreases with increasing temperature at lower temperatures, at least down to 0ºC. At higher temperatures, typically well above 298 K, the value will increase with temperature. Over limited temperature ranges, the value is well represented by a linear relationship between the logarithm of H and the reciprocal of temperature:

$$\mathrm{Ln}(H) = \mathrm{A} + \mathrm{B}/\mathrm{T}$$

For a number of gasses, the experimental data are sufficient to display the expected curvature in a plot of Ln H vs. 1/T. In this review, we have represented these results by the three-parameter equation:

$$\mathrm{Ln}(H) = \mathrm{A} + \mathrm{B}/\mathrm{T} + \mathrm{C}\ \mathrm{Ln}(\mathrm{T})$$

Below 0ºC, measurements in strong acid solutions have suggested that the Henry's Law constant for a substrate would continue to increase as the temperature is lowered. A study on the solubility of benzene, alkyl benzenes, and methyl and ethyl *tert*-butyl ethers, however, indicate that this is not the case.[11] In this study, the values were found to decrease with temperature in supercooled water. Indeed, the results from 25ºC to –25ºC are almost symmetrical around 0ºC. Additional studies on this phenomenon are clearly needed, particularly for smaller solutes.

If the gas phase species is simply solvated, a physical Henry's law constraint holds; if the gas phase species reacts with a condensed phase substituent, as in the sulfur dioxide or formaldehyde hydrolysis cases noted above, a "chemically modified" or "effective" Henry's law constraint holds (Clegg and Brimblecombe,[1] Schwartz,[9] Watson et al.[12]). This value will typically involve an equilibrium constant for the chemical process, along with the physical Henry's law constant.

The solubility of a gas also depends upon the presence of other substances in the solution. The best known effect is that of an added salt. In most cases, the addition of a salt to the solution results in a lowering of the solubility of the gas. This effect is usually described by the Sechenov equation:

$$\mathrm{Log}(c^{\mathrm{o}}/c) = \mathrm{Log}(H^{\mathrm{o}}/H) = K_S\, c_S$$

which relates the relates the ratio of the concentrations of gas dissolved for a given pressure in the absence, c^o, and presence, c, of a given concentration of salt, c_S. The proportionality constant is the Sechenov coefficient, K_S. The Sechenov coefficient is specific to both the gas and the specific salt. Thus, in general, one needs a new value for any particular gas-salt combination, a tremendous amount of data. For this reason, models have been developed to extend measurements of K_S to systems for which no measurements have been made. Schumpe and co-workers[8,13] developed the particular procedure adopted in this review. It assumes that K_S is composed of ion- and gas-specific constants:

$$K_S = \Sigma\, (h_i + h_G)\, n_i$$

where h_i is the ion-specific constant, h_G is the gas-specific constant, and n_i is the ion index. For a mixed electrolyte solution,

$$\mathrm{Log}(H^{\mathrm{o}}/H) = \Sigma\, (h_i + h_G)\, c_i$$

The small temperature dependence of K_S is assumed to lie completely in h_G. Thus,

$$h_G = h_{G,0} + h_T\, (T - 298.15\ \mathrm{K})$$

Weisenberger and Schumpe[13] analyzed 892 Sechenov constants for various gases in salt solutions over the temperature range 273 K to 363 K. They derived an optimum set of h_i, $h_{G,0}$, and h_T parameters for a diverse set of ions and gases. Values for O_2 and H^+ were set to zero to make the set unique. The standard deviation in the predicted Sechenov constants is 0.026. We have included their values for the ion-specific parameters in Table 5-5.

Available gas-specific constants, $h_{G,0}$ and h_T, are included in Table 5-4, along with the Henry's law constants for pure water. In Table 5-4, we present those "salting out" parameters included in the optimum set derived by

Weisenberger and Schumpe, along with some parameters derived from other studies. In the latter cases, the ion parameters are considered fixed and we solve for the gas-specific parameters.

Available Henry's law parameters for sulfuric acid/water, and in a few cases, sulfuric acid/nitric acid/water solutions are presented in Table 5-6. Effective Henry's law constants are designated H*, while simple physical Henry's law constants are represented by H. Effective Henry's law constants are also employed to represent decreased trace gas solubilities in moderate ionic strength acid solutions via a Sechenov coefficient formulation which relates H* to the concentration of the acid.[4] Available Henry's law constants for reactive upper tropospheric/stratospheric species in binary sulfuric acid/water solutions, and for a few cases of ternary sulfuric acid/nitric acid/water solutions, are tabulated as a function of acid weight percent and temperature. It is presently unclear whether "surface solubility" effects govern the uptake on nominally solid water ice or HNO_3/H_2O ice surfaces in a manner analogous to bulk solubility effects for liquid substrates and no solubility parameters for these "ice" systems are presented; the reader is referred to the ice uptake studies in Table 5.1.

In Table 5-7, Henry's Law parameters are presented for uptake into seawater, or into water with a salinity of 35‰. The major focus is on halogenated organic compounds, due to the possibility that this could have an impact on their atmospheric lifetimes. Due to the limited temperature ranges of these studies, only a two-parameter fit was utilized.

For some trace species on some surfaces, experimental data suggest that mass accommodation coefficients untainted by experimental saturation limitations have been obtained. These are tabulated in Table 5–1. In other cases experimental data can be shown to be subject to Henry's law constraints, and Henry's law constants, or at least their upper limits, can be determined. Some experimental data sets are insufficient to determine if measured "uptake" coefficients are true mass accommodation coefficients or if the measurement values are lower limits compromised by saturation effects. These are currently tabulated, with suitable caveats, in Table 5–1.

Also included in the specific notes in Table 5–1 are parameters relating to the non-reactive uptake of gases to solid atmospheric surfaces, such as ice. These quantities are useful for determining the likelihood that gas-phase species will be scavenged to the condensed phase, and to interpret the rates of surface-phase reactions. Many experimental approaches that can measure reactive uptake or mass accommodation coefficients can also assess the degree of non-reactive uptake, so these data are reported in the same Table. Experimental studies usually measure a total uptake (i.e. molecules or moles of adsorbate per unit surface area) at a specific temperature and gas-phase partial pressure or concentration.

By varying the gas-phase amounts, an adsorption isotherm is measured. For surfaces such as ice, simple isotherms such as the Langmuir form have been utilized. While this isotherm neglects adsorbate-adsorbate interactions and assumes that all adsorption sites are equivalent, these may be reasonable assumptions for ice surfaces, which are highly dynamic and where adsorbate molecules are likely to be strongly hydrated. From the isotherm, the saturated surface coverage at high gas-phase concentrations and the gas-surface partition coefficient can be assessed:

$$\theta \equiv \text{fractional surface coverage} = K_{conc}\,[\text{gas}] / (1 + K_{conc}\,[\text{gas}]) = K_p\,P_{gas} / (1 + K_P P_{gas})$$

where K_{conc} and K_P are the adsorption coefficients, depending on whether concentration or pressure units are used for the gas phase. For consistency with the rest of the evaluation and to match the approach typically used in the literature, surface uptakes will be reported in units of molecules/cm^2. Correspondingly, adsorption coefficients will be converted into K_{conc} units, i.e. cm^3 molecules^{-1}. Note that a partitioning coefficient (K_{part}, units molecules cm^{-2} / molecules cm^{-3}) can also be derived by taking the slope of a plot of uptake to gas-phase concentration in the surface-unsaturated regime. The relationship between a K_{conc} value derived from a Langmuir adsorption isotherm to a partition coefficient (K_{part}) is:

$$K_{part} = K_{conc}\,N_{sat}$$

where N_{sat} is the saturated surface coverage in units of molecules cm^{-2}.

By varying the temperature in uptake studies, the heat of adsorption can be derived in a van't Hoff analysis from the temperature dependence of the partition or adsorption coefficients. This approach is most accurate at low surface coverages where adsorbate-adsorbate interactions are likely to be fewest. While we report such values from the literature, care should be taken in their interpretation because an assumption of this approach is that the surface structure and the strength of the adsorbate-surface interactions remain constant as a function of temperature. Also, as the temperature changes, the degree of adsorbate-adsorbate interactions may change as well. Surface reaction probabilities (γ) are kinetic values for generally irreversible reactive uptake of trace gas species on condensed surfaces. The rates of such processes may not be limited by Henry's law constraints; however, the fate of the uptake reaction products may be subject to saturation limitations. For example, N_2O_5 has been shown to react with sulfuric acid aerosol surfaces. However, if the H_2SO_4/H_2O ratio is too high, the product HNO_3 will be insoluble, and a large fraction will be expelled back into the gas phase. Surface reaction probabilities for substantially irreversible processes are presented in Table 5-2. Reaction products are identified where known.

Surface reaction probabilities on crystalline and non-ice amorphous solid surfaces, such as alumina and alkali salts are particularly susceptible to surface saturation effects, especially when exposed to the relatively high trace gas concentrations sometimes employed in laboratory experiments. In the case of gaseous HNO_3 reacting with NaCl for example, there is a rapid initial uptake of HNO_3 and formation of nitrate on the surface, followed by a decrease to a relatively constant (but slowly declining) value. When they are available, we tabulate the initial uptake coefficient, γ_0, in Table 5-2, since that value often sets the upper limit for atmospheric uptake. In the corresponding note we may also site the reactive uptake coefficient appropriate to longer time exposure when the uptake appears to have reached an approximate steady-state, γ_{ss}.

The total experimental uptake coefficient measured in laboratory heterogeneous kinetic experiments are also often represented by the symbol γ. In those cases where surface and/or bulk reaction dominate the uptake, the total uptake coefficient (γ_{total}) and reactive uptake coefficient (γ_{rxn}) may well be identical. More formally, for cases where bulk liquid phase reaction is facile and there are no gas phase diffusion constraints, the total uptake coefficient for aerosol or cloud droplets can be approximated in terms of γ_{rxn} and γ_{sol} as:[6]

$$\frac{1}{\gamma_{total}} = \frac{1}{\alpha} + \frac{1}{\gamma_{sol} + \gamma_{rxn}}$$

where

$$\gamma_{sol} = \frac{8HRT}{\pi^{1/2}\bar{c}} \left(\frac{D}{t}\right)^{1/2}$$

and

$$\gamma_{rxn} = \frac{4HRT}{\bar{c}} \ (Dk_{rxn})^{1/2}$$

where t is the time integrated exposure of the trace gas to the liquid surface, R is the gas constant, D is the liquid phase diffusion coefficient, and $\bar{c}$ is the mean trace gas molecular speed. In the limit of low solubility or long exposure time γ_{sol} becomes negligible and

$$\frac{1}{\gamma_{total}} = \frac{1}{\alpha} + \frac{1}{\gamma_{rxn}}$$

Discussion of how to use this approach to model chemical reactions in liquid stratospheric aerosols can be found in Hanson et al.[2] and Kolb et al.[6] Note that these formulations are approximate. In cases where separate terms are competitive, more rigorous solution of the kinetic differential equations may be appropriate.

For solid surfaces, bulk diffusion is generally too slow to allow bulk solubility or bulk kinetic processes to dominate uptake. For solids, reactive uptake is driven by chemisorption/chemical reaction at the interface, a process that can also influence trace gas uptake on liquids. For liquids, surface reaction (γ_{surf}) occurs in parallel, rather than in series with mass accommodation, thus:

$$\gamma_{total} = \gamma_{surf} + \left[\frac{1}{\alpha} + \frac{1}{\gamma_{sol} + \gamma_{rxn}}\right]^{-1}$$

Examples where this more complex situation holds for liquid surfaces can be found in Hu et al.[3] and Jayne et al.[5] In such cases γ may be significantly larger than α.

Uptake of gases on soot may occur due to three different processes: (1) physisorption (e.g. SO_2 or HNO_3 at room temperature and low nitric acid pressures); (2) reaction with the surface (e.g. NO_2), and (3) catalytic decomposition/reactions of the gas on the surface. All three processes may occur in parallel, and the relative contributions of each of these three may vary during the course of the reaction as the surface "ages." As discussed above, there are different types of reactive sites on soot, leading in some cases to a rapid initial uptake followed by a slower uptake; these are often characterized as reactions on "fresh" and "aged" surfaces respectively. Another complexity is that in some cases the geometric surface areas were used to calculate the uptake coefficients from the experimental data while in others, the available reactive surface area was estimated and used.

Because of these complexities with soot heterogeneous chemistry, uptake coefficients for soot interactions with gases have been broken out into a separate Table 5-3 rather than being included with the other surfaces in Tables 5-1 and 5-2. When the uncertainty is more than an order of magnitude, a recommendation is not given in Table 5-3 and the range of reported values is given in the Notes. In most cases, the available reactive surface area rather than the geometric areas have been used in obtaining the uptake coefficients; in those cases where the geometric area was used but a higher available surface area was involved in the measured uptake, the uptake coefficient is given as an upper limit. Data are most commonly available for room temperature or there are very limited data at lower temperatures characteristic of the upper troposphere.

The data in Tables 5-1 and 5-2 for uptake on non-soot surfaces are organized by trace gas species, since some systematic variation may be expected for surface accommodation or reaction as the surface composition and/or phase is varied. Data presented for one surface may be judged for “reasonableness” by comparing with data for a “similar” surface. In some cases it is not yet clear if surface uptake is truly reversible (accommodation) or irreversibly reactive in nature. In such cases the available uptake coefficients are generally tabulated in Table 5-1 as mass accommodation coefficients, a judgment that will be subject to change if more definitive data become available.

Where a specific evaluated value for an accommodation coefficient or reaction probability has been obtained, an estimated uncertainty factor is also tabulated. However, when the data evaluation yielded only a lower or upper limit, no uncertainty factor can be reliably estimated and none is presented.

Description of and reference citations to many of the laboratory techniques used to obtain the data in the following tables can be found in Kolb et al.[6] Reactions of N_2O_5, $ClONO_2$, HOCl and $BrONO_2$ on/in sulfuric acid are generally dependent on the species’ Henry's law solubility and liquid phase diffusion coefficient in the liquid acid as well as the surface and/or liquid phase reaction rate parameters. All of these processes are generally functions of the acid composition and temperature (Hanson et al.,[2] Robinson et al.,[7] Shi et al.[10]). Thus, these reactions’ reactive uptake coefficients must be represented by a complex phenomenological or empirical models that defy simple entry into Table 5-2. The notes in Table 5-2 for these reactions discuss and present the models adopted.

To aid in visualizing the resulting reactive uptake parameters the results for several reactions have been plotted in Figure 5.1 as a function of temperature for a background pressure of 50 mbar and background water vapor and HCl mixing ratios of 5 ppmv and 2 ppbv, respectively. These calculations are presented for monodisperse background sulfate aerosol particles with a radius of 1×10^{-5} cm (0.1 μm).

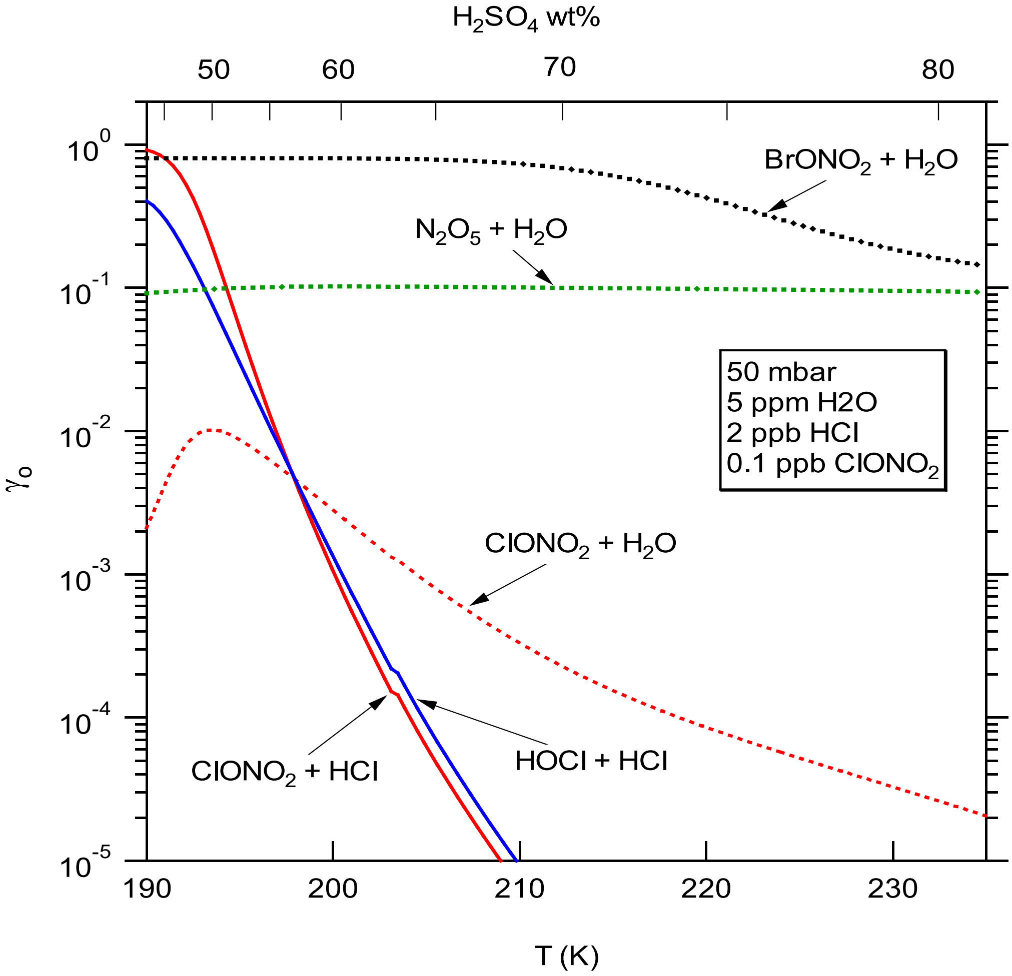

Figure 5-1. Recommended reactive uptake coefficients as a function of temperature for key stratospheric heterogeneous processes on sulfuric acid aerosols. For $ClONO_2$ and HOCl species, the aerosol radius used in the calculation is 10^{-5} cm, a typical value in the stratosphere. Because the current uptake models for N_2O_5 and $BrONO_2$ hydrolysis do not provide the information about the reacto-diffusive length (ℓ), the aerosol radius used in the calculation is assumed to be much larger than their reacto-diffusive length (i.e. ℓ for N_2O_5 and $BrONO_2$ are set to zero.)

The heterogeneous processes section has been expanded to include an evaluation of optical properties of atmospherically relevant aerosol components. Atmospheric particles are composed of one or more components, the relative abundance of which varies dramatically throughout the atmosphere.

Scattering and absorption by aerosol particles depends on both the size and composition of the particles, and on the wavelength of light. Further, scattering and absorption depend on particle shape. This assessment focuses on the complex refractive index (CRI) of major particulate components. The CRI = $n - ki$, where n is the real part and k is the imaginary part, can be used to calculate scattering and absorption by particles of a given shape. A commonly made assumption is that the particle average CRI can be calculated using a volume-weighted method:

$$\bar{n}(\lambda) = \sum_j X_j n_j\,(\lambda)$$

and

$$\bar{k}(\lambda) = \sum_j X_j k_j\,(\lambda)$$

where X_j is the volume fraction of component j and n_j and k_j are the real and imaginary components of the CRI for component j, respectively.

It is necessary to know how n and k for a given component vary with wavelength. For Earth's atmosphere, most important are the values for wavelengths between ca. 0.3 μm and 2 μm and between ca. 5 μm and 40 μm, corresponding to solar radiation and Earth's emitted radiation, respectively.

For this initial effort, we limit the assessment to a common component of submicron particulate matter, ammonium sulfate. Future assessments can include other key particulate constituents, including components that absorb in the visible wavelength range.

‡ May be affected by surface saturation

5.2.1 Notes for Table 5-1

1. **O on $H_2O(s)$.** Murray and Plane[1] measured the uptake of O atoms on water ice at temperatures relevant to the upper mesosphere (112–151 K), where noctilucent clouds are present. Their results indicate that in the absence of oxygen molecules the uptake coefficient α is small (7×10^{-6}). They recommend the following expression: $\alpha = 7 \times 10^{-6} + 1.5 \times 10^{-10} \exp(11.4 \text{ kJ/mol/RT})$, with an uncertainty of ± 24%.

2. **O on H_2SO_4•nH_2O.** Knudsen cell experiment of Baldwin and Golden[1] measured an uptake coefficient limit of $<10^{-6}$, this result probably cannot be equated with an accommodation coefficient due to surface saturation.
   Back to Table

3. **O_3 on $H_2O(s)$ and HNO_3•nH_2O.** Undoped ice surfaces saturate too quickly for reliable measurements. When ice is doped with Na_2SO_3 to chemically remove absorbed O_3 the apparent α increases to 1×10^{-2} (0.1 M) or up to 4×10^{-2} (1 M) (Dlugokencky and Ravishankara[1]). Limit of $\gamma < 10^{-6}$ for undoped ice is consistent with earlier measurement by Leu[3] of $\geq 1 \times 10^{-4}$ and with $<6 \times 10^{-5}$ obtained by Kenner et al.[2] Dlugokencky and Ravishankara also measured the tabulated value of an uptake coefficient for O_3 on a NAT "like" surface, but the data were difficult to reproduce and the surfaces were not well characterized. Kenner et al. also measured a lower limit for an uptake coefficient of 8×10^{-5} on NAT at 183 K, but this measurement is also certainly limited by surface saturation.

4. **O_3 on $H_2O(l)$.** Utter et al.[9] used a wetted wall flow tube technique with various chemical scavengers to measure a lower limit for α of 2×10^{-3}. The stopped flow measurement technique using an SO_3^{2-} scavenger (Tang and Lee[8]) is subject to saturation effects, so their quoted α of 5.3×10^{-4} is also taken as a lower limit. Using a droplet train flow reactor Hu et al.[1] measured a value of ~0.1 at 277 K with I^- as a reactive scavenger, consistent with a more extensive droplet train flow reactor measurement by Magi et al.[2] yielding a value of ≥0.1 also using I^- as a reactive scavenger and with the aerosol flow tube work of Rouvière at al.[5] that also obtained a value of >0.1 at room temperature. Schurath et al.[6] used a coaxial flow liquid jet to obtain a value of 4.5×10^{-3} at 298 K, probably limited by surface saturation although they also used I^- as a reactive scavenger. Müller and Heal[3] obtained a value of 4×10^{-2} at 293 K in a wetted wall flow tube with $S_2O_3^{2-}$ as a reactive scavenger. Schütze and Herrmann[7] measured a lower limit of 2×10^{-2} at 298 K using a suspended droplet flow reactor method that also employed I^- as a reactive scavenger. It is highly likely that the mass accommodation coefficient for ozone on liquid water is ≥0.01 between ~275 and 300 K and may be significantly higher, although it is possible that interfacial reactions with near surface I^- bias some mass accommodation evaluations high because surface reactive uptake occurs in parallel with mass accommodation. Molecular dynamic simulations of O_3 uptake on water by Roeselová et al.[4] indicate a mass accommodation coefficient of order 0.1.

5. **O_3 on H_2SO_4•nH_2O.** Flow tube measurements (Dlugokencky and Ravishankara[2]) of an uptake coefficient limit of $<10^{-6}$ on both 50 and 97 wt% H_2SO_4 surfaces are consistent with earlier, but probably less quantitative, static systems measurements of Olszyna et al.[5] and aerosol chamber measurements of Harker and Ho,[3] who report uptake coefficients of the order 10^{-8} or less for a variety of sulfuric acid concentrations and temperatures. In these earlier experiments, doping the H_2SO_4 with $Ni^{2+,}$ Cr^{2+}, Al^{3+}, Fe^{3+}, and NH_4^+ (Olszyna et al.[5]) or Al_2O_3 or Fe_2O_3 (Harker and Ho[3]) did not significantly increase measured O_3 loss. An upper limit of 1×10^{-6} was also reported by Baldwin and Golden[1] for 97 wt% H_2SO_4 at 295 K. Il'in et al.[4] performed static tube reactor measurements on 98 wt.% sulfuric acid at 239, 258, 273 K measuring uptake coefficients between 1.2 and 1.75×10^{-6}. Although these measurements are slightly larger than the limits in the other studies, uptake values this small are extremely hard to quantify and these measurements are not seen to be in serious disagreement with other studies finding slightly lower upper limits. All measurements are subject to solubility limitations and probably do not reflect true limits on mass accommodation.

6. **OH on $H_2O(s)$.** Cooper and Abbatt[1] analyzed uptake rates in a wall-coated flow tube to determine an initial γ ~0.1 over the temperature range of 205–230 K. Uptake coefficients decreased at longer exposure times, indicating surface saturation. These data indicate that α is at least 0.1 and possibly much larger. This is confirmed by an earlier experiment using a coated insert/flow tube technique by Gershenzon et al.,[2] which yielded α >0.4 at 253 K.

7. OH on $H_2O(l)$. A lower limit of α on pure water of 3.5×10^{-3} at 275 K was determined by Hanson et al.[1] using a liquid-wall flow tube. Takami et al.[4] using a gas/liquid impinging flow technique obtained a pure water value near pH 7 at 293 K of $(4.2 \pm 2.8) \times 10^{-3}$ while values 2 to 3 times higher where obtained for acid (pH=1) and basic (pH=10–13) aqueous solutions; a value of $(1.1 \pm 0.4) \times 10^{-2}$ was obtained when benzoic acid was added as a radical scavenger. Takami et al. also observed that uptake for pure water solutions decreased with gas/liquid contact times, indicating a saturation limitation and explaining the higher uptake values observed for solutions with H^+, OH^-, or benzoic acid reactive scavengers. Based on these experimental results a value of $\alpha \geq 0.1$ is suggested. This recommendation is consistent with molecular dynamics calculations by Roeselová et al.[2,3] who first published simulation values at room temperature 0.2 to 0.3, but later reported a value of 0.83 at 300 K using revised intermolecular potentials.

8. HO_2 on $H_2O(l)$, aqueous salt solutions and $H_2SO_4 \cdot nH_2O$. Determination of α in liquid-wall flow tube (Hanson et al.[2]) is dependent on gas-phase diffusion corrections; measured limit ($\alpha > 0.02$) is consistent with $\alpha = 1$. In the aqueous salt aerosol measurements of Mozurkewich et al.,[3] HO_2 was chemically scavenged by Cu^{++} from added $CuSO_4$ to avoid Henry's law constraints; the measured limit of >0.2 is also consistent with $\alpha = 1$. Thornton and Abbatt[6] and Taketani et al.[4,5] have raised the upper limit to the mass accommodation coefficient to >0.4 for Cu^{++} doped aqueous particles composed of sulfuric acid, ammonium sulfate, sodium chloride and potassium chloride, for relative humidities between 35 and 75% at room temperature. George et al.[1] report a value of >0.1 for copper-doped salt solutions as measured at low HO_2 gas phase concentrations in an aerosol flow tube reactor. This is consistent with the mass accommodation coefficient inferred by prior studies.

9. **H_2O on $H_2O(s)$.** Uptake coefficient measurements are available from Leu[5] (0.3 (+0.7, –0.1)) at 200 K, Haynes et al.[4] (1.06 ± 0.1 to 0.65 ± 0.08 from 20 to 185 K), Brown et al.[1] (0.99 ± 0.03 between 85 and 150 K and 0.97 ± 0.10 between 97 and 145 K), Fluckiger et al.[3] (0.43 at 200 K using D_2O^{18}), and Magee et al.[6] (0.006 at 223 K using levitated particles, in a wind tunnel). Uptake coefficients measured by Delval et al.[2] and Pratte et al.,[8] that should be viewed as lower limits to the mass accommodation coefficient, show a strong negative temperature dependence consistent with a precursor adsorption model; values are about 0.1 at 200 K. The sticking coefficient of D_2O on ice at a translational energy of 69 kJ/mole has been measured under ultrahigh vacuum conditions to be close to unity, consistent with other measurements (Hundt et al.[7]). At higher temperatures, Skrotzki et al.[9] have measured the growth of ice particles formed by deposition nucleation from 190 to 235 K in a large, cooled cloud chamber where supersaturations are generated by pressure expansion. Ice crystal number density and size, and ice water content are monitored. By comparing microphysical models to measured ice properties, the mass accommodation coefficient has been inferred to be 0.7(+0.3/–0.5), independent of temperature and particle size indicating that there is not a significant kinetic barrier to the uptake of water over these temperatures. The lower value measured by Magee et al. at elevated temperatures is not consistent with this report.

10. **H_2O on $H_2O(l)$.** Because the uptake of water vapor on and evaporation of water from liquid water are fundamental processes that are linked by microscopic reversibility and play extremely important roles in cloud physics, they have been the subject of over 75 published experimental studies spanning over eight decades. Many of these studies were reviewed by Marek and Staub,[7] who note values of α deduced from these experiments range from ~0.001 to 1.0, with experiments involving growing water drops tending to higher values. Recently published experiments support values near the higher end of the range. Shaw and Lamb[8] used an electrodynamic droplet levitation cell to make simultaneous ice nucleation/water droplet evaporation rate observations to deduce a range of $0.04 < \alpha < 0.1$ at 237 K. Li et al.[5] used a droplet train flow reactor to measure the uptake of small excesses of $H_2{}^{17}O$ on water droplets that were in equilibrium with the surrounding normal water vapor, deducing a value of 0.17 ± 0.03 at 280 K that increased to 0.32 ± 0.04 at

258 K. Winkler et al.[11] used Mie scattering analyses of the growth of freshly nucleated droplets in an expansion chamber to deduce 0.4< α <1.0 over a temperature range of 270 to 290 K and 0.8< α <1.0 for 250–270 K. Voigtländer et al.[10] analyzed droplet growth in a laminar diffusion flow reactor to estimate 0.3< α <1.0 at 275–277 K. Saykally, Cohen, and co-workers[1,3,9] performed a series of evaporation experiments from liquid jets and jet breakup droplet trains in very low-pressure reactors that approximate free evaporation conditions. Their studies of H/D isotope fraction in vapor from D_2O doped water jets yielded estimates of ~0.15< α <~0.3 for the temperature range of 255–295 K.[1] Further experiments with jet break-up droplet trains produced an estimate of α = 0.62 ± 0.09 for H_2O between 245 and 298 K[9] and α = 0.57 ± 0.06 for D_2O between 255 and 295 K.[3] Maerefat and coworkers used a unique shock tube method to study the time resolved evolution of water film thickness on a window surface to estimate that α = 0.35 over the temperature range 297.1–299.1 K.[6] Jakubczyk and co-workers applied an atmospheric pressure single droplet evaporation electrodynamic trap technique[4,13,14] and a continuum vapor diffusion and heat transfer model, which they argue is more complete than that employed by Winkler et al.[12] and Voigtländer et al.[10] When applied to temperature dependent data Jakubczyk and co-workers report α = 0.13 ± 0.01 at 293.1 K increasing to 0.18 ± 0.05 at 273.1 K,[14] in close agreement with magnitude and temperature dependence reported by Li et al.[5] Given the results from this wide range of experiments, it seems clear that mass accommodation values of water vapor on liquid water for temperatures below 295 K must exceed 0.1. The Li et al. and Winkler et al. experiments are further discussed in Davidovits et al.,[2] which notes that reasons for the differences in their deduced values are not yet understood.

11. **H_2O on HNO_3/H_2O(l).** Rudolf and Wagner[1] used aerosol expansion chamber techniques to illustrate that α on liquid water/nitric acid aerosols is greater than 0.3 and is consistent with 1.0 at 278 K. Experiments are similar to those at Winkler et al.;[2] supersaturated vapor may lead to a larger value of α than found for near equilibrium conditions.

13. **H_2O on H_2SO_4•nH_2O.** Baldwin and Golden[1] using a Knudsen cell measured ~2×10^{-3} at 96 wt%, which is strongly affected by surface saturation (see Note for H_2O_2 on H_2SO_4•nH_2O). Gershenzon et al.[2] used a droplet train flow reactor to measure the uptake of $H_2{}^{17}O$ on 50 wt% sulfuric acid from 250 to 278 K, on 70 wt% from 250 to 295 K, and on 82 wt% from 272 to 298 K. Measured mass accommodation coefficients range from 0.4 to 0.9, increasing with acid wt% and decreasing temperature.

14. **H_2O on NaCl(s).** Fenter et al.[3] used Knudsen cell/mass spectrometry methods to measure $\gamma < 2 \times 10^4$ for H_2O(g) uptake on NaCl powders, an observation confirmed by Beichert and Finlayson-Pitts,[1] who found $\gamma < 1 \times 10^{-5}$. However, Dai et al.[2] used FTIR spectroscopy on NaCl crystallite films at 240 and 296 K to determine that a water adlayer does adhere to dry salt and that a small fraction of surface sites (<1%) cause H_2O dissociation. It is likely that the measurements of Fenter et al. and Beichert and Finlayson-Pitts were affected by surface saturation.

15. **H_2O on NaCl(aq).** Fung et al.[1] used Mie resonance scattering techniques to quantify aqueous NaCl droplet growth (5.8 to 7.8 μm), yielding fitted values of α >0.5 and consistent with 1.0. Such droplet growth measurements require modeling of heat and mass transfer and may not correspond to atmospheric conditions near vapor/liquid equilibrium.

16. **H_2O_2 on $H_2O(s)$.** The uptake of H_2O_2 on ice surfaces has been studied by Clegg and Abbatt[1] who measured relatively small, reversible uptake between 213 and 238 K in a coated-wall flow tube experiment. The uptake scaled linearly with partial pressure and there was a weak temperature dependence, increasing with increasing temperature. By contrast, using the same flow tube technique but with a more direct H_2O_2 detection technique, values reported by Crowley and co-workers[2] are several orders of magnitude higher. A value of $K_{part} = 2.1 \times 10^{-5} \exp(3800/T)$ cm is reported. Although the source of discrepancy between these studies is not clear, the later study by Crowley and co-workers is preferred by virtue of the more direct detection technique.

Back to Table

17. **H_2O_2 on $H_2O(l)$.** Measured accommodation coefficient (Worsnop et al.[1]) has a strong negative temperature dependence over the measured range of 260–292 K, with $\alpha = 0.3$ at 260 K decreasing to 0.1 at 292 K.

Back to Table

18. **H_2O_2 on H_2SO_4•nH_2O.** Knudsen cell uptake measurements are subject to surface saturation, thus uptake coefficient value of 7.8×10^{-4} quoted by Baldwin and Golden[1] is almost certainly a lower limit for α. This effect is probably also responsible for the lack of measured uptake ($\gamma < 10^{-6}$) for NO, NO_2, SO_2, Cl_2, and other species reported in this reference and Baldwin and Golden.[2]

21. NO_2 on $H_2O(s)$. In the absence of a chemical sink, Leu[2] measured no sustained uptake of NO_2 on ice yielding an apparent $\alpha < 1 \times 10^{-4}$. Saastad et al.[3] measured a lower limit of 5×10^{-5} for temperatures between 193 and 243 K. However these values are probably influenced by surface saturation. Using a radioactive tracer in a chromatographic technique, the adsorption enthalpy has been measured to be –22 kJ/mole by Bartels-Rausch et al.[1]

22. NO_3 on $H_2O(l)$. Rudich et al.[2] analyzed uptake on KI solutions as a function of $[I^-]$ at 273 K. This work suggested that $\alpha > 0.04$, but this result may be biased due to reactive uptake by interfacial I^-. Potentially smaller estimates of α were suggested by the work of Thomas et al. as quoted in Mihelcic et al.[1] at 293 K on pure water and Thomas et al.,[4] on 293 K 0.1 M NaCl solutions, which reported uptake coefficients of 2.5×10^{-3} and 2×10^{-3}, respectively. Schütze and Herrman[3] used a single suspended droplet flow reactor technique and the resistor model to analyze uptake data on aqueous Alizarin Red S dye and NaCl solutions to estimate a 293 K value of $\alpha = 4.2\ (+2.2, -1.7) \times 10^{-3}$, consistent with the limits suggested by Thomas and co-workers. However, their data do not rule out possible surface reactions with either interfacial Cl^- or Alizarin Red S. A lower limit of 2×10^{-3} for 273–293 K is recommended.

23. HONO on $H_2O(s)$. Fenter and Rossi[3] measured reversible uptake on water ice between 180 and 200 K using a Knudsen cell technique. An initial uptake coefficient of 1×10^{-3} suggests that α equals or exceeds this value. Chu et al.[2] used a cylindrical flow reactor to measure the uptake coefficient as a function of temperature, obtaining values ranging from 3.7×10^{-3} at 178 K to 6.4×10^{-4} at 200 K, in good agreement with the results of Fenter and Rossi. On the other hand, Chu et al. report significantly lower values after correction for the effects of surface porosity, i.e. 1.4×10^{-4} at 178 K and 1.3×10^{-5} at 200 K (see Keyser et al.[6]). The adsorption enthalpy has been measured to be –32 kJ/mole by Bartels-Rausch et al.[1] Using radioactively labeled HONO uptake on ice was studied in a packed ice bed between 213 and 253 K by Kerbrat et al.,[5] who attempted to disentangle surface adsorption and bulk diffusion. A partition coefficient to the ice surface is reported ($K_{\text{Part}} = 7.4 \times 10^{-9} \exp(5.4 \times 10^3/T)$ cm) with an enthalpy of adsorption of -45 ± 20 kJ/mole. The kinetics of the diffusion into the bulk ice were studied. In another study from the same group, nitrous acid and acetic acid simultaneous uptake measurements to packed ice beds were found to be well described by a competitive Langmuir adsorption isotherm between 213 and 243 K. Labeled nitrous acid was monitored by radioactive methods, and acetic acid by CIMS (Kerbrat et al.[4]).

24. **HNO_3 on $H_2O(s)$.** Leu[10] report a lower limit of 0.2 at 195 K, Hanson[5] measured an uptake coefficient of greater than 0.3 at 191.5 and 200 K, and Aguzzi and Rossi[2] measured an uptake coefficient of 0.3 over the temperature range from 180 to 190 K with the value decreasing at T >195 with an exponential temperature dependence of –(3400 ± 500)/T. Aguzzi and Rossi attributed this change to an increasing evaporation rate, concluding that the accommodation coefficient most likely remains large. In a higher temperature regime, Hynes et al.[7] measured uptake coefficients as a function of temperature decreasing from 0.03 at 215 K to 0.006 at 235 K and Hudson et al.[6] report initial uptake coefficients ranging from 0.007 at 209 K to 0.003 at 220 K. On the other hand, Ullerstam et al.[14] report a temperature independent lower limit to the uptake coefficient of 0.1 from 200 K up to 239 K. It is unclear the extent to which the work of Aguzzi and Rossi, Hudson et al., and Hynes et al. are affected by outgassing of nitric acid from wall surfaces during uptake experiments at high temperatures, which would lead to apparently low uptake coefficients. Also, uptakes on surfaces that have already been exposed to nitric acid are smaller than on those that are freshly exposed. Additional uncertainty is introduced by the effective ice surface area in the older fast-flow measurements (see Keyser et al.[8]) but these effects should be absent in the work of Hynes et al. and Ullerstam et al., which used smooth ice surfaces.

For low partial pressure experiments and temperatures above about 190 K, the uptake of nitric acid displays both reversible and irreversible components in amounts that do not exceed monolayer coverage.[1,14,15] For high partial pressures and/or low temperatures, a different uptake regime is encountered where much larger uptakes can occur that are not necessarily atmospherically relevant. In particular, the ice surfaces may melt to form a thermodynamically stable nitric acid solution on the surface, or nitric acid hydrate layers may form. Focusing only on the sub-monolayer, atmospherically-relevant uptake regime, it is believed that the uptake proceeds initially via adsorption to the ice surface, with some degree of diffusion along grain boundaries and into the underlying ice bulk then proceeding. The relative fractions of adsorbed molecular nitric acid and dissociated nitric acid are not fully known, although it is likely that nitrate is present to a large degree.[15] Indeed, XPS and NEXAFS spectra of ice at 230 K which contains surface nitrate, formed from NO_2 hydrolysis, indicate that the nitrate is similar in character to that of ions present in a concentrated solution (Křepelová et al.[9]). The implication is that the chemical environment on the surface of ice of adsorbed nitric acid is similar to that of pure ice and concentrated nitrate solutions. For initial exposures, uptakes are saturated at between 1 to 3×10^{14} molecules cm^{-2} [1,7,14,15] when the gas phase concentrations are high (roughly 10^9 to 10^{10} molecules/cm^3) for temperatures between roughly 200 and 230 K. At lower concentrations, the surface is unsaturated and the uptakes obey temperature-dependent Langmuir adsorption curves, with enhanced uptake at low temperatures.[14] In this regime, for temperatures between 214 to 239 K, the adsorption coefficient (converted to concentration units) for the initial uptake is $K_{conc} = -8.2 \times 10^{-12}\ T + 2.01 \times 10^{-9}$ cm^3/molecule. The temperature dependence is qualitatively consistent with observations of nitric acid uptake to cirrus cloud particles, with more uptake at low temperature.[14] For repeated exposures, the amounts of nitric acid decrease relative to the initial uptake value. Cox et al.[4] have used a numerical model of the Ullerstam et al.[14] data to decouple adsorptive uptake from uptake arising by nitric acid diffusing into the upper layers of the ice. As a result, an effective temperature-dependent adsorption equilibrium constant has been deduced, which shows that roughly 85% of the uptake measured by Ullerstam et al. is adsorptive. The related enthalpy of adsorption is –31 kJ/mole. Using a radioactive tracer, chromatographic technique Bartels-Rausch et al.[3] have measured the adsorption enthalpy to be –44 kJ/mole, and Hynes et al.[7] report a value of –54 kJ/mole from a Van't Hoff analysis.

Note that uptake may be affected by co-adsorbed species. Studies by Hynes et al.[7] and Sokolov and Abbatt[11] involving co-adsorption of HCl indicate that HNO_3 binds more strongly than HCl, but that the presence of HCl does lead to suppressed HNO_3 uptake relative to behavior on bare ice surfaces. Also, enhanced uptake is observed if the ice surfaces are growing and not at equilibrium,[13] probably arising through the formation of a metastable solution of HNO_3 in ice. The uptakes are larger under burial conditions than the amounts of nitric acid that are thermodynamically stable.[12]

25. **HNO_3 on H_2O(l).** Measurements using a droplet train flow reactor show that α has a strong negative temperature dependence varying from 0.19 ± 0.02 at 268 K to 0.07 ± 0.02 at 293 K (Van Doren et al.[3]). Ponche et al.[1] measured a very consistent mass accommodation coefficient of 0.05 ± 0.01 at 297 K using the same technique. Schütze and Herrmann[2] measured a lower limit of 3×10^{-2} at 298 K using a suspended droplet flow reactor method, consistent with the droplet train flow reactor measurements.

26. **HNO_3 on HNO_3•nH_2O(s).** Hanson[1] measured uptake coefficients of >0.3 and >0.2 on NAT surfaces at 191 K and 200 K, respectively. Middlebrook et al.[2] measured an uptake coefficient of 0.7 on NAT at 197 K under conditions where both nitric acid and water vapor were co-depositing.
Back to Table

27. **HNO_3 on HNO_3•nH_2O(l).** Rudolf and Wagner[1] used an aerosol expansion chamber techniques to deduce that α for HNO_3 on 278 K H_2O/HNO_3 droplets is >0.3 and probably close to 1. The consistency of this value with smaller (~0.2) values measured for uptake on pure water by Van Doren et al.[2] is unclear, since the mechanism of co-condensation is unknown and the composition of the surface in the aerosol expansion chamber experiments may be kinetically controlled and has not been well determined.

28. **HNO_3 on H_2SO_4•nH_2O and H_2SO_4•$4H_2O$(s).** Initial uptake at 73 wt% H_2SO_4 allows a measurement of $\alpha = 0.11 \pm 0.01$ at 283 K (Van Doren et al. [7]). This value is expected to increase at lower temperatures, in a manner similar to H_2O(1) uptake (Van Doren et al.[6]). Total HNO_3 uptake is subject to Henry's law solubility constraints, even at stratospheric temperatures (Reihs et al.[4]). Solubility limitations also affected the earlier "sticking coefficient" measurements of Tolbert et al.[5] for 75 wt% H_2SO_4 at 230 K. Hanson[2] measured an uptake coefficient of >0.3 for frozen 57.7 wt% sulfuric acid at 191.5 and 200 K. Baldwin and Golden[1] reported a lower limit of 2.4×10^{-4} on 97 wt% H_2SO_4 at 295 K, also reflecting solubility limits. Iraci et al.[3] monitored nitric acid trihydrate growth on sulfuric acid tetrahydrate with infrared techniques, measuring HNO_3 uptake coefficient limits of >0.03 at 192.5 K and >0.08 at 192 K. These measurements involved co-deposition of water vapor.

29. **N_2O_5 on Aqueous Aerosol.** Gržinić et al.[1] have demonstrated that the bulk mass accommodation coefficient for N_2O_5 into nitrate water solutions is larger than 0.4 at room temperature. The experiments were performed with an isotopically labelled gas phase reactant. The data are consistent with rapid N_2O_5 dissociation in solution into NO_2^+ and NO_3^-, with the isotopically labelled nitrate undergoing significant dilution into the non-isotopically labelled pool of nitrate. This is indirect confirmation of the dissociation pathway that has been invoked previously as the first step of the mechanism by which N_2O_5 undergoes hydrolysis in aqueous solutions.

30. **HO_2NO_2 on $H_2O(s)$.** Li et al.[1] measured an uptake coefficient of 0.15 ± 0.10 at 200 K, where the uptake may be limited by surface saturation and appears to be reversible with no decomposition. Consistent with this, adsorption of $HOONO_2$ to ice was studied in a coated wall flow tube using CIMS for gas phase detection (Ulrich et al.[2]) at temperatures between 230 and 253 K. Only reversible uptake was observed, with a partition coefficient, K_{Part}, of $3.74 \times 10^{-12} \times \exp(7098/T)$ cm. Uptake is much smaller than for stronger acids, such as HNO_3.

31. **HO_2NO_2 on H_2SO_4•$nH_2O(l)$.** Baldwin and Golden[1] measured $\gamma = 2.7 \times 10^{-5}$, which is probably solubility limited; see Note for H_2O_2 on H_2SO_4•nH_2O.

32. **NH_3 on $H_2O(s)$.** NH_3 interacts somewhat efficiently with ice surfaces according to the coated-wall flow tube results of Jin and Chu[1] at 190 K. The porosity-corrected uptake coefficients are 4×10^{-4}, with no evidence for surface saturation when partial pressures of 10^{-6} Torr are used over hours of exposure time. This suggests that the surface is being substantially modified by the NH_3 exposure.
Back to Table

33. **NH_3 on $H_2O(l)$.** Ponche et al.[3] used a droplet train technique to obtain $\alpha = (9.7 \pm 0.9) \times 10^{-2}$ at 290 K, and Bongartz et al.[1] used a liquid jet technique to obtain $\alpha = 4.0\ (+3.0, -0.05) \times 10^{-2}$ at the same temperature. These experiments where extended to other temperatures by Carstens et al.,[2] demonstrating a negative temperature dependence. Ammonia uptake on liquid water as a function of both pH and temperature was investigated by Shi et al.[4] using a droplet train apparatus, yielding values that also demonstrated negative temperature dependence, varying between 0.08 at 290 K to 0.35 at 260 K. The data from these four studies are all in reasonable agreement and a temperature dependent data plot with a non-linear least squares fit to all of these measurements has been published by Worsnop et al.[6] Earlier levitated droplet evaporation experiments[5] on NH_4Cl obtained a larger evaporation coefficient of $\alpha = 0.29 \pm 0.03$, which is discounted because of the indirect nature of the experiment.

34. CO_2 on $H_2O(s)$. The uptake of carbon dioxide on ice has been studied in a classical BET adsorption experiment from 209 to 263 K by Ocampo and Klinger.[1] The system is unusual in that the measured uptakes are higher at higher temperatures, unlike the behavior displayed by most gases that physically adsorb to ice surfaces. Similar to SO_2, the uptake may occur via formation and decomposition of H_2CO_3 in which case the ice surfaces may be somewhat acidified by this process.

Back to Table

(1) Ocampo, J.; Klinger, J. Adsorption of N_2 and CO_2 on ice. *J. Colloid Interface Sci.* **1982**, *86*, 377-383, doi:10.1016/0021-9797(82)90083-2.

35. CO_2 on $H_2O(l)$. Noyes et al.[2] used a dynamic stirring technique to monitor pressure decreases in a closed cylinder. They inferred $\alpha = (5.5 \pm 0.5) \times 10^{-8}$ at 293 K. This technique is uncalibrated against more widely used procedures and probably suffers from severe surface saturation effects. Schurath et al.[3] employed a coaxial jet flow technique to measure a 298 K value of α of $1–2 \times 10^{-4}$, noting that its low Henry's law solubility in water made the measurement very difficult. For this reason, the measurement probably also suffered from surface saturation even at their shortest gas/liquid contact times, so this value is most likely a lower limit. Boniface et al.[1] used a bubble train reactor to study the uptake by water as a function of pH. At high pH the reaction of CO_2 with OH^- partially relieves surface saturation allowing determination that the uptake coefficient, and therefore α, is $\geq 1 \times 10^{-5}$, consistent with the value measured by Schurath et al. and completely inconsistent with the much lower value obtained by Noyes et al.[2]

36. CH_3OH on $H_2O(s)$. The uptake of methanol on ice has been measured in a coated-wall flow tube from 198 to 213 K[2,3] and in a Knudsen cell from 150 to 180 K.[1] Reversible uptakes are observed. Winkler et al. fit their data to a Langmuir adsorption isotherm and report $K_{part} = 6.24 \times 10^{-12} \exp(6178/T)$ cm and $N_{sat} = 3.2 \times 10^{14}$ molecules/cm^2. Hudson et al. measure the initial uptake coefficient and find it to be strongly temperature dependent, decreasing with increasing temperature to less than 0.01 at 180 K.

38. **CH_3CH_2OH on $H_2O(s)$.** The uptake of ethanol on ice has been measured in coated-wall flow tubes by Sokolov and Abbatt[3] from 217 to 236 K, by Peybernes et al.[2] from 193 to 223 K, by Kerbrat et al.[1] from 213 to 243 K, and by Symington et al.[4] from 208 to 228 K. In all cases, either BET or Langmuir adsorption isotherms are obeyed and saturated surface coverage is observed at 2 to 3 × 10^{14} molecules/cm^2, with reversible adsorption and desorption of ethanol displayed. Similar adsorption enthalpies are reported: –62 kJ/mole (Sokolov and Abbatt), –57 kJ/mole (Peybernes et al.), –68 kJ/mole (Kerbrat et al.), and –54 kJ/mole (Symington et al.). Symington et al. report a partition coefficient, K_{Part}, of $1.36 \times 10^{-11} \exp(5573/T)$ cm.

39. **CH_3CH_2OH on $H_2O(l)$.** Jayne et al.[1] measured uptake from 260–291 K with a droplet train flow reactor and derived mass accommodation coefficients fitting $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -11.0$ kcal/mol + 46.2 cal mol^{-1} K^{-1} T(K). Similar, but somewhat larger values were reported for chloro-, bromo-, and iodo-ethanols. Shi et al.[3] used the same technique to measure the uptake of both normal and deuterated ethanol over the temperature range of 263–291 K as a function of pH. Normal ethanol uptake was not dependent on pH, while the uptake of the deuterated species was enhanced by surface isotopic exchange, especially at high and low pH. The mass accommodation values obtained for normal ethanol obtained by Shi et al. ranged from 0.128 ± 0.023 at 263 K to 0.057 ± 0.005 are consistent, within experimental error, with the lowest temperature value measured by Jayne et al., but are significantly higher above ~275 K. Katrib et al.[2] also used the droplet train technique to measure the ethanol mass accommodation coefficient between ~266 and 281 K, obtaining lower values than those measured by Shi et al.,[3] but agreeing with the higher temperature data of Jayne et al.[1] Katrib et al. obtained mass accommodation coefficients fitting $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -(5.6 \pm 1.5)$ kcal/mol + (27.4 ± 5.5) cal mol^{-1} K^{-1} T(K). While the data of Shi et al. and Katrib et al. are off-set by about a factor of three, the negative temperature dependencies measure by the two groups are very similar. The differences among the three data sets are difficult to explain, given that all three used essentially the experimental same technique; the recommended lower limit is consistent with the lower values measured by Katrib et al.[2]

40. $CH_3CH_2CH_2OH$ on $H_2O(s)$. The uptake of propanol by ice surfaces was studied in a coated-wall flow tube by Sokolov and Abbatt.[1] Uptake was well described by a Langmuir adsorption isotherm at 228 K, with a saturated surface coverage of 3.1×10^{14} molecules/cm^2 and an adsorption coefficient $K_{conc} = 8.3 \times 10^{-14}$ cm^3/molecule.

41. $CH_3CH_2CH_2OH$ and $CH_3CH(OH)CH_3$ on $H_2O(l)$. Jayne et al.[1] measured uptake coefficients between 260 and 291 K and derived accommodation coefficients fitting $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -9.2$ kcal mol^{-1} + 40.9 cal mol^{-1} K^{-1} T(K) for 1-propanol and -9.1 kcal mol^{-1} + 43.0 cal mol^{-1} K^{-1} T(K) for 2-propanol. Similar data for t-butanol were also reported.

43. CH_3O_2 on NaCl(s). Gershenzon et al.[1] measured the uptake of CH_3O_2 on crystalline NaCl(s) in a central rod flow apparatus. They determined a value of $\gamma = (4 \pm 1) \times 10^{-3}$ at 296 K, suggesting that $\alpha \geq 4 \times 10^{-3}$.
Back to Table

(1) Gershenzon, Y. M.; Grigorieva, V. M.; Ivanov, A. V.; Remorov, R. G. O_3 and OH sensitivity to heterogeneous sinks of HO_x and CH_3O_2 on aerosol particles. *Faraday Discuss.* **1995**, *100*, 83-100.

44. CH_3OOH on $H_2O(l)$. Magi et al.[1] used a droplet train flow reactor to measure α over a temperature range of 261–281 K, showing a negative temperature dependence with values ranging from 9.2×10^{-3} at 281 to 20.8×10^{-3} at 261 K. Allowing for measurement uncertainty produces a recommendation that $\alpha \geq 7 \times 10^{-3}$ from 260 to 282 K.

45. CH_2O on $H_2O(s)$. The uptake of formaldehyde on ice in a coated-wall flow tube has been measured by Winkler et al.[2] They report reversible uptake behavior with a partition coefficient of $K_{part} = 0.7$ cm, temperature independent between 198 and 208 K. At much higher temperatures (238 to 268 K), the

partitioning to ice was studied by Burkhart et al.[1] using artificial snow. It was found that the partitioning increased at lower temperatures, in accord with Winkler et al. Although there is also likely to be a significant surface component, the partition coefficients in this work are expressed in bulk solubility format, ranging from 56 to 245 M/atm from 268 to 238 K.

46. CH_2O on $H_2O(l)$ and H_2SO_4•$mHNO_3$•$nH_2O(l)$. Jayne et al.[4] report uptake measurements for 0–85 wt% H_2SO_4 and 0–54 wt% HNO_3 over a temperature range of 241–300 K. Measured uptake coefficients vary from 0.0027–0.027, increasing with H^+ activity (Jayne et al.[4] and Tolbert et al.[5]), and with increasing pH above 7 (Jayne et al.[3]). Reversible uptake is solubility limited through reactions to form $H_2C(OH)_2$ and CH_3O^+. A model of uptake kinetics (Jayne et al.[4]) is consistent with $\gamma = 0.04 \pm 0.01$ for all compositions. A chemisorbed surface complex dominates uptake at 10–20 wt% H_2SO_4, and CH_3O^+ formation dominates above 20 wt% (Tolbert et al.,[5] Jayne et al.,[4] and Iraci and Tolbert[2]). Low temperature (197–214 K) uptake studies by Iraci and Tolbert[2] confirm that uptake is solubility limited for uptake coefficients in the 10^{-3} to 10^{-2} range even at low temperatures. These chemical mechanisms allow γ to greatly exceed α for strong acidic and basic solutions. A full uptake model for acid solutions is presented in Jayne et al.,[4] and for basic solutions in Jayne et al.[3] XPS surface analysis by Fairbrother and Somorjai[1] failed to see CH_3O^+ surface species reported by Jayne et al.; however, their sensitivity of 1% of surface coverage is too poor to see the predicted amounts of the surface species.

47. CH_3CHO on $H_2O(s)$. The uptake of acetaldehyde to ice surfaces was measured in a Knudsen cell from 120 to 160 K by Hudson et al.[1] finding the uptake to decrease with increasing temperature. Fitting the results to a Langmuir adsorption model and extrapolating to 210 K, the authors conclude that there will be low surface coverages under upper tropospheric conditions of <5 × 10^9 molecules/cm^2. Hudson et al. report the initial uptake coefficient and find it to be strongly temperature dependent, decreasing with increasing temperature to less than 0.01 at 160 K. Petitjean et al.[2] have used a coated-wall flow tube to measure relatively small reversible uptakes. They report saturated surface coverages of between 1 and 2 × 10^{14} molecules/cm^2 and a heat of adsorption of –16 kJ/mole from 203 to 233 K. A higher heat of adsorption is calculated if the entropy of adsorption is fixed according to Trouton's rule. Larger uptakes are observed on mixed ice and nitric acid solution surfaces.

49. CH(O)CH(O) on $H_2O(l)$. Schweitzer et al.[1] used a droplet train flow reactor to investigate the uptake of glyoxyl by water droplets over a temperature range of 263–283 K; measured uptake was near their detection limit. They reported an average α over their experimental temperature range of $2.3\ (+1.1/-0.7) \times 10^{-2}$.

50. $CH_3C(O)CH_3$ on $H_2O(s)$. The uptake of acetone to ice surfaces has been measured in both coated-wall flow tubes[1,2,4-6] and in a Knudsen cell.[3] Reversible uptake that is described by the simple Langmuir adsorption isotherm is demonstrated. Winkler et al. report a partition coefficient $K_{part} = 1.25 \times 10^{-10} \exp(5575/T)$ cm, an enthalpy of adsorption of –46 kJ/mole, and a saturated surface coverage of 3×10^{14} molecules/cm^2, for temperatures between 198 and 218 K. Symington et al.[5] report a partition coefficient $K_{part} = 3.04 \times 10^{-9} \exp(4625/T)$ cm, an enthalpy of adsorption of –39 kJ/mole, and a saturated surface coverage of 3×10^{14} molecules/cm^2, for temperatures between 208 and 228 K. Between 193 to 223 K, Peybernes et al.[4] report an adsorption enthalpy of –49 kJ/mole with a smaller saturated surface coverage of 1.3×10^{14} molecules/cm^2. By fitting observed adsorption and desorption profiles at 190 to 220 K, Behr et al. conclude that a two-site model best represents their observations. Total adsorbed species are close to 3×10^{14} molecules/cm^2 at saturation but the modeling suggests the presence of two crystallographic surfaces, one which binds acetone more strongly than the other. The relative proportion of the sites changes with ice film age, and adsorption energies are between –32 and –49 kJ/mole. Bartels-Rausch et al. report very similar adsorption enthalpies (–51 ± 2 kJ/mole) on a range of ice surfaces, including single and polycrystalline laboratory crystal ice, and snow from the field, at 198 to 223 K. Hudson et al. report somewhat smaller adsorption enthalpies at low temperatures (140 to 170 K) ranging from –28 to –39 kJ/mole. They also measure the initial uptake coefficient and find it to be strongly temperature dependent, decreasing with increasing temperature to less than 0.1 at 170 K.

51. **$CH_3C(O)CH_3$ on $H_2O(l)$.** Duan et al.[1] measured uptake between 260 and 285 K, deriving $\alpha = 0.066$ at the lower temperature and 0.013 at the higher, with several values measured in between. Measured values fit $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -12.7$ kcal/mol + 53.6 cal mol^{-1} K^{-1} T(K). Schütze and Herrmann[2] used a single suspended droplet flow reactor to measure the uptake of acetone and several larger carbonyl compounds at 293 K; their value for acetone of $\alpha = 5.4(+4.5/-2.6) \times 10^{-3}$ agrees well with the values of Duan et al. extrapolated to 293 K.
Back to Table

54. **$CH_3OC(O)OCH_3$ on $H_2O(l)$.** Katrib et al.[1] measured the uptake of dimethyl carbonate on pure water and 0.1 M aqueous NaOH over a temperature range of 270–278 K using a droplet train flow reactor. Uptake was not obviously dependent on $[OH^-]$ and displayed a negative temperature dependence with individual measurements varying from $(11 \pm 2) \times 10^{-2}$ at 270 K to $(1.2 \pm 0.9) \times 10^{-2}$ at 276 K. Although the data are fairly noisy the authors derived a mass accommodation coefficient fitting of $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -(26 \pm 9)$kcal mol^{-1} + (99 ± 35) cal mol^{-1} K^{-1} T(K). Similar mass accommodation data for diethyl carbonate are also presented.

55. **$HC(O)OH$ on $H_2O(s)$.** The uptake of formic acid on ice has been measured in coated-wall flow tube from 187 to 221 K by von Hessberg et al.[3] and Jedlovsky et al.[1] Reversible uptakes are observed. Von Hessberg et al. fit their data to the Langmuir adsorption isotherm and report the adsorption constant to be $K_{conc} = 1.54 \times 10^{-24} \exp(6150/T)$ cm^3/molecule, for a saturated surface coverage of 2.2×10^{14} molecules/cm^2. Using a coated-wall flow tube coupled to a mass spectrometer, Symington et al.[2] report partition coefficients from 208 to 238 K. The uptake was reversible with partition coefficients, K_{Part}, of $1.5 \times 10^{-8} \exp(5143/T)$ cm.

57. $CH_3C(O)OH$ on $H_2O(s)$. The uptake of acetic acid on ice has been measured in coated-wall flow tubes by Sokolov and Abbatt[3] from 222 to 245 K, by Picaud et al.[2] from 193 to 223 K, by von Hessberg et al.[5] from 197 to 227 K, and Symington et al.[4] from 208 to 238 K. In all cases, either BET or Langmuir adsorption isotherms are demonstrated and saturated surface coverage is observed with between 2 to 3 × 10^{14} molecules/cm^2. The values of the partition coefficients between the Sokolov and Abbatt, von Hessberg et al. and Symington et al. studies agree to within roughly a factor of two, whereas the Picaud et al. results are one to two orders of magnitude smaller at low temperatures. The overall adsorption coefficient expressions from the Sokolov and Abbatt data, von Hessberg et al. and Symington et al. are $K_{conc} = 8.3 \times 10^{-28} \exp(7825/T)$, $6.55 \times 10^{-25} \exp(6610/T)$, and $2.2 \times 10^{-23} \exp(5703/T)$ cm^3/molecule (assuming a saturated surface coverage of 2.5×10^{14} molecules/cm^2), respectively. Nitrous acid and acetic acid simultaneous uptake measurements to packed ice beds were found to be well described by a competitive Langmuir adsorption isotherm between 213 and 243 K. Labeled nitrous acid was monitored by radioactive methods, and acetic acid by CIMS (Kerbrat et al.[1]).

58. $CH_3C(O)OH$ on $H_2O(l)$. Jayne et al.[1] using a droplet train flow reactor measured uptake coefficients for acetic acid between 260 and 291 K and derived a mass accommodation coefficient fitting $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -8.1$ kcal mol^{-1} + 34.9 cal mol^{-1} K^{-1} T(K). Shi et al.[2] used the same technique to measure the uptake of both normal and deuterated acetic acid at 258 K and pH = 7. They obtained α = 0.19 (± 0.03) for normal acetic acid, while the uptake coefficient of the deuterated species was enhanced by surface isotopic exchange, equaling 0.96 (± 0.21).

61. **OClO + $H_2O(s)$.** Brown et al.[1] and Graham et al.[2] used complementary ultra high-vacuum (UHV) and coated-wall flow tube techniques to show sub-monolayer reversible absorption of OClO on water ice at 100 K (UHV) and 189 and 200 K (flow tube). No kinetic data are available at stratospheric temperatures but the mass accommodation coefficient for 100 K ice surfaces is near unity, with values of 0.8 ± 0.2 reported for amorphous ice and 0.6 ± 0.2 for crystalline ice.[2]

62. **HCl on $H_2O(s)$.** The uptake coefficients of Leu[17] (0.4; +0.6, –0.2) and Hanson and Ravishankara[10] (≥0.3) are in reasonable agreement at stratospheric ice temperatures. At somewhat higher temperatures (205 K), Hynes et al.[13] measured slightly lower values (0.1) which decreased at higher temperatures. At very low temperatures (80 to 120 K), Rieley et al.[22] measured $\alpha = 0.95 \pm 0.05$.

A great deal of experimental effort (Abbatt et al.;[1,2] Barone et al.;[3] Koehler et al.;[14] Chu et al.;[4] Foster et al.;[6] Graham and Roberts ;[8] Graham and Roberts;[9] Hanson and Ravishankara;[10] Henson et al.;[11] Hynes et al.;[13] Leu et al.;[18] Marti et al.;[19] McNeil et al.;[21] and McNeil et al.[20], Kong et al.,[15] Zimmerman et al.[25]) has gone into understanding the magnitude and nature of the uptake of HCl by ice surfaces under stratospheric and upper tropospheric conditions. A general observation is that water ice at stratospheric temperatures can take up a significant, but sub-monolayer, amount of HCl even at HCl partial pressures typical of the stratosphere. However, quantitative agreement in the size of the uptake is lacking, with a range of close to three orders of magnitude for partial pressures of 10^{-7} Torr at roughly 200 K. One issue is that the specific surface area of the ice was not measured in a number of early studies. Because the ice surface may have some roughness, depending on how it is prepared, a number of these uptakes may be biased high, if the surfaces were assumed to be smooth. Another issue is the partial pressure dependence of the uptake. In accord with a number of uptake measurements of other species on ice, saturated surface coverages are observed at about 2 to 3 × 10^{14} molecules/cm^2 in experiments where the specific surface area of the ice is well known (e.g. Henson et al.,[11] Hynes et al.,[13] McNeil et al.[20] and Zimmerman et al.[25]). The drop-off into the unsaturated part of the adsorption isotherm appears to vary from experiment to experiment, as the HCl partial pressure is lowered. For example, Hanson and Ravishankara,[10] do not observe a drop off down to partial pressures well below 10^{-7} Torr, whereas others (e.g. Henson et al.[11] and McNeil et al.[20]) see a significant drop-off at higher partial pressures. And so, at the very low partial pressures of the upper troposphere, the surface coverage may be quite unsaturated; even in the stratospheric regime, there may not exist a full monolayer coverage.

A number of studies have been particularly thorough. For example, in a coated-wall flow tube study on a variety of ice surfaces at close to 200 K McNeill et al.[20] show that uptakes obeyed conventional Langmuir adsorption isotherms, and that they did not scale as well with the dissociative Langmuir isotherm. A weak adsorption enthalpy of –15 kJ/mole was derived. Langmuir adsorption constants, $K_{conc} = 3.1 \times 10^{-11}$, 8.4×10^{-11}, and 3.9×10^{-11} cm^3/molecule, were obtained at 213, 203, and 196 K, respectively. There is good agreement between McNeill et al. and the work of Zimmerman et al.[25] which used a similar experimental approach, and obtained a temperature independent K_{conc} value of 3.7×10^{-11} cm^3/molecule over the temperature range from 190 to 220 K. By contrast the work of Henson et al.[11] using a static adsorption technique yields a much lower (one to two orders of magnitude) surface coverage for the same HCl partial pressures and temperatures.

Note that for the same experimental conditions, the uptake may be affected by co-adsorbed species. Studies by Hynes et al.[12] and Sokolov and Abbatt[23] involving co-adsorption of HNO_3 indicate that HNO_3 binds more strongly than HCl, but that the presence of HCl does lead to suppressed HNO_3 uptake relative to behavior on bare ice surfaces. Fernandez et al.[5] also show that HCl uptake is significantly suppressed on a surface that has been exposed to HNO_3.

Both the thermodynamic and spectroscopic properties of adsorbed HCl suggest that a large fraction dissociates to ions, forms ionic hydrates (especially at low temperatures), and is highly reactive (with $ClONO_2$, HOBr and HOCl). Also, adsorption and desorption profiles in flow tubes suggest that uptake occurs via both reversible and irreversible processes, probably related to partitioning to different surface sites such as the ice faces or grain boundaries. Measurements using x-ray photoelectron spectroscopy at high pressure have directly observed both dissociated and undissociated states at the surface of ice at 253 K (Kong et al.[15]). The physisorbed molecular state is closer to the surface than the dissociated molecules. These experimental results contrast with initial theoretical calculations that predicted undissociated HCl hydrogen bonded to the ice surface and a very small adsorption probability at stratospheric temperatures (Kroes and Clary[16]); more recent simulations result in higher adsorption energies and theoretical accommodation coefficients of one for 190-K surfaces (Wang and Clary[24]). Molecular dynamics calculations by Gertner and Hynes[7] also show that ionic absorption is thermodynamically favorable by about 5 kcal/mole, facilitated by the role of mobile water molecules on the ice surface that can hydrate the ions. Using ellipsometry McNeil et al.[21] have experimentally shown the presence of a disordered layer on the ice surface, sometimes referred to as the quasi liquid layer, arising from HCl adsorption at low temperatures and partial pressures. The work of Kong et al.[15] confirms the disruption of the hydrogen bonding network. By contrast, at HCl partial pressures significantly above those typical of the stratosphere, a thermodynamically stable liquid surface layer forms on the ice, greatly enhancing the total amount of HCl that the surface can absorb (Abbatt et al.[2]). These conditions should be avoided for lab studies as they are not atmospherically appropriate.

63. HCl on H_2O(l). Recommendation is based on Van Doren et al.[4] and Schweitzer et al.[2] Using a droplet train flow reactor, Van Doren et al.[4] measured α's decrease from 0.18 ± 0.02 at 274 K to 0.064 ± 0.01 at 294 K, demonstrating strong negative temperature dependence. Schweitzer et al.[2] used the same technique over a temperature range of 262 to 281 K obtaining values decreasing from 0.24 to 0.13 that agree very well with the Van Doren et al. data. Tang and Munkelwitz[3] have measured a larger (0.45 ± 0.4) HCl evaporation coefficient for an aqueous NH_4Cl droplet at 299 K. In accord with large mass accommodation coefficients, dynamical studies by Faust et al.[1] with a liquid microjet of lithium halide solutions at 238 K indicate that HCl is efficiently ionized and taken up into solution, rather than experiencing efficient desorption to the gas phase.

64. **HCl on HNO_3•nH_2O.** There was previously severe disagreement between Hanson and Ravishankara[3] ($\alpha \geq 0.3$) for NAT (54 wt% HNO_3), and Leu and coworkers (Moore et al.[5] and Leu et al.[4]). However, subsequent experiments at lower HCl concentrations by Leu and coworkers[2] as well as Abbatt and Molina[1] are generally consistent with Hanson and Ravishankara. The measurements of Hanson and Ravishankara are consistent with $\alpha = 1$. The experiments at stratospherically representative HCl concentrations show that HNO_3-rich NAT surfaces adsorb significantly less HCl than H_2O-rich surfaces, with the uptake at a fixed temperature determined by the partial pressure of water.[1]

65. **HCl on H_2SO_4•nH_2O.** Measurements by Watson et al.[9] at 284 K show $\alpha = 0.15 \pm 0.01$ independent of n for $n \geq 8$. Experimental uptake and, therefore, apparent α falls off for $n \leq 8$ ($\geq$40 wt% H_2SO_4). This behavior is also observed at a stratospheric temperature (218 K) by Hanson and Ravishankara.[4] Hanson and Lovejoy[3] reported a value of 0.75 ± 0.2 for 26 wt% H_2SO_4 at 272 K. More extensive measurements performed by Robinson et al.[7] at lower temperatures, also yielded higher values, reaching 1.03 ± 0.10 for 39 wt% H_2SO_4 at 230 K; they also observed enhanced uptake for 69 wt% H_2SO_4 that was attributed to the formation of chlorosulfonic acid. Solubility constraints also controlled earlier low temperature uptake measurements of Tolbert et al.[8] A review of the most recent solubility data is presented in Table 5-6.

Molecular beam measurements of HCl impingement on liquid deuterated sulfuric acid surfaces determine the fraction of HCl scattered with no reaction and the fraction that is reactively converted and emitted as DCl. The fraction converted to DCl is assumed to have undergone interfacial transport, representing a lower limit to the mass accommodation coefficient, which varies from ~0.7 at 53–55 wt% D_2SO_4 to ~0.1 near 70 wt.% Behr et al.[1] More recent measurements indicate that the conversion fraction is relatively insensitive to HCl kinetic energy over the range of 6 to 140 kJ mol^{-1}, and that the conversion fraction for 72 wt% D_2SO_4 varies less dramatically, from~0.33 at 213 K to ~0.47 at 243 K Behr et al.[2] The basic technique and analysis rationale are reviewed by Nathanson.[5] The impact of organic surfactants on mass accommodation sulfuric acid, including the surprising fact that a surface layer of butanol actually significantly enhances HCl uptake in 213 K, 56–68 wt% D_2SO_4 is reviewed in Park et al.[6] These studies strongly indicate that the mass accommodation coefficient for 50–72 wt% sulfuric acid surfaces for temperatures below 243 K is >0.1.

70. HBr on H_2O(s) and $HNO_3 \cdot nH_2O$. Hanson and Ravishankara[5,6] have reported large uptake coefficients for HBr on 200-K ice and NAT. Lower limits of >0.3 and >0.2 for ice are reported in the two referenced publications, respectively, and a limit of >0.3 is reported for NAT. No surface saturation was observed, leading to the supposition that HBr, like HCl, dissociates to ions on ice surfaces at stratospheric temperatures. Abbatt[1] measured an uptake coefficient lower limit of >0.03 on water ice at 228 K consistent with Hanson and Ravishankara. Rieley et al.[9] measured an α of 1.0 ± 0.05 for water ice at 80–120 K. Flückiger et al.[4] report α values of ~0.2 at 210 K, increasing to ~0.3 at 190 K, while Percival et al.[8] measured an α of 0.03 ± 0.005 for water ice at T >212 K, and $\alpha > 0.1$ at T <212 K, attributing the apparent increase in the uptake coefficient to an increase in the surface area of the ice. Hudson et al.[7] report $\alpha = 0.61 \pm 0.06$ at 140 K, and $\alpha = 0.24 \pm 0.05$ at 100 K, for HBr pressures ranging from 3×10^{-8} to 1.4×10^{-7} Torr. Equilibrium HBr coverages for ice are reported by Chu and Heron[3] at 188 and 195 K, and by Chu and Chu[2] at 180–220 K. The latter authors also report the formation of various solid HBr hydrates. Given that no surface saturation is observed in the kinetics experiments leads to the supposition that HBr, like HCl, dissociates to ions. In addition to hydrate formation, it is likely that bulk melting of the ice surfaces may occur at stratospheric temperatures and the partial pressures used in the lab, to form thermodynamically stable HBr-H_2O solutions. Such behavior may not occur in the atmosphere where partial pressures of HBr are typically much lower than those used in the lab.

71. HBr on H_2O(1). Schweitzer et al.[2] used the droplet train flow reactor technique over a temperature range of 262 to 281 K obtaining values decreasing from 0.16 to 0.0.68. Li et al.[1] and Zhang et al.[3] used the same technique to measure higher values of 0.14 ± 0.02 at 283 K and 0.21 ± 0.3 at 273 K, respectively. Given the good agreement between the two groups for HCl mass accommodation coefficients on water, there is no obvious reason for the discrepancy of a factor of 2-3 for HBr.

72. HBr on H_2SO_4•nH_2O. Molecular beam measurements of HBr impingement on liquid deuterated sulfuric acid surfaces determine the fraction of HBr scattered with no reaction and the fraction that reacts, exchanging H for D, and is emitted as DBr. The fraction converted to DBr is assumed to have undergone interfacial transport, representing a lower limit to the mass accommodation coefficient, which varies from ~0.7 at 55 wt% D_2SO_4 to ~0.2 near 70 wt% Behr et al.[1] This strongly indicates that the mass accommodation coefficient for HBr is >0.1 for 55–72 wt% H_2SO_4 at 213 K.

73. HOBr on $H_2O(s)$. Abbatt[1] measured an uptake coefficient for water ice of 2×10^{-3} at 228 K. Chu and Chu[3] report an uptake coefficient corrected for porosity effects in the range 0.11 to 0.007 at 190–218 K, with an exponential temperature dependence of (3809 ± 76)/T, and in the range 2×10^{-3} to 6×10^{-4} at 223–239 K, with an exponential temperature dependence of (4658 ± 456)/T. Chaix et al.[2] measured the uptake coefficient as a function of temperature on three different types of water-ice, obtaining values ranging from ~0.3 at 185 K to ~0.03 at 205 K, with an exponential temperature dependence of (4900 ± 500)/T. Mössinger et al.[5] report an uptake coefficient value of 0.003 at 227 K increasing to 0.040 at 205 K. The four sets of results are in reasonable agreement with each other, and the temperature dependence of the uptake coefficient is attributed predominantly to changes in the evaporation rate. The results indicate that the uptake of HOBr on ice cannot be explained with Langmuir-type adsorption isotherms and that the process is not reversible, probably proceeding via the self-reaction of HOBr to form Br_2O, or possibly by formation of hydrates. Using a common precursor model, Flückiger and Rossi[4] have estimated accommodation coefficients α which are considerably larger than the measured uptake coefficients, with α values ranging from 0.18 at 215 K to 0.46 at 190 K.

74. HOBr on $H_2O(l)$. See Note on HOBr + KBr and NaBr in reactive uptake table.
Back to Table

75. HOBr on H_2SO_4•$nH_2O(l)$. Abbatt[1] measured an uptake coefficient of 0.06 ± 0.02 by measuring HOBr gas phase loss at 228 K. This result may well be a lower limit due to surface saturation effects and the uptake may have been due to Br_2O formation.
Back to Table

(1) Abbatt, J. P. D. Heterogeneous reaction of HOBr with HBr and HCl on ice surfaces at 228 K. *Geophys. Res. Lett.* **1994**, *21*, 665-668, doi:10.1029/94GL00775.

76. **$BrONO_2$ on H_2O(1).** Deiber et al.[1] used a droplet train apparatus to measure the uptake of $BrONO_2$ on NaBr aqueous solutions to deduce the mass accommodation coefficient of 0.063 ± 0.021 at 274.5 K. This value may be affected by the reaction with interfacial Br^-.
Back to Table

77. **$BrONO_2$ on H_2SO_4•nH_2O.** Hanson[1] modeled wetted-wall flow reactor data and aerosol flow reactor data to estimate $\alpha = 0.80$ over a wide range of temperatures and acid concentrations.
Back to Table

(1) Hanson, D. Reactivity of $BrONO_2$ and HOBr on sulfuric acid solutions at low temperatures. *J. Geophys. Res.* **2003**, *108*, 4239, doi:10.1029/2002JD002519.

78. **$CHBr_3$ on H_2O(s) and H_2SO_4•nH_2O(l).** Hanson and Ravishankara[1] investigated the uptake of bromoform on ice and 58 wt% sulfuric acid at 220 K. No uptake on ice was observed, with a measured uptake coefficient of $<6 \times 10^{-5}$. Reversible uptake by the sulfuric acid surface was observed with an initial uptake coefficient of $>3 \times 10^{-3}$; both measurements are probably limited by surface saturation.
Back to Table

(1) Hanson, D. R.; Ravishankara, A. R. In *The Tropospheric Chemistry of Ozone in the Polar Regions*; Niki, H., Becker, K. H., Eds.; NATO, 1993; pp 17281-17290.

79. **BrCl on H_2O(1).** Katrib et al.[1] used a droplet train flow reactor to measure the uptake of BrCl as a function of NaOH concentration over the temperature range of 270–285 K. Data were too noisy to assign a clear temperature dependence, but an average over measurements at 270, 274, 280, and 285 K for higher [NaOH] where reactive scavenging relieved solubility constraints yielded $\alpha = 0.33 \pm 0.18$. The recommended lower limit is consistent with this value.
Back to Table

80. **I_2 on H_2O(1).** Takami et al.[1] used the impinging flow technique to investigate the uptake of I_2 at 293 K as a function of pH. While solubility constraints prevented a clear measure of mass accommodation, they modeled high pH data where solubility constraints were relaxed by reactive scavenging by OH^- to determine that $\alpha \geq 0.1$.

81. **HI on H_2O(s).** The uptake of HI has been studied by Chu and Chu[1] in a coated-wall flow tube to be large between 188 and 195 K, in the multi-layer coverage regime. Under their experimental conditions, it is likely that the surface is melting to form a bulk solution and/or hydrates are forming. Percival et al.[2] also report efficient uptake with the same technique between 200 and 233 K, with the uptake coefficient of 0.02 ± 0.004 above 212 K and larger than 0.1 for temperatures below 212 K.
Back to Table

(1) Chu, L. T.; Chu, L. Uptake and interaction of HI on ice films. *J. Phys. Chem. B* **1997**, *101*, 6271-6275, doi:10.1021/jp963185y.
(2) Percival, C. J.; Mossinger, J. C.; Cox, R. A. The uptake of HI and HBr on ice. *Phys. Chem. Chem. Phys.* **1999**, *1*, 4565-4570, doi:10.1039/a904651h.

82. **HI on H_2O(1).** Schweitzer et al.[1] used the droplet train flow reactor technique over a temperature range of 262 to 281 K, obtaining values decreasing from 0.19 to 0.079. Zhang et al.[2] used the same technique to

obtain a value of 0.17 ± 0.02 at 273 K, which is a little less than a factor of two higher than indicated by the Schweitzer et al. measurements for that temperature.
Back to Table

(1) Schweitzer, F.; Mirabel, P.; George, C. Uptake of hydrogen halides by water droplets. *J. Phys. Chem. A* **2000**, *104*, 72-76, doi:10.1021/jp992621o.

83. **HOI on H_2SO_4•nH_2O.** Knudsen cell studies by Allanic and Rossi[1] measured uptake at several temperatures for 40, 50, and 70 acid wt%. Time dependent studies show no sign of saturation, so uptake coefficients should correspond to mass accommodation coefficients. Some acid concentration data in the table have been averaged for similar temperatures and rounded to one significant figure. An uncertainty factor of three has been assigned due to the relatively small number of temperature/concentration points studied and a lack of confirming studies from other laboratories. The authors note evidence of HOI disproportionation to form I_2, however, this second order reaction is unlikely to occur under atmospheric conditions.

84. **HF on H_2O(s) and HNO_3•nH_2O(s).** Hanson and Ravishankara[1] attempted to measure the uptake of HF by 200 K water ice and NAT surfaces but were unable to observe measurable adsorption. They surmise that, unlike HCl and HBr, HF does not dissociate to ions on ice or NAT surfaces at 200 K. Lack of measurable uptake is probably due to surface saturation.

92. **SO_2 on $H_2O(s)$.** Uptake experiments in coated–wall flow tubes have been conducted by Chu et al.[1] and by Clegg and Abbatt[3] who observe sub-monolayer reversible uptakes for temperatures between 190–211 K and 213–233 K, respectively. Chu et al. report an uptake coefficient of 1×10^{-5} at 191 K. Earlier studies from Clappsaddle and Lamb[2] using chromatographic-like uptake experiments with small ice spheres packed into a column, are in good quantitative agreement with those of Clegg and Abbatt. Both studies report that uptake increases with increasing temperature, unlike most other species that demonstrate more adsorption at lower temperatures. From the partial pressure dependence of the uptake and from the behavior on basic and acidic surfaces, Clegg and Abbatt infer the uptake occurs by formation of bisulfite on the surface, in the quasi-liquid layer on the surface of ice.

93. **SO_2 on $H_2O(1)$.** Using a droplet train flow reactor Worsnop et al.[7] measured an α of 0.11 ± 0.02 with no significant temperature variation over a temperature range of 260–292 K. Ponche et al.[4] measured 0.13 ± 0.01 at 298 K, in agreement with the earlier measurement. Shimono and Koda[6] estimated an α of 0.2 at 293.5 K from analysis of pH-dependent uptake coefficients in a liquid impingement technique. Schurath et al.[5]

used a coaxial flow liquid jet to obtain a value of 0.1 at 298 K. Boniface et al.[1] performed more extensive droplet train flow reactor measurements at high pH to relieve solubility constraints, obtaining a negative temperature dependence with α values ranging from 0.43 ± 0.4 at 264 K to 0.175 ± 0.015 at 291 K, their data can be fit to $\alpha/(1-\alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs} = -(7.6 \pm 0.6)$ kcal/mol + (29.2 ± 2.1) cal mol^{-1} K^{-1} T(K). Donaldson et al.[2] have used second harmonic generation spectroscopy to detect a chemisorbed SO_2 surface species which was predicted from earlier uptake measurements by Jayne et al.;[3] this surface complex may play a role in SO_2 heterogeneous reactions on aqueous surfaces.

Back to Table

95. **H_2S on H_2O(l).** Boniface et al.[1] performed droplet train flow reactor measurements over at 260–298 K at high pH to relieve solubility constraints, measured uptake coefficients were consistent with α ≥0.05.
Back to Table

(1) Boniface, J.; Shi, Q.; Li, Y. Q.; Chueng, J. L.; Rattigan, O. V.; Davidovits, P.; Worsnop, D. R.; Jayne, J. T.; Kolb, C. E. Uptake of gas-phase SO_2, H_2S, and CO_2 by aqueous solutions. *J. Phys. Chem. A* **2000**, *104*, 7502-7510, doi:10.1021/jp000479h.

96. **H_2SO_4 on H_2SO_4•nH_2O.** Pöschl et al.[2] measured 0.43< α <1.0 for 73–98 wt% H_2SO_4 at 303 K in a wetted wall flow tube. Lower temperatures and acid concentrations would be expected to lead to larger values of α. As discussed in Pöschl et al.[2] this contradicts an indirect measurement of 0.02 < α < 0.09 at 42.5 wt% at 298 K by Van Dingenen and Raes[3] in a photochemical aerosol reactor. The Pöschl et al.[2] result is consistent with room temperature α values very near that measured for $(NH_4)_2SO_4$ particles in an aerosol flow reactor by Jefferson et al.[1]

97. $CH_3S(O)CH_3$, $CH_3S(O_2)CH_3$ and $CH_3S(O_2)OH$ on $H_2O(l)$. De Bruyn et al.[1] measured uptake over the temperature range ~262–281 K and derived accommodation coefficients fitting $\alpha / (1 - \alpha) = \exp(-\Delta G^{\ddagger}_{obs}/RT)$, where $\Delta G^{\ddagger}_{obs}$ =

- –0.12 kcal $mole^{-1}$ + 23.1 cal $mole^{-1}$ K^{-1} T(K) for dimethylsulfoxide
- –10.7 kcal $mole^{-1}$ + 43.0 cal $mole^{-1}$ K^{-1} T(K) for dimethylsulfone
- –3.50 kcal $mole^{-1}$ + 16.7 cal $mole^{-1}$ K^{-1} T(K) for methanesulfonic acid.

Schweitzer et al.[2] used a droplet train flow reactor to investigate the uptake of $CH_3S(O_2)OH$ by water over a temperature range of 262–281 K, obtaining mass accommodation coefficient values decreasing from 0.17 to 0.11, in excellent agreement with those obtained by De Bruyn et al.[1]

5.3 Table 5-2. Gas/Surface Reaction Probabilities (γ) for Surfaces Other Than Soot

Gaseous Species	Surface Type	Surface Composition	T (K)	γ	Uncertainty Factor	Note
O_3 + Surface $\rightarrow$ Products						
O_3	Water Ice	$H_2O(s)$	223–258	$<10^{-8}$		1
	Alumina	α-$Al_2O_3(s)$, γ-$Al_2O_3(s)$	210–300	$\gamma_o<2\times10^{-4}$		2
	Sodium Chloride	NaCl(s)	223–300	$\gamma_o<10^{-4}$		3
		NaCl(aq)	298	$\gamma_o<10^{-4}$		3
	Sodium Bromide	NaBr(s)	300	$\gamma_o<10^{-4}$		4
		NaBr(aq)	298	See Note		4
	Potassium Bromide	KBr(s)	300	$\gamma_o<10^{-4}$		4
	Potassium Iodide	KI(s)	~298	See Note		5
	Sea Salt	See Note	300	$\gamma_o<2\times10^{-2}$		6
	Organic Surfaces	See Note	298	See Note		7
OH + Surface $\rightarrow$ Products						
OH	Water Ice	$H_2O(s)$	205–230	>0.01		8
	Hydrochloric Acid	$HCl{\bullet}nH_2O(l)$	220	>0.2		9
	Nitric Acid Ice	$HNO_3{\bullet}3H_2O(s)$	200–228	>0.2		10
	Sulfuric Acid	$H_2SO_4{\bullet}nH_2O(l)$	200–298	>0.2	3	11
	Sodium Chloride	NaCl(s)	245–300	$\gamma_o\sim10^{-2}$		12
		NaCl(aq)	298	≥0.1		12
	Alumina	$Al_2O_3(s)$	250–300	$\gamma_o<0.1$		13
	Organic Surfaces	See Note	298	$\gamma_o>0.1$		14
HO_2 + Surface $\rightarrow$ Products						
HO_2	Water Ice	$H_2O(s)$	223	0.025	3	15
	Sulfuric Acid	$H_2SO_4{\bullet}nH_2O(l)$		See Note		15
		(28 wt%)	275			
		(47–50 wt%)	293			
		(55 wt%)	223			
		(80–96 wt%)	243	≤0.1		15
	Aqueous Salt	$(NH_4)_2SO_4(aq)$ and NaCl(aq)	298	See Note		16
	Sodium Chloride	NaCl(s)	245–300	See Note		17
	Potassium Chloride	KCl(s)	295			
	Ammonium Sulfate	$(NH_4)_2SO_4(s)$	298	See Note		18
	Organic Aerosol	Organic	298	See Note		19
	Mineral Dust	See Note	298	See Note		20
H_2O + Surface $\rightarrow$ Products						
H_2O	Alumina	α-$Al_2O_3(s)$	295–300	$\gamma_o<0.2$		21
H_2O_2 + Surface $\rightarrow$ Products						
H_2O_2	Alumina	α-$Al_2O_3(s)$, γ-$Al_2O_3(s)$	268-320	$\gamma_o<5\times10^{-3}$		22
$2NO_2 + H_2O(l) \rightarrow HONO + HNO_3$						
NO_2	Liquid Water	$H_2O(l)$	270–295	$<1\times10^{-2}$		23
	Sulfuric Acid	$H_2SO_4{\bullet}nH_2O$ (40–98 wt%)	250–325	5×10^{-7}	3	24
	Alumina	γ-$Al_2O_3(s)$	298	$\gamma_o<1\times10^{-7}$		25
		α-$Al_2O_3(s)$	298	$\gamma_o<5\times10^{-5}$		25
$2NO_2$ (N_2O_4) + MX $\rightarrow$ Products						
NO_2/N_2O_4	Sodium Chloride	NaCl(s)	298	See Note		26
		NaCl(aq)	298	$<1\times10^{-4}$		26
	Sodium Bromide	NaBr(s)	298	See Note		27
	Sea Salt	See Note for O_3 + Sea Salt	298	See Note		28
$NO_3 + H_2O \rightarrow HNO_3 + OH$						
NO_3	Water Ice	$H_2O(s)$	170–200	$<10^{-3}$		29
	Liquid Water	$H_2O(l)$	273	$\geq2\times10^{-3}$		30

Gaseous Species	Surface Type	Surface Composition	T (K)	γ	Uncertainty Factor	Note
$NO_3 + NaX \rightarrow$ Products						
NO_3	Sodium Chloride	NaCl(s)	293	$\gamma_o < 6\times10^{-2}$		31
		NaCl(aq)	273–293	See Note		31
	Sodium Bromide	NaBr(s)	293	$\gamma_o = 0.2\pm0.1$	2	32
		NaBr(aq)	273	See Note		32
	Sodium Iodide	NaI(aq)	273	See Note		32
NO_3 + Organic Surfaces $\rightarrow$ Products						
NO_3	Organic Surfaces	See Note	298	See Note		33
$N_2O_5 + H_2O \rightarrow 2HNO_3$						
N_2O_5	Water Ice	$H_2O(s)$	188–195	0.02	2	34
	Liquid Water/Solutions	$H_2O(l)/(NH_4)_2SO_4(aq)$	260–295	See Note	See Note	35
	Nitric Acid Ice	$HNO_3 \bullet 3H_2O(s)$	200	4×10^{-4}	3	36
	Sulfuric Acid	$H_2SO_4 \bullet nH_2O(l)$	195–300	See Note*	See Note	37
	Ternary Acid	$H_2SO_4 \bullet nHNO_3 \bullet nH_2O(l)$	195–218	See Note		37
	Sulfuric Acid Monohydrate	$H_2SO_4 \bullet H_2O(s)$	200–300	See Note	3	38
	Sulfuric Acid Tetrahydrate	$H_2SO_4 \bullet 4H_2O(s)$	195–207	0.006	2	39
	Mineral Dust	See Note	298	See Note		40
$N_2O_5 + HCl \rightarrow ClNO_2 + HNO_3$						
N_2O_5	Water Ice	$H_2O(s) \bullet HCl(s)$	190–220	0.03	See Note	41
	Nitric Acid Ice	$HNO_3 \bullet 3H_2O(s) \bullet HCl(s)$	200	0.003	2	42
	Sulfuric Acid Monohydrate	$H_2SO_4 \bullet H_2O(s)$	195	$<1\times10^{-4}$		43
$N_2O_5 + HBr \rightarrow BrNO_2 + HNO_3$						
N_2O_5	Water Ice	H_2O	180–200	See Note		44
	Nitric Acid Ice	$HNO_3 \bullet 3H_2O(s)$	200	0.005	10	45
$N_2O_5 + MX \rightarrow$ Products						
N_2O_5	Sodium Chloride	NaCl(s)	295	$\gamma_o < 5\times10^{-3}$		46
		NaCl(aq)	262–291	$\gamma_o < 0.05$		46
	Potassium Bromide	KBr(s)	298	$\gamma_o < 5\times10^{-3}$		47
	Sodium Bromide	NaBr(aq)	270–277	$\gamma_o < 0.05$		47
	Sodium Iodide	NaI(aq)	262–278	$\gamma_o < 0.05$		47
	Sea Salt	See Note for O_3 + Sea Salt	295	See Note		48
$HONO + H_2O \rightarrow$ Products						
HONO	Liquid Water	$H_2O(l)$	245–295	0.03	5	49
$HONO + H_2SO_4 \rightarrow$ Products						
HONO	Sulfuric Acid	$H_2SO_4 \bullet nH_2O(l)$	180–200	See Note		50
$HONO + HCl \rightarrow ClNO + H_2O$						
HONO	Water Ice	$H_2O(s)$	180–200	0.05	3	51
	Sulfuric Acid	$H_2SO_4 \bullet nH_2O(l)$		See Note	See Note	52
$HONO + HBr \rightarrow BrNO + H_2O$						
HONO	Water Ice	$H_2O(s)$	180–200	See Note		53
$HONO + NaCl \rightarrow$ Products						
HONO	Sodium Chloride	NaCl(s)	~300	$<1\times10^{-4}$		54
$HONO + Al_2O_3(s) \rightarrow$ Products						
HONO	Alumina	γ-$Al_2O_3(s)$	274-320	See Note		55
$HNO_3 + NaX(s) \rightarrow HX + NaNO_3$						
HNO_3	Sodium Chloride	NaCl(s)	295–298	$\gamma_o = 2\times10^{-3}$	2	56
		NaCl(aq)	298	$\gamma_o > 0.2$		56
	Sodium Bromide	NaBr(s)	298	$\gamma_o < 3\times10^{-2}$		57

*γ is temperature dependent

5.3.1 Notes for Table 5-2

1. **O_3 on H_2O(s).** Ozone loss on pure ice is highly inefficient, with uptake coefficients in the range of 10^{-8} to 10^{-9} for partial pressures between 2×10^{-8} and 10^{-6} atm at 223 and 258 K, as measured in an ice-coated column. The uptake coefficients are dependent on the ozone partial pressure, increasing at low partial pressures Langenberg et al.[1]

2. **O_3 + Al_2O_3(s).** Very low ozone decomposition efficiencies for reaction on coarse (3 µm dia.) and fine (0.1 µm dia., partially hydroxylated) γ-alumina and coarse (3 µm dia.) α-alumina were measured in flowing and static systems by Hanning-Lee et al.[3] at temperatures ranging between 212 and 473 K. Based on measured BET surface areas, γs ranged from 2×10^{-11} to 4×10^{-10} over the 212 to 298 K temperature range. γs for γ-alumina at lower temperatures exceeded those for α-alumina. Results are roughly consistent with earlier, unpublished flow tube data from L. F. Keyser and from fluidized bed reactor studies of Alebić-Juretić et al.[1] Note that γs based on geometric surface particle surface areas would be significantly (10^4–10^7) larger. Additional fluidized bed reactor studies by Alebić-Juretić et al.[2] demonstrated that room temperature uptake are initially first order in O_3, but change to a slower second order reaction at longer exposure times. Klimovskii et al.[4] reported an initial uptake coefficient (γ_o) of 1×10^{-4} on a γ-alumina surface at 293 K assuming a geometric surface area, BET surface correction presumably would have yielded a lower value. Michel et al.[5,6] reported Knudsen cell uptake studies at 296 K on α-alumina particles that yielded γ_o values of $(8 \pm 5) \times 10^{-5}$ and $(1.4 \pm 0.3) \times 10^{-4}$ after BET surface area corrections. Sullivan et al.[9] used a coated wall flow reactor to obtain 298 K γ_o values of 7×10^{-6} to 1.6×10^{-5} for α-alumina powder films exposed to no more than $[O_3]$ of 10^{13} cm^{-3} after BET surface area correction. Higher $[O_3]$ yielded lower apparent γ_os. Usher et al.[10] demonstrated the pretreatment of α-alumina with HNO_3 vapor reduced O_3 Knudsen cell γ_o values by ~70%. Mogili et al.[7]measured O_3 uptake on α-alumina particles in a room temperature environmental chamber obtaining an uptake coefficient of $(3.5 \pm 0.9) \times 10^{-8}$ for dry (RH ≤1%) particles that fell to $(4.5 \pm 1.1) \times 10^{-9}$ for measurements at 19% RH. Roscoe and Abbatt[8] demonstrated spectroscopically that there is a competition for surface sites when gas phase ozone and water vapor are exposed to the alumina surface.

3. **O_3 + NaCl.** The reaction of O_3 with NaCl is slow. Il'in et al.[3] measured the loss of O_3 in a coated reactor over the temperature range 223–305 K, and found the same uptake coefficients, $\gamma \sim 10^{-6}$, independent of temperature, for NaCl and NH_4NO_3 and $(NH_4)_2SO_4$, suggesting that even the small uptake is not due to reaction with the chloride. Alebić-Juretić[2] did not observe any uptake on NaCl powders using a fluidized bed reactor but did not report an upper limit to the uptake coefficient. Akimoto and coworkers[6,7] reported an upper limit of $\gamma_o < 1 \times 10^{-5}$ on NaCl. When the NaCl was mixed with 0.5–1% w:w $FeCl_3$, γ_0 increased to 3×10^{-2} and production of gaseous Cl_2 was observed with yields from 25–50% of the ozone taken up. With 0.1% $FeCl_3$, no production of Cl_2 was observed but the initial uptake coefficient was still 3×10^{-2}. These experiments were carried out with a Knudsen cell using multiple salt layers and the measured initial uptake coefficients were converted to the reported values using the pore diffusion model of Keyser et al.[4,5]
Abbatt and Waschewsky[1] followed O_3 in a flow tube containing deliquesced 1–5 μm NaCl particles (75% RH); no significant loss was observed on unbuffered particles or particles buffered at pH of 7.2. An upper limit of $\gamma_o < 1 \times 10^{-4}$ was derived from these measurements.

4. **O_3 + NaBr and KBr.** Mochida et al.[6] did not observe any uptake of O_3 on NaBr or KBr powders, from which they derived an upper limit of $\gamma < 1 \times 10^{-5}$. Hirokawa et al.[3] reported production of gas phase Br_2 from the reaction of O_3 with NaBr only when water vapor was added so that the salt was near deliquescence.

Uptake of O_3 and production of gas phase Br_2 has been observed for deliquesced NaBr salt on a glass surface.[1] Production of Br_2 has also been measured by Hunt et al.[4] in the reaction of O_3 with deliquesced NaBr particles in the dark in an aerosol chamber; the production of Br_2 exceeded that from known aqueous phase chemistry by about an order of magnitude, suggesting that a surface reaction of O_3 with bromide at the air-solution interface was occurring with a reaction probability of $\gamma_0 = (1.9 \pm 0.8) \times 10^{-6}$ (2σ).

The uptake of O_3 by frozen salt solutions and cold liquid solutions containing bromide have been studied in a coated wall flow tube from 233 to 273 K by Oldridge and Abbatt.[7] Br_2 was the sole product formed. Reaction kinetics were well described by a combination of a bulk reaction in the associated solution and a surface reaction component, so that the overall ozone uptake coefficients increased with decreasing ozone concentrations. The similarity between the results on both liquid solutions and frozen solutions implied the reaction was occurring only with the liquid component of the substrates. The simultaneous occurrence of significant reactivity within sodium bromide solutions and at their surfaces has been confirmed by Artiglia et al.[2] As well, this study identified for the first time the presence of an ozonide reaction intermediate that is formed at the gas-aqueous interface at the first stage of the reaction between ozone and bromide ions. The efficiency of this oxidation reaction was shown by Lee et al.[5] to be increased by the presence of dissolved citric acid, perhaps due to the stronger partitioning of ozone into an organic substrate than to water.

Using glancing angle LIF and Raman spectroscopy, Wren et al.[8] have studied the reactions of ozone with both frozen and unfrozen bromide solutions with sea water concentrations. They demonstrate that the kinetics proceed one to two orders of magnitude faster on the frozen substrates than on the corresponding unfrozen solutions. Back to Table

5. **O_3 + KI.** Brown et al.[1,2] report that KIO_3 forms on single crystal, water-free KI surfaces with a reaction probability of 1.4×10^{-4}. On room temperature KI solutions, Sakamoto et al.[8] report that ozone exposure yields gas-phase I_2 and small amounts of IO (ratio of I_2 to IO >100). The reaction kinetics are indicative of a Langmuir-Hinshelwood mechanism, exhibiting saturation in the gas-phase yields as both ozone and iodide concentrations are increased. The reaction forming I_2 proceeds more rapidly with increasing acidity for pH <4, but there is a pH-independent pathway operative to pH 11.

Complex chemistry for ozone reacting at the surface of solutions containing iodide and other reactants is illustrated from studies of solution microdroplet analysis by electrospray ionization (Pillar et al.,[5] Enami et al.,[3] and Hayase et al.[4]). In particular, a number of researchers have shown that surfactants and/or dissolved organic species can affect the rate of iodide oxidation by ozone (Hayase et al.,[4] Shaw and Carpenter,[9] Reeser et al.,[6] and Rouvière et al.[7]).

6. **O_3 + sea salt.** Akimoto and coworkers[11,14] reported uptake coefficients for O_3 on synthetic and natural sea salt powders of ~1 × 10^{-3} using a Knudsen cell with multiple salt layers. Similar uptake coefficients were reported for the hydrates of $MgBr_2$ and $CaBr_2$. These are the initial uptake coefficients after correction for the available surface area using the pore diffusion model of Keyser et al.[9,10] The measured values before this correction was applied were about a factor of 20 larger. Given the uncertainty associated with these corrections, the final values derived have a large uncertainty associated with them as well. When $FeCl_3$ was added to synthetic sea salt (Fe/Na weight ratio of 1%), the uptake coefficient increased by an order of magnitude to $(3.2 \pm 1.1) \times 10^{-2}$. Br_2 was the gas phase product, with variable yields up to 100% of the O_3 lost. The enhanced reactivity of sea salt compared to NaCl and NaBr is due to the significant amounts of surface-adsorbed water (SAW) present on sea salt; the component of sea salt present in the second highest concentration is magnesium chloride which forms a stable hydrate and is quite hygroscopic. Reactions with powders of $MgCl_2$•$6H_2O$ and sea salt are often observed to be similar to reaction with aqueous salt solutions (see note on SO_2 uptake). The formation of Br_2 is favored over Cl_2 by a number of factors: (1) surface segregation of bromide ions[3,4,15] in mixed solid crystals of NaCl and NaBr, (2) higher solubility of NaBr which increases its concentration in the surface layer as a mixture of NaCl and NaBr crystallizes, (3) faster oxidation of Br^- compared to Cl^-,[2,5,6,13] (4) solution phase chemistry of chloride and bromide ion mixtures that favors the production of gas phase bromine compounds,[2,13] (5) enhanced interfacial bromide ion concentrations compared to chloride ions at the air-water interface of aqueous solutions of mixed salts.[7,8] The yields of I_2 from exposure of sea water to ozone have been studied by Carpenter et al.[1] under ambient ozone concentrations. I_2 was quantified by conversion to small particles, which were sized and counted. On frozen sea-salt solutions, gas phase Br_2 was formed by exposure of O_3 (44 ppbv to 2.9 ppmv) to frozen sea salt solutions, at temperatures below 272 K.[12] No other products were reported and the production of Br_2 scaled with increasing O_3.

7. **O_3 + organic surfaces.** Reactive initial uptake of ozone occurs on organic substrates that contain unsaturated carbon-carbon bonds, whereas uptake to substrates that are fully saturated is minimal. This reaction occurs not only with simple alkenes, but with electron-rich conjugated systems such as PAHs as well. Ozone adds across carbon-carbon double bonds forming an ozonide, which then falls apart into more reactive intermediates. The product distributions are complex. Initial uptake coefficients are highly dependent upon the chemical nature of the substrate, ranging from values of roughly 10^{-3} on pure alkene aerosol particles such as oleic acid, to much lower values of 10^{-6} or below with PAH-coated particles. A more detailed discussion of this complex chemistry is given in two review articles: Kolb et al.[3] and Abbatt et al.[1] Note that the ozone uptake can be photochemically enhanced on some organic substrates, via a photosensitization process as described in a review article by George et al.[2]

8. **OH + H_2O(s).** Cooper and Abbatt[1] measured initial irreversible OH uptake coefficients of ~0.1 for water ice between 205–230 K; these decayed to $\gamma = 0.03 \pm 0.02$ after repeated exposure to OH. Self-reaction to form H_2O or H_2O_2 was indicated by the lack of observable gas phase products despite observation of first-order OH loss**.** It cannot be ruled out that contamination of the ice surface drove the initial reactivity.

12. **OH + NaCl.** Ivanov et al.[2] measured the uptake of OH on solid NaCl and on NH_4NO_3 over the temperature range from 245–340 K using a fast flow discharge reactor with a coated rod along the axis and EPR detection of OH. The initial values of the uptake coefficient approached 10^{-2}. The OH was generated from the reaction of H atoms with excess NO_2; it is not clear whether NO_2 might have also reacted with the salt surface. Given that the uptake coefficients were similar for NaCl and NH_4NO_3, the uptake likely does not reflect oxidation of the chloride. The pseudo-steady state value, γ_{ss}, was measured to be 4×10^{-3} at 298 K and the temperature dependence was described by $\gamma_{ss} = (1.2 \pm 0.7) \times 10^{-5} \exp[(1750 \pm 200)/T]$. This value is quite close to later measurements by Park et al.[6] who see little dependence of the uptake coefficient on relative humidity, up to 38% at room temperature. Product studies have been performed by Sjostedt and Abbatt[8] who have exposed dessicated NaCl salts to gas-phase OH in a coated-wall flow tube at 298 and 253 K. Gas-phase Br_2 is formed with a yield of 0.6, relative to the loss of OH. The source of the Br_2 is the trace Br^- impurity in commercial, high purity $NaCl_{(s)}$. BrCl was formed at a considerably smaller yield, 0.008. Humidification of the salt surface led to more sustained production but somewhat smaller yields.

Aerosol chamber studies by Finlayson-Pitts and coworkers showed that there was no Cl_2 production from NaCl particles when OH was generated by reaction of $O(^1D)$ from photolysis of O_3 at relative humidities below the deliquescence point of NaCl; above the deliquescence point, however, a rapid reaction of OH with Cl^- at the interface to generate gas phase Cl_2 is observed.[3,5] Because the mechanism is uncertain, and clearly must involve multiple steps, a unique value of the reaction probability for this interface reaction could not be obtained. At 269 K Frinak and Abbatt[1] have exposed acidic solutions containing molar levels of NaCl to gas-phase OH. The gas-phase product observed is Br_2, unless considerable OH exposure has reduced Br^- levels in the solution, in which case the product is Cl_2. The source of the Br_2 is the trace Br^- impurity in commercial, high purity $NaCl_{(s)}$. At neutral pH, the products were below detection limit. Shaka et al.[7] and Laskin et al.[4] have both exposed chloride solutions to gas-phase OH, observing changes in solution alkalinity and chloride concentrations, respectively. This is another indication that chloride ions in solution are readily heterogeneously oxidized by OH. Laskin et al. report an uptake coefficient of ≥ 0.1 at room temperature. However, the OH concentrations were not measured which may lead to uncertainty in this value.

14. **OH + organic surfaces.** It has been shown through a large number of studies that the OH radical is efficiently lost on organic surfaces via condensed phase reactions that add oxygenated functional groups to the organics, and lead to some carbon-carbon bond breakage as well. The uptake coefficient for OH loss has been studied at room temperature on both chemically reduced and oxidized surfaces, and found to be larger than 0.1, as determined both by monitoring loss of OH directly and by monitoring loss of specific organics within the aerosol. A more detailed discussion of this complex chemistry is given in three review articles: Kolb et al.,[3] George and Abbatt,[2] and Abbatt et al.[1]

15. **HO$_2$ + H$_2$O(s) and H$_2$SO$_4$•nH$_2$O(l).** Uptake of HO$_2$ on ice and super–cooled 55 wt.% sulfuric acid at 223 K has been demonstrated to be limited by HO$_2$ surface saturation by Cooper and Abbatt.[1] They argue that self-reaction, presumably $2HO_2 \rightarrow H_2O_2 + O_2$ is controlling measured uptake coefficients of 0.025 ± 0.005 for ice and 0.055 ± 0.020 for 55 wt.% H_2SO_4. Thornton and Abbatt[4] report room temperature aerosol flow reactor submicron droplet measurements on 47–50 wt% H_2SO_4, without HO_2 scavenger species, yielding γ <0.01. Gershenzon et al.[2] measured γ >0.2 for 80 and 96 wt.% H_2SO_4 at 243 K and Hanson et al.[3] measured a lower limit for 28 wt% H_2SO_4 at 275 K of 0.07. However, large gas phase diffusion corrections mean these values are consistent with $\gamma = 1$. Thornton et al.[5] have used available experimental data to develop a parameterized HO_2 self-reaction uptake model valid for pH <6 aqueous droplets and gas phase HO_2 generation rates exceeding 1×10^5 cm^{-3} s^{-1}. They also assess the relative role of Cu^{++} catalyzed oxidation of HO_2 in aqueous aerosols.

16. HO_2 + $(NH_4)_2SO_4$(aq) and NaCl(aq). HO_2 uptake on aerosol particles has been studied in aerosol flow tubes. At high HO_2 concentrations detected by CIMS, Thornton and Abbatt[6] observed loss of HO_2 on aqueous ammonium sulfate particles, buffered to pH 5.1 at RH 42% and room temperature. An uptake coefficient of 0.1 could describe the kinetics, but the HO_2 decays were best fit by second-order kinetics consistent with a bulk-phase reaction between dissolved HO_2 species, when using literature HO_2 solubility and bulk liquid-phase rate constants. Because of the second-order kinetics, it was inferred that the uptake coefficient would be substantially smaller at lower (atmospheric) HO_2 gas-phase concentrations.[7] This prediction is confirmed by the detailed study of George et al.[1] which examined HO_2 uptake at gas phase concentrations between 10^8 and 10^9 molecules/cm^3 in an aerosol flow tube using LIF detection methods. The uptake coefficients measured were between 0.003 and 0.02 on deliquesced particles of $(NH_4)_2SO_4$, NaCl and NH_4NO_3. These results are not in agreement with the work performed using LIF by Taketani et al.[3,4] who reported much larger uptake coefficients on ammonium sulphate (0.11 to 0.19, 45 to 75% RH), sodium chloride (0.1, 50 to 75% RH) and sea salt (0.1, 35 to 75% RH) at atmospheric HO_2 concentrations about two orders of magnitude lower (<10^8 molecules/cm^3) than those of Thornton and Abbatt, but similar to those of George et al. George et al. observed much more efficient loss when transition metals were present in solution, highlighting the importance of working with clean aerosol samples. As well, there are complex dependencies of the kinetics on HO_2 concentration and on reaction time. However, these dependencies do not appear to explain the large discrepancy between the results from the Taketani et al. and George et al. experiments, performed under nominally similar conditions. In the absence of transition metal impurities such as iron or copper ions, there is no known reactive chemistry that will deplete HO_2 as rapidly as observed in the Taketani et al. experiments.

Using the technique described above, Taketani et al.[5] have separately measured the HO_2 uptake coefficients at 75% relative humidity on ambient aerosol material that has been collected on a filter, extracted and then re-atomized to produce suspended particles. The uptake coefficients measured (between 0.1 and 0.4) are large, consistent with the large uptake coefficients measured by this group previously on laboratory-prepared aerosol systems. Such large values are likely arising from the presence of transition metal ions that catalyze the HO_2 self-reaction in the aqueous phase. In the ambient environment these transition metals may only be present in a subset of particles but in these experiments they will have been mixed into all the particles. The composition of the atomized ambient material was analyzed, indicating large iron and significant copper abundances, along with sulfate, nitrate, organics etc. The acidity was largely neutralized by high levels of

ammonium. Note that studies by Lakey et al.[2] have shown that the presence of some organic constituents can reduce this catalytic role, if present in the same particles. This inhibition effect does not appear to be important for the results of Taketani et al.[5]

17. **HO_2 + NaCl(s) and KCl(s).** Gershenzon and coworkers[2,5] used a combination of matrix isolation EPR and gas phase EPR with a fast flow tube to measure the uptake of HO_2 on NaCl from 245–335 K. Early studies by Gershenzon et al.[2] measured values of $\gamma = 1.8 \times 10^{-2}$ for KCl and 1.6×10^{-2} for NaCl, both at 295 K, supplementing an even earlier value of $\gamma \sim 8 \times 10^{-3}$ measured by Gershenzon and Purmal.[3] In later studies on NaCl[5] the uptake was reported to remain constant for at least 30 min, so this is likely to be a steady-state value, $\gamma_{ss} = 1.2 \times 10^{-2}$ at 295 K. The temperature dependence is given by $\gamma_{ss} = (5.7 \pm 3.6) \times 10^{-5} \exp[(1560 \pm 140)/T]$. Above 330 K, the uptake coefficient was significantly smaller than expected from this temperature dependence. The data are indistinguishable, within experimental error, from the uptake of HO_2 on NH_4NO_3, suggesting that the uptake of HO_2 likely involves recombination on the surface rather than oxidation of the chloride. The surface recombination was interpreted in terms of a combined Eley-Rideal and Langmuir-Hinshelwood mechanism. The addition of small amounts of water vapor decreased the uptake coefficient for HO_2; the authors attributed this to water adsorption on the active sites. Another possibility is formation of HO_2-H_2O complexes whose uptake and recombination on the surface is not as fast as for uncomplexed HO_2. A study by Loukhovitskaya et al.[4] using a coated-wall flow tube finds temperature dependent uptake coefficients on salt surfaces, reporting uptake coefficient between 10^{-3} and 10^{-2} at room temperature. They report that gas-phase H_2O_2 was observed as a product, indicative of self-reaction. George et al.[1] and Taketani et al.[6] report uptake coefficients of less than 0.0004 and 0.01, respectively, on dry NaCl aerosol in aerosol flow tubes using HO_2 concentrations of 10^8 to 10^9 molecules/cm^3. The small upper limit for this process from George et al., measured at low concentrations of HO_2, suggests that the earlier measurements may have been dominated by radical recombination on salt surfaces.

18. **HO_2 + $(NH_4)_2SO_4$(s).** George et al.[1] report uptake coefficients of less than 0.0004 on dry $(NH_4)_2SO_4$ aerosol in an aerosol flow tube using HO_2 concentrations of 10^8–10^9 molecules/cm^3. Taketani et al.[2] report a considerably larger value, 0.04, measured with the same experimental approach. The discrepancy between these measurements is mirrored by an equivalent disagreement between these groups' measurements of HO_2 loss on aqueous salt solutions. The source of the disagreement is not clear but trace metal impurities have the potential to drive very efficient uptake and might be the cause of the higher values by Taketani et al.

19. **HO_2 + Organic Aerosol.** The uptake coefficients of HO_2 to organic-containing aerosol particles have been measured by two groups, both using nominally the same approach of an aerosol flow tube coupled to chemical conversion/laser induced fluorescence for the detection of HO_2. Just as described in the note for HO_2 uptake to inorganic aqueous aerosol, these two groups likewise disagree on the magnitude of the uptake coefficients measured with organic substrates. For example, Taketani et al.[4] report values of 0.02 to 0.07 for a range of small di-carboxylic acids at 28% relative humidity, increasing to values of 0.06 to 0.18 at 68% RH. On the other hand, Lakey et al.[3] report values of 0.008 or below for a range of organic species, including di-carboxylic acids across a wide range of RH values. This group measured higher values on humic acid aerosol, but this behavior could be explained by high dissolved copper and iron concentrations in those particles, with the transition metal ions able to catalyze the self-reaction of HO_2 in the condensed phase. As in the case of the aqueous inorganic aerosols, the source of this discrepancy is not understood. Lakey et al.[2] show that the addition of specific organics, such as oxalic acid, to an aqueous inorganic aerosol that contains dissolved copper can lead to a significant inhibition of the reactive uptake, likely because of complexation of the transition metal ion thus making it unavailable for catalysis. This effect could significantly impact the importance of reactive HO_2 loss on aerosol, if transition metals and oxidized organics are present in the same particles. Likewise, Lakey et al.[1] demonstrate that the viscosity of the organic material may also be important, with the uptake coefficients measured on sucrose particles being larger on less viscous particles at RH=65% versus a more viscous, solid-like substrate at 17% RH.

20. **HO_2 + Mineral Dust.** Uptake coefficients for the interaction of HO_2 with Arizona Test Dust (ATD) from 5 to 76% relative humidity at room temperature have been reported by Matthews et al.[2] who used LIF to detect HO_2 in an aerosol flow tube. The HO_2 concentrations are quite low, on the order of 10^8 to 10^9 molecules/cm^3. The uptake coefficients are between 0.02 and 0.03, with larger values measured at short reaction times. The decrease of the uptake coefficient with longer reaction times may be due to some degree of surface modification or perhaps because the reaction is not first order, i.e. some self-reaction of HO_2 on the surface is occurring. Thus, these uptake coefficients may be upper limits to values that will prevail in the atmosphere. For comparison, James et al.[1] have reported uptake coefficients using the same technique on igneous-type dusts, such as synthetic olivine ($MgFeSiO_4$, uptake coefficient = 0.069), forsterite (Mg_2SiO_4, 0.0043) and fayalite (Fe_2SiO_4, 0.073).

21. **H_2O (g) + Al_2O_3 (s).** Isotopic thermal programmed desorption studies at 300 K by Elam et al.[2] show that H_2O dissociatively absorbs on α-alumina surfaces and that initial uptake coefficient (γ_o) is ~0.1. Pre-hydroxylation or long term exposure to water vapor decreases the H_2O uptake coefficient nearly exponentially. Al-Abadleh et al.[1] used FTIR techniques to study water vapor uptake at 296 K on α-alumina crystal 0001 surfaces as a function of relative humidity (RH). Below 10% RH uptake is dissociative, but molecular absorption dominates uptake between 10 and 70% RH. FTIR spectra of water absorbed on both α-alumina and γ-alumina powder surfaces are similar to those on 0001 crystal surfaces. Goodman et al.[3] used FTIR to show that α-alumina surfaces saturated with HNO_3 vapor has the same water absorption isotherm as untreated samples at 296 K.

22. **H_2O_2 + Al_2O_3(s).** Zhao et al.[3] measured H_2O_2 uptake on a bed of ~35nm α-alumina particles in a solid sample flow reactor as a function of relative humidity at room temperature and ambient pressure. BET surface area was used in analyzing uptake coefficients. Uptake was RH dependent, which was varied over a wide range (2–76%). Gas phase hydrogen peroxide leaving the reactor was scrubbed and quantified using liquid chromatography. Uptake was largely irreversible with reactive uptake ~75% at low RH rising to ~85% at high RH. Reported uptake coefficients (γ) were lower at higher RHs: γ(RH-2%) = $(1.21 \pm 0.04) \times 10^{-7}$**;** γ(RH-21%) = $(0.84 \pm 0.07) \times 10^{-7}$ and γ(RH ≥42%) = $(0.72 \pm 0.04) \times 10^{-7}$. Use of BET surface areas probably led to underestimated γ values. Uptake experiments were performed for 30 minutes; larger uptake coefficients may have characterized shorter uptake times. The authors also reported largely reversible H_2O_2 uptake coefficients on SiO_2 submicron particles that were about an order of magnitude lower than those measured for alumina.[3]

Wang et al.[2] report Knudsen cell studies, also on α-alumina and other mineral oxide surfaces at room temperature and very low RH. For α-alumina the measured gas phase products also indicate catalytic decomposition. Measured γ_o values using BET surface areas were $(1.00 \pm 0.11) \times 10^{-4}$ for α-Al_2O_3, $(1.66 \pm 0.23) \times 10^{-5}$ for MgO, $(9.70 \pm 1.05) \times 10^{-5}$ for Fe_2O_3 and $(5.22 \pm 0.9) \times 10^{-5}$ for SiO_2. Their γ_o value for α-Al_2O_3 is roughly a factor of a thousand higher than the steady-state γ values reported by Zhao et al.[3]

Romanias et al.[1] used a coated wall flow reactor with solid films of ~20 nm γ-alumina particles to measure H_2O_2 uptake coefficients over a RH range of 0.003 to 73% and a temperature range of 268–329 K. Near ultraviolet (315-400 nm) illumination had no effect on uptake. BET surface area measurements were also used to calculate uptake coefficients. They observed that longer exposure times lead to saturated surfaces, so initial γ_o uptake coefficients as well as steady-state γ values were reported. Desorption measurements showed reversible H_2O_2 uptake was 5% or less of total uptake. Initial uptake values were dependant on both RH and T; for instance, γ_o (for 0.003% RH and 300 K) = $(9.0 \pm 2.7) \times 10^{-4}$, is nearly constant for (0.003–0.02% RH) then falls off to $\sim 2 \times 10^{-5}$ at 73% RH. The steady-state uptake coefficient also decreases at higher RH values, γ(280 K) falls from about 2.5×10^{-5} at about 0.005% RH to $\sim 5 \times 10^{-7}$ at RH of 73%. Clearly adsorbed water vapor competes with irreversible H_2O_2 chemisorption. At fixed RH the initial uptake of H_2O_2 increases with falling temperature, $\gamma_o(0.03\%\ RH) = 8.7 \times 10^{-4}/(1 + 5.0 \times 10^{13} \exp(-9700/T)$ rising from 2.0 $\times 10^{-4}$ at 320 K to 8.8×10^{-4} at 268 K.[1] Note that the low RH γ_o values reported in this work are the same order of magnitude as the dry α-Al_2O_3 value reported by Wang et al.[2]

Given that there is little reason to expect that α-alumina and γ-alumina have the same initial uptake coefficients, not to mention similar RH or temperature dependencies, the available data will support only a conservative upper limit estimate of $\gamma_o < 5 \times 10^{-3}$.

23. **$NO_2 + H_2O(l)$.** Value for γ of $(6.3 \pm 0.7) \times 10^{-4}$ at 273 K (Tang and Lee[9]) was achieved by chemical consumption of NO_2 by SO_3^{2-}; their stopped-flow measurement was probably still affected by surface saturation, leading to the measurement of a lower limit. Ponche et al.[7] measured an uptake coefficient of (1.5 $\pm$ 0.6) $\times 10^{-3}$ at 298 K, which was also probably subject to saturation limitations. Mertes and Wahner[5] used a liquid jet technique to measure a lower limit of $\gamma \geq 2 \times 10^{-4}$ at 278 K, and they observed partial conversion of the absorbed NO_2 to HONO. Msibi et al.[6] used a cylindrical/annular flow reactor to derive $\gamma = (8.7 \pm 0.6)$ $\times 10^{-5}$ on pH = 7 deionized water surfaces and $(4.2 \pm 0.9) \times 10^{-4}$ on pH = 9.3 wet ascorbate surfaces; it seems likely that these results are also subject to surface saturation given the gas/surface interaction times involved in the experiment. Harrison and Collins[3] performed aerosol flow reactor experiments on deliquescent sodium chloride and ammonium sulfate droplets at 279 K obtaining reactive uptake coefficients in the range of (2.8–10) $\times 10^{-4}$, probably with some surface saturation constraints. Cheung et al.[1] used a droplet train flow reactor to show that the reactive uptake coefficient for NO_2 at number densities between 10^{13} and 10^{16} on pure water at 273 K is $<5 \times 10^{-4}$, contradicting many of the earlier experiments. Cheung et al. also used a bubble train reactor to demonstrate that the reactive uptake of NO_2 is second order, so that experimental uptake coefficients will be dependent on gas phase NO_2 concentrations.

Colussi and co-workers[2,4,10] measured the adsorption/reaction of gaseous NO_2 on ~293 K aqueous microstreams by measuring the nitrate ion content by electrospray mass spectrometry after the microstreams break up into small charged droplets. In Yabushita et al.[10] the aqueous microstreams were doped with alkali salts (NaCl, NaBr and NaI), in Kinugawa et al.[4] doping agents were cationic and anionic surfactants (tetrabutylammonium bromide, tetradecyltrimethylammonium bromide and potassium perfluorooctanesulfonate) as well as NaBr, and in Colussi et al.[2] the additives were dicarboxylic acids representing components of secondary organic aerosol (SOA) including malonic, glutaric and glutamic acids with low enough pK1 values to dissociate to monoanions. The nitrate detected is assumed to be produced by the surface reaction: $2\ NO_2 + H_2O \rightarrow HONO + HNO_3$. This experimental process is semi-quantitative, Colussi et al. estimate that the non-detectable nitrate levels in undoped water microstreams indicate a $\gamma_o < 2$ $\times 10^{-7}$ for pure water. However, when the aqueous microstreams are doped with gas/liquid interface active anions or cations, the apparent NO_2 γ_o values increase nonmonotonically with electrolyte concentrations peaking at $\gamma_o \sim 10^{-4}$ for [NaX] concentrations of ~1 mM.[10] Colussi et al.[2] also present theoretical models of NO_2 interactions with water clusters containing Cl^- in a aqueous interfacial environment that identify electrostatic interactions strong enough to potentially enhance the reactivity of adsorbed NO_2.

Sosedova et al.[8] measured the uptake of radioactive $^{13}NO_2$ (half-life 10 min.), which can be detected at extremely low concentrations, by deliquesced sodium salts of hydroquinone (1,4-dihydroxybenzene) and gentisic acid (2,5-dihydroxybenzoic acid) in a flow tube reactor at 296 K and 40% RH. Reactant $^{13}NO_2$ and product $HO^{13}NO$ are trapped on chemically selective denuder surfaces and quantified by counting ^{13}N decay gamma rays. Observed reactive uptake coefficients (γs) ranged from $\sim 5 \times 10^{-4}$ to $\sim 6 \times 10^{-3}$. The measured time dependence of NO_2 reactive uptake was fitted to a kinetic model of reactant consumption in the droplet phase using the NO_2 mass accommodation coefficient and the rate constants for dissolved NO_2 with the deprotonated phenolic compounds as variables, yielding an estimated room temperature bulk liquid mass accommodation coefficient: $\alpha = 0.024$ (+0.018/-0.003). If accurate for pure water, it indicates that the lower reactive uptake coefficients measurements above are subject to some degree of surface saturation.

Data are consistent with reactive uptake coefficients less than 1×10^{-2} for 270–295 K and a liquid-phase second-order hydrolysis of NO_2 to HONO and HNO_3, which depends on temperature and pH. However, the interplay between mass accommodation, possible surface reaction, and bulk reaction may be complex.

24. **$NO_2 + H_2SO_4 \bullet nH_2O$.** Kleffmann et al.[2] performed bubble tube reactor uptake measurements for 0–98 wt% acid at 298 K and for 44.6 and 56.1 wt% from 250–325 K. At 298 K, measured uptake coefficients varied between 6 and 3×10^{-7} with a minimum near 70 wt%. Most measurements at 44.6 and 56.1 wt% overlapped within their error limits and showed little temperature dependence although there is evidence that uptake increases at the lowest temperatures. The data can all be captured with a recommended value of 5×10^{-7} with an uncertainty factor of three.

This recommendation is consistent with earlier upper limits of 1×10^{-6} by Baldwin and Golden[1] for 96 wt% at 295 K and 5×10^{-6} for 70 wt% between 193 and 243 K by Saastad et al.[3] Kleffmann et al.[2] conclude that their uptake measurements are mass accommodation limited; however, it is not clear that their values are not influenced by bulk or surface reaction of two NO_2 with H_2O to form HONO and HNO_3 at lower acid wt% values and the formation of nitrosyl sulfuric acid at higher acid concentrations. Kleffmann et. al.[2] did perform separate static wetted wall reactor studies showing the formation of gas phase HONO at acid concentrations below 60 wt%. It is more likely that reactive uptake is a controlling factor and the measured uptakes are solubility and/or reaction rate limited. Thus, the mass accommodation coefficient may be much larger than the recommended uptake values.

25. **NO_2 + Al_2O_3.** Miller and Grassian[5] observed NO_2 adsorbed reactively on γ-alumina using FTIR and UV spectroscopy to observe surface nitrite and nitrate. Szanyi et al.[7] used FTIR and thermal programmed desorption/mass spectrometry to determine products formed on γ-alumina surfaces at 300 K, observing nitrites and nitrates (at higher NO_2 only nitrate). Exposure to water vapor converted most bridging nitrates to bidentate and monodentate nitrates. Baltrusaitis et al.[1] also used FTIR to observe monodentate, bidentate and bridging nitrates products on both α-alumina and γ-alumina particles at 296 K. They also observed that co-absorbed water solvates surface nitrates. Underwood et al.[8-10] report Knudsen cell studies measuring γ_o values on γ-alumina particles of 2×10^{-8}, 2.0×10^{-8}, and 2.2×10^{-8} at 298 K based on BET surface area corrections and either Keyser, Moore, Leu (KLM) formulation[4] or linear mass dependent (LMD) corrections for porosity, with the KML and LMD corrections leading to very similar values.[8] They also report larger γ_o values for α-alumina of 9.3×10^{-6} and 9.1×10^{-6}.[8,10] Underwood et al.[10] also suggest a final "multiple collision" that would raise the γ_o values for γ-alumina by factor of 1.1 and α-alumina by 9.4. This proposed correction is not included in the recommended upper limits. Börensen et al.[2] report diffuse reflectance FTIR measurements of uptake on γ-alumina showing that the reaction order is 1.86 ± 0.1 in NO_2. They report BET corrected γ_o values varying linearly from 7.3×10^{-10} to 1.3×10^{-8} as [NO_2] was increased from 2.5×10^{13} to 8.5×10^{14}. Rubasinghege and Grassian[6] irradiated nitrate absorbed on γ-alumina particles with broad band light (>300 nm) as a function of RH (at ~1, 20, 45 and 80% and with and without gas phase O_2) observing photolytic production of gas phase NO (primary product), NO_2 and N_2O.

Guan et al.[3] report α-Al_2O_3 BET uptake coefficients at 298 K for both dark measurements ($9.9 \pm 4.8 \times 10^{-10}$) and simulated sunlight (350–700 nm) conditions ranging from 2.55 to 3.33×10^{-9} for light fluxes of 0.45–2.25 mW/cm^2. They also showed that NO_2 uptake was independent of its gas phase concentration between 2.7 and 53.8×10^{14} molecules/cm^3, so surface saturation was probably not an issue.[3] However, they assumed that all NO_2 uptake resulted in surface NO_3^- production and integrated the observed nitrate bands to estimate nitrate surface concentrations. For gaseous mixtures of NO_2 and O_2 they determined that the nitrate production rate reaction order was 0.960 ± 0.111 for NO_2 and 0.620 ± 0.083 for O_2.[3] Note, that they cite Börensen et al. (2000), but do not discuss the fact that Zellner's group measured a NO_2 uptake order on γ-alumina of 1.86 ± 0.1. Wu et al.[11] report the effect of temperature (250–318 K) on "dry air" NO_2 uptake and nitrate production on γ-alumina surfaces using a DRIFTS set-up. They obtained geometrical γ_o values increasing from $(7.42 \pm 0.77) \times 10^{-4}$ at 318 K to $(23.0 \pm 2.58) \times 10^{-4}$ at 250 K, corresponding to γ_o(BET) values of $(2.58 \pm 0.27) \times 10^{-10}$ and $(8.17 \pm 0.92) \times 10^{-10}$. There is no discussion of the very large (>10^6) differences between γ_o(BET) and γ_o(GEO).

Given the currently available data and the extremely low uptake coefficients reported for BET estimated surface areas, only upper limits for γ_o's on α-alumina and γ-alumina are listed.

26. **NO_2/N_2O_4 + NaCl.** Schroeder and Urone reported that NO_2 at Torr concentrations reacted with NaCl to form ClNO.[7] Subsequently, Finlayson-Pitts[4] showed that the reaction continued at ppm concentrations of NO_2 and estimated a lower limit to the uptake coefficient for NO_2 of 5×10^{-8}, assuming the reaction was first order in NO_2. Winkler et al.[11] used XPS to follow the increase in nitrate during the reaction of NO_2 with NaCl and reported that the rate was proportional to the square of the NaCl surface sites and the square root of NO_2. Vogt and Finlayson-Pitts[8-10] used diffuse reflectance Fourier transform infrared spectrometry (DRIFTS) to follow the formation of nitrate and showed that the reaction was second order in NO_2; assuming that N_2O_4 was the reactant, the uptake coefficient was measured to be $(1.3 \pm 0.6) \times 10^{-4}$ (1σ). Peters and Ewing[6] followed the formation of nitrate on single crystal NaCl(100) and also found the reaction was second order in NO_2. Assuming that N_2O_4 is the reactant, the uptake coefficient was $(1.3 \pm 0.3) \times 10^{-6}$, two orders of magnitude less than reported by Vogt and Finlayson-Pitts. However, in the presence of 9.5 mbar water vapor, the uptake coefficient increased by a factor of about 100. It is likely that the difference is that their single crystals did not hold significant amounts of surface adsorbed water, whereas the powders used by Vogt and Finlayson-Pitts are known to hold significant amounts of SAW[2] which enhances the reactivity through mobilization of the nitrate ions and exposure of fresh NaCl during the reaction. Caloz et al.[3] measured using a Knudsen cell an upper limit of $<10^{-7}$ for uptake of NO_2 on NaCl and $<2 \times 10^{-7}$ for uptake on KBr, with the reaction being first order in NO_2. Yoshitake[13] also used DRIFTS to study this reaction and reported that for "dry" NaCl, the reaction was second order in NO_2 with an uptake coefficient assuming the reactant is N_2O_4 of $(4 \pm 2) \times 10^{-5}$. However, if the NaCl had been pretreated with water vapor, the uptake was first order in NO_2 with $\gamma = (1.5 \pm 0.2) \times 10^{-8}$. Karlsson and Ljungstrom[5] generated NaCl particles and measured the loss of chloride and formation of nitrate using ion chromatography on particles collected on filters; they obtained a lower limit for the reaction probability of 3×10^{-4}. Surprisingly, the conversion of NO_2 to nitrate decreased as the relative humidity increased from 9 to 79%. These reactions are sufficiently slow that they are unlikely to be important in the atmosphere.

Abbatt and Waschewsky[1] measured the loss of NO_2 in a flow tube containing deliquesced 1–5 μm NaCl particles (75% RH); no significant loss was observed on unbuffered particles or particles buffered at pH of 7.2 or having pH of 0.3 using HCl. An upper limit of $\gamma_o < 1 \times 10^{-4}$ for the uptake of NO_2 was derived from these measurements. Yabushita et al.[12] have recently shown using ESI-MS that uptake of NO_2 to aqueous droplets, yielding the nitrate anion, is facilitated by the presence of halide anions, perhaps through the formation of a complex with NO_2 on the surface.

27. **NO_2 + NaBr(s).** Vogt et al.[1] used diffuse reflectance infrared spectroscopy to study NO_2 + NaBr(s) at 298 K. The reaction was determined to be approximately second order in NO_2. Assuming that adsorbed N_2O_4 is the reactant leads to $\gamma = 2\ (+4, -1.3) \times 10^{-4}$.

28. **NO_2/N_2O_4 + sea salt.** Sverdrup and Kuhlman[2] measured the uptake of NO_2 on artificial sea salt using the NO_2 loss measured in a flow tube lined with the salt. The uptake coefficient was reported to increase from 10^{-7} to 10^{-6} as the relative humidity increased from 44% to 88%. Langer et al.[1] used diffuse reflectance Fourier transform infrared spectrometry to follow nitrate formation on synthetic sea salt and found the reaction was approximately second order (1.8 ± 0.2) in NO_2 in He carrier gas but approximately first order (1.2 ± 0.2) in NO_2 in air. Assuming that N_2O_4 was the reactant in He, $\gamma_{ss} = 1 \times 10^{-4}$, and assuming NO_2 is the reactant in air, $\gamma_{ss} = 1 \times 10^{-8}$. These reactions are sufficiently slow that they are unlikely to be important in the atmosphere.

30. **$NO_3 + H_2O(l)$.** Rudich et al.[3,4] used wetted-wall flow tube techniques to measure uptake coefficients for NO_3 on pure water and aqueous NaCl, NaBr, NaI, and $NaNO_2$ solutions. These studies were extended to other aqueous solutions by Imamura et al.[1] Uptake on pure water was consistent with reaction of NO_3 to produce HNO_3 and OH. Uptake coefficients with solutions containing I^-, Cl^-, Br^-, NO_2^-, and other anions were larger and scaled with anion concentration, indicating electron transfer reactions to produce NO_3^-. Reactions with these anions and/or adsorbed organic contaminants may well dominate the reactive uptake of NO_3 by real atmospheric aqueous surfaces. The γ of $(2.0 \pm 1.0 \times 10^{-4})$ at 273 K determined for pure water by Rudich et al. is significantly lower than the lower limit of 2.5×10^{-3} from Thomas and co-workers as quoted by Mihelcic et al.[2] and further discussed in Thomas et al.,[6] who also dispute that reactive uptake coefficient on pure water reported by Rudich et al. is due to nitric acid production. A detailed analysis of uptake coefficients for KI aqueous solutions by Rudich et al.[3] indicated that the NO_3 mass accommodation coefficient is >0.04,[3] but this result may be biased due to reactive uptake by interfacial I^-. Single droplet uptake results on Alizarin Red S dye and NaCl solutions at 293 K by Schütze and Herrman[5] suggest a value an order of magnitude smaller (see Table 5–1).

31. **NO_3 + NaCl.** Also see note for $NO_3 + H_2O(l)$. Recommended value for the initial uptake coefficient on solid NaCl is based on work of Seisel et al.,[4,5] Gershenzon and coworkers,[1] and Gratpanche and Sawerysyn[2]. Seisel et al.[4,5] used a Knudsen cell with mass spectrometric and laser-induced fluorescence detection of the NO_3. Salt powders from 60–630 μm in size were used, as well as spray-deposited samples; no dependence on the sample mass for powders or between powders and the spray-deposited samples was observed so no corrections for diffusion into underlying layers were applied. They obtained values for γ_0 of $(4.9 \pm 3) \times 10^{-2}$ and $(4.6 \pm 4) \times 10^{-2}$ (1σ), respectively. Gershenzon and coworkers used flow reactors with ESR and MS detection and measured the loss of NO_3 on an axially located rod coated with salt; they interpret their results, and the associated value of γ_0 derived from their data based on a multi-step mechanism involving adsorption and then reaction of NO_3 on the salt. The value for γ_0 is sensitive to several unknown parameters in the model, and they give a range from $(0.2–3.9) \times 10^{-2}$. Gratpanche and Sawerysyn[2] used a flow tube coated with NaCl and ESR detection of NO_3, and reported a value of $(1.7 \pm 1.2) \times 10^{-2}$ (1σ); on very dry NaCl, no uptake was observed, again indicating the importance of small amounts of water for the reaction. Gershenzon et al.[1] reported that the uptake coefficient decreased by about a factor of 20 over about half an hour, suggesting that the steady state value of γ_{ss} is approximately 1.5×10^{-3}. Zelenov et al. reported that the uptake coefficient for NO_3 on NaCl (and NaBr; see next note)[7,8] could be fit by a time-dependent term and a time-independent term: $\gamma(t) = \gamma_0 \exp(-t/\tau) + \gamma_{ss}$. They observed that γ_{ss} depends on the type of salt, as well as the NO_3 and water concentrations, while γ_0 depended only on the type of salt and NO_3 concentration. They concluded that the products are chemisorbed Cl atoms. No temperature dependence has been observed over the temperature range 258–301 K by Gratpanche and Sawerysyn,[2] consistent with only an ~10% change in the uptake coefficient from 293 to 373 K observed by Gershenzon et al.[1]

The uptake of NO_3 on aqueous solutions of NaCl has been measured at 273 K by Rudich et al.[3] and at 293 K by Thomas et al.[6] NO_3 reacts in solutions with the halide ions. The measured uptake coefficients varied from (0.8–6) × 10^{-3} for solutions of activity ranging from 0.008 to 0.45 at 273 K[3] and was reported to be >2 × 10^{-3} on 0.1 M NaCl at 293 K.[6]

32. **NO_3 + NaBr and NaI.** Also see notes for NO_3 + NaCl and NO_3 + $H_2O(l)$. Recommended value of γ_0 for the reaction with solid NaBr is based on reported values of 0.16 ± 0.08,[4] 0.20 ± 0.10,[5] a range of 0.1 to 0.3 [1] and 0.11 ± 0.06 [2] (all errors cited are 1σ). Gershenzon et al.[1] observed a decrease of about a factor of two with time, suggesting that γ_{ss} ~0.05. Gratpanche and Sawerysyn[2] found a slight negative temperature dependence, $\gamma_0 = (1.6^{+1.8}_{-0.9} \times 10^{-3}) \exp[(1210 \pm 200)/T]$ over the range from 243–293 K. Gershenzon et al.[1] also reported a small (30%) decrease in γ_0 from 293 to 373 K. Zelenov et al.[6,7] reported that the uptake coefficient for NO_3 on NaBr (and NaCl; see preceding note) could be fit by a time-dependent term and a time-independent term: $\gamma(t) = \gamma_0\exp(-t/\tau) + \gamma_{ss}$. They observed that γ_{ss} depends on the type of salt, as well as the NO_3 and water concentrations, while γ_0 depended only on the type of salt and NO_3 concentration. They concluded that the products are bromine atoms in agreement with the observations of the branching ratio as well as the mass balance by Seisel et al.[4,5]

Rudich et al.[3] measured the uptake of NO_3 on aqueous KI solutions; NO_3 is taken up and reacts with I^- in solution. Uptake coefficients increased with the concentration of I^-, ranging from $\gamma = 0.9 \times 10^{-3}$ at 5×10^{-6} M KaI to 3.2×10^{-3} at a concentration of 8×10^{-5} M.

33. **NO_3 + organic surfaces.** Initial uptake of the nitrate radical occurs on organic surfaces that contain both unsaturated carbon-carbon bonds and saturated carbon-carbon bonds. The former reactions occur with large initial uptake coefficients (as large as 0.1) whereas smaller uptake coefficients describe uptake to saturated organic surfaces. The product distributions are highly complex. A more detailed discussion of this complex chemistry is given in two review articles: Kolb et al.[2] and Abbatt et al.[1]

34. **N_2O_5 + H_2O(s).** Leu[4] and Hanson and Ravishankara[1] measured nearly identical values of 0.028 (±0.011) and 0.024 (±30%) in the 195–202 K range on relatively thick ice films in coated wall flow tubes. Quinlan et al.[5] measured a maximum value for γ on ice surfaces at 188 K of 0.03 in a Knudsen cell reactor. The average of these three studies is 0.027 with a standard deviation of 0.003. Hanson and Ravishankara[2,3] presented new and re-analyzed data as a function of ice thickness, with a value of ~0.008 for the thinnest ice sample, rising to 0.024 for the thickest. From these data there would appear to be no strong dependence on temperature, at least over the 188–195 K range. It is unclear whether the measured dependence on ice film thickness is due to added porosity surface area in the thicker films or decreased ice film integrity in thinner films. The error estimate in the table is driven by the possible systematic error due to unresolved film thickness effects rather than the small statistical error among the "thick film" values from the three groups.

Zondlo et al.[6] report the formation of a supercooled H_2O/HNO_3 liquid layer at 185 K as a reaction product, forming NAT or NAD only after decreasing the relative humidity below the ice frost point. This effect is similar to that resulting from the interaction of gaseous HNO_3 or $ClONO_2$ with the ice surface. These authors measured $\gamma = (7 \pm 3) \times 10^{-4}$ at 185 K for the reaction of N_2O_5 with this supercooled liquid layer.

35. **N_2O_5 + H_2O(l).** This reaction has now been studied widely on both pure water and on aqueous surfaces. The kinetics of the reaction are dependent on a number of conditions, as described below.

On pure water, Van Doren et al.[26] measured γs of 0.057 ± 0.003 at 271 K and 0.036 ± 0.004 at 282 K using a droplet train uptake technique, indicating that the reaction has a negative temperature dependence. George et al.[8] also used a droplet train technique to measure γs of $(3.0 \pm 0.2) \times 10^{-2}$ (262 K), $(2.9 \pm 1.2) \times 10^{-2}$ (267 K), $(2.0 \pm 0.2) \times 10^{-2}$ (273 K), $(1.6 \pm 0.8) \times 10^{-2}$ (276 K), and $(1.3 \pm 0.8) \times 10^{-2}$ (277 K) on pure water, while Schweitzer et al.[23] used the same approach for pure water and salt solutions between 262 and 278 K, obtaining similar results. Msibi et al.[17] measured a smaller γ of 2.5×10^{-3} for water adsorbed on a denuder flow tube well under 66–96% relative humidity conditions at room temperature, making the nature of the surface unclear. After correction for gas-phase diffusion effects, Schütze and Herrmann[22] measured a γ of 1.1×10^{-2} at 293 K using a single suspended droplet flow reactor method that was probably constrained by nitrate build-up in the droplet's surface layer.

A number of other groups have measured the uptake coefficients of N_2O_5 on aqueous solutions where, in the absence of halide ions, the reactivity of the N_2O_5 is with the water solvent molecules. These studies include: Mozurkewich and Calvert[16] on $NH_3/H_2SO_4/H_2O$ aerosols in an aerosol flow tube, Hu and Abbatt[13] on $(NH_4)_2SO_4$ aerosols at 297 K in an aerosol flow tube, Mentel and co-workers[15,28] on sodium sulfate and sodium nitrate particles in a large aerosol chamber, Thornton et al.[25] for uptake on malonic acid aerosols in an aerosol flow tube, Hallquist et al.[12] studied ammonium sulfate and sodium nitrate particles, and Griffiths et al.[9] measured uptake on a variety of soluble organic acids with and without ammonium sulfate present. Note that the studies conducted with sodium chloride or sea salt as the solute are listed in the N_2O_5 + NaCl note below.

Overall, the γ values measured at high relative humidity by Van Doren et al., Mozurkewhich and Calvert, Hu and Abbatt, Thornton et al., Hallquist et al., Griffiths et al., Gaston et al.[7] and Gaston and Thornton,[6] and those from experiments with NaCl at high relative humidity (Behnke et al.[2] and Thornton and Abbatt[24]) are quite consistent when temperature and RH effects are factored in, yielding uptake coefficients in the 0.02 to 0.04 range at room temperature. The lower values from the Louis Pasteur (George et al. and Schweitzer et al.) and Birmingham (Msibi et al.) groups appear to have much less pronounced temperature dependence and are inconsistent with the other measurements. The same function used to fit the N_2O_5 uptake on sulfuric acid as a function of temperature and concentration, discussed below, has been extended to the Van Doren et al. and Hu and Abbatt data for pure water and very high RH aerosols. See note on N_2O_5 + $H_2SO_4 \bullet nH_2O$(l) for the functional fit and its error discussion.

However, other factors that affect the uptake coefficient include: 1. At low relative humidities, the γ values are reduced from the values close to water saturation, with the uptake coefficient scaling linearly with the water content of the aerosol below a specific relative humidity (roughly 50% RH). This is indicative of a competition for water of a reactive intermediate formed via N_2O_5 initial uptake (see in particular Thornton et al.,[25] Thornton and Abbatt,[24] Hallquist et al.,[12] and Griffiths et al.[9]). 2. At high aerosol nitrate concentrations the kinetics are slower, falling below 0.001 in some cases, indicative that a reactive intermediate along the reaction pathway is less stable under such conditions (see Mentel and co-workers[15,28] and Hallquist et al.[12]). Note that high nitrate levels may develop in laboratory experiments where high N_2O_5 concentrations are used, potentially biasing the uptake coefficients to lower values than are atmospherically significant. This may be manifest as an uptake coefficient that is dependent on the concentration of N_2O_5 used.[25] 3. By varying particle diameters, the reacto-diffusive length has been measured to be 48 nm at 50% RH on malonic acid aqueous particles, indicating that this process is not fully occurring at the surface of the particle and that there might be a particle-size dependence to the uptake coefficient.[25] Likewise, studies by Gaston and Thornton[6] have indicated the reacto-diffusive length to be 32 nm in the case of uptake to aqueous ammonium sulfate and bisulfate particles. 4. The uptake coefficients can be substantially suppressed when large organic molecules, such as those formed by the reaction of ozone with alpha-pinene or those present in humic-like materials are present in/on aqueous inorganic aerosol.[1,5] The uptake coefficients in these systems can be substantially below 0.01, with only a few weight percent of organic present. Also, monolayers of surfactant organics on aqueous particles can have the same effect (Thornton and Abbatt[24] and McNeill et al.[14]). Gaston et al.[7] have further explored the role of organics, showing that the chemical nature of the organic material (as described by its O/C ratio) and the relative humidity need to be taken into consideration. Low O/C substances generally depress the uptake coefficient more effectively, but not universally, than high O/C substances. The picture that arises is that core-shell morphologies arise in many mixed organic-inorganic particles, with the solubility and/or diffusivity of N_2O_5 in the organic shell driving the reduction of the uptake coefficient relative to its value for the pure inorganic system. Consistent with this model is the work of Gržinić et al.,[11] which demonstrated the viscosity of the organic material (in particular, citric acid at different relative humidities) has a strong role in affecting the uptake. Higher viscosity presumably sets the diffusion of either water or N_2O_5 as the rate determining step in the reaction, sometimes confining the reactive uptake to the surface of the particle. Finally, as observed with pure water by Van Doren et al.,[26] there is a negative temperature dependence to the uptake coefficient over the small temperature range that has been studied.[9,12] For example, the most recent measurements by Griffiths et al.[10] show the uptake coefficient changing from 0.035 to 0.005 from 263 to 303 K at 50% RH with ammonium sulfate particles. A parameterization of laboratory kinetics that takes into account the water, nitrate, dissolved organic, and chloride concentrations has been published by Bertram and Thornton.[3]

Beyond the laboratory, the uptake coefficient of N_2O_5 has been measured from decays on ambient (outdoor air) particles in an aerosol flow tube. It has been observed that the uptake coefficients are smallest (<0.005) when the organic content of the particles is high. Uptake coefficients of 0.03 were measured, but only on some occasions and when the sulphate/organic content of the particles was highest.[4] Additional studies with ambient particles have confirmed the wide range of uptake coefficients under ambient conditions with a wide range of relative humidities, observing a substantial amount of day-to-day variability that may be due to variable particle phase and/or organic composition.[18-21,27] As examples, Phillips et al.[18] observed uptake coefficients that varied from 0.004 to 0.11 at a semi-rural, non-coastal, mountain site. Yields of $ClNO_2$ were also variable from 0.035 to 1.38, dependent on the amount of chloride in the particles. Wagner et al.[27] illustrate the importance of the nitrate inhibition of uptake, via measurements in wintertime in Colorado. Ryder et al.[20] show that marine sea spray aerosol does not exhibit much uptake inhibition arising from organic components in the particles, relative to a purely inorganic aqueous particle.

36. **N_2O_5 + HNO_3•$3H_2O$(s).** Hanson and Ravishankara[1] have measured $\gamma = 0.0006$ (± 30%) near 200 K. They re-analyzed their results and give additional data as a function of ice thickness (Hanson and Ravishankara[2,3]), deriving a value of 3×10^{-4} for the thinnest nitric acid trihydrate (NAT) covered ice layer, with values up to three times higher for thicker NAT-covered ice layers. As in the case of uptake on water ice this may be due to increased surface area from porosity in the thicker films, or less integrity in the thinner films. The uncertainty listed in the Table is driven by this observed effect. All of the Hanson et al. data are in poor agreement with the $\gamma = 0.015 \pm 0.006$ reported by Quinlan et al.[4] from their Knudsen cell measurements; this measurement may have been biased by formation of a super-cooled aqueous nitric acid surface and is judged to be unreliable. It is possible that the uptake coefficients will be affected by whether the NAT surfaces are water-rich or poor.

37. **N_2O_5 + H_2SO_4•nH_2O(l).** This reaction has been intensively studied between 195 and 296 K for a wide range of H_2SO_4 wt.% values using four complementary experimental techniques. Data are available from aerosol flow tube studies (Fried et al.,[3] Hanson and Lovejoy,[5] Hu and Abbatt,[7] and Hallquist et al.[4]), coated wall flow tube studies (Hanson and Ravishankara[6] and Zhang et al.[14]), a stirred Knudsen cell (Manion et al.[9]) and droplet train studies (Van Doren et al.[12] and Robinson et al.[11]). All studies have yielded γs between ~0.05 and 0.20 with modest dependence on surface H_2SO_4 wt.% and temperature. The Knudsen cell studies, aerosol flow tube studies at higher N_2O_5 exposure and the ternary $H_2SO_4/HNO_3/H_2O$ studies of Zhang et al.[14] all illustrate that significant levels of HNO_3 in the H_2SO_4/H_2O solutions will reduce γ measurably; this fact explains some of the scatter in aerosol flow tube studies and the surface saturation evident in the Knudsen cell studies. The "nitrate effect" reduction of γ was also studied in extensive aerosol chamber studies at 193.6 K by Wagner et al.[13] The effect of 5.0×10^{-7} Torr HNO_3 on γ as a function of temperature at two water vapor concentrations are plotted in Zhang et al.;[14] the decrease in γ is greatest at low temperatures, approaching a factor of 2–5 between 200 and 195 K.

Experimental data on sulfuric acid surfaces between 40 and 80 wt% sulfuric acid deemed to be free of saturation effects, plus the pure water uptake data of Van Doren et al.[12] and high relative humidity ammonium sulfate aerosol uptake data of Hu and Abbatt[7] were all fit to a polynomial expression to yield a single model describing γ for N_2O_5 uptake valid between 0 and 80 wt% H_2SO_4 and 180 to 300 K (Robinson et al.[11]). The form of this function is: $\gamma_o = \exp(k_o + k_1/T + k_2/T^2)$, where T is the temperature in K. The parameters k_o, k_1, and k_2 obtained from the best-fit are:

$$k_o = -25.5265 - 0.133188wt + 0.00930846wt^2 - 9.0194 \times 10^{-5}wt^3$$

$$k_1 = 9283.76 + 115.345wt - 5.19258wt^2 + 0.0483464wt^3$$

$$k_2 = -851801 - 22191.2wt + 766.916\,wt^2 - 6.85427wt^3$$

where wt is the weight percentage of H_2SO_4.

The overall error of applying the uptake function provided here consists of two components. One is the standard deviation of the model-calculated value with respect to measured data, σ_m, which is given by

$$\sigma_m = \sqrt{\frac{\sum_{i=1}^{N}\left(1-\frac{\gamma_i}{\gamma_{model}}\right)^2}{N-1}}.$$

The other is the standard deviation of relative experimental measurement error from the mean, σ_d, which is given by

$$\sigma_d = \sqrt{\frac{\sum_{i=1}^{N}\left(\frac{\Delta\gamma_i}{\gamma_i}\right)^2}{N(N-1)}}.$$

The overall error is

$$\sigma = \sqrt{\sigma_m^2 + \sigma_d^2}\,.$$

(These formulations are also applied below in the error estimation for the $ClONO_2 + H_2O$ and HCl, $BrONO_2 + H_2O$, and HOCl + HCl reaction system. For N_2O_5, the error is estimated to be 15% (1σ), with $\sigma_m = 14.7\%$ and $\sigma_d = 2.9\%$).

Liquid trough flow reactor studies on 60–80 wt%H_2SO_4 at 273–280 K by Bertram and co-workers demonstrated that adsorbed single and dual component coatings of organics like 1-hexadeconal, 1-octadeconal and stearic acid could reduce γ by well over a factor of 10, while coatings of phytanic acid had little effect. Even 0.75 monolayer coatings of 1-octadeconal reduced γ by a factor of 10.[1,2,8] Park et al.[10] impinged a molecular beam of N_2O_5 on 72 wt% H_2SO_4 at 216 K, observing that sub-monolayer coverage of 1-butanol and 1-hexanol reduced bare acid reactive uptake coefficients from ~0.15 to ~0.10 and 0.06, respectively.

38. **N_2O_5 + H_2SO_4•H_2O(s).** Zhang et al.[1] used coated flow tube techniques to measure the uptake of N_2O_5 on solid sulfuric acid monohydrate over a temperature range of 200 to 225 K. The measurement values of γ were significantly higher at 200 K (γ ~1 × 10^{-3}) than at 225 K (γ ~10^{-4}) and were well fit by log γ = [4.78 – 0.0386T(K)]. Acid-rich H_2SO_4•H_2O surfaces had a lower γ than water rich surfaces (log γ = [0.162 – 0.789 × log p_{H2O}] where p_{H2O} is their experimental water vapor partial pressure in Torr).

39. **N_2O_5 + H_2SO_4•$4H_2O$(s).** Hanson and Ravishankara[1] studied N_2O_5 uptake by frozen 57.5 and 60 wt.% H_2SO_4 as a function of temperature and relative humidity. The 57.5 wt% surface was not sensitive to relative humidity and was slightly more reactive (γ = 0.008 vs 0.005) at 205 K than at 195 K. Reaction probabilities on the 60 wt% surface dropped off with temperature and relative humidity.

40. **N_2O_5 + Mineral Dust.** Tang et al.[1] have studied the room temperature reactive uptake of N_2O_5 to two different mineral dust aerosol types using an aerosol flow tube coupled to a thermal-dissociation cavity ring-down detection technique. It is notable that the reactive uptake of N_2O_5 to illite clay particles is large, on the order of 0.09 under dry conditions. This value is larger than values commonly measured for N_2O_5 uptake to aqueous substrates, such as ammonium sulfate or sodium chloride salts. Clays take up water at elevated relative humidity and so it is interesting that the uptake coefficient drops to 0.04 at an RH of 67%. The value of 0.04 is much closer to the values for gamma on deliquesced salt solutions. Given that there is a drop of the uptake coefficient with increasing relative humidity, it is possible that there is a change in uptake mechanism occurring. By contrast, the uptake coefficient of N_2O_5 to Arizona Test Dust (ATD), a multicomponent dust mixture, is much smaller, about 0.006, and it does not show a strong relative humidity dependence.
Back to Table

41. **N_2O_5 + HCl on H_2O(s).** Leu[3] measured γ = 0.028 ± 0.011 at 195 K, while Tolbert et al.[5] measured a lower limit of 1 × 10^{-3} at 185 K. Seisel et al.[4] measured γ ~0.03 at 200 K using a Knudsen flow reactor with a range of HCl flows. The uptake coefficient at low HCl flows is only slightly enhanced compared to the uptake on a pure ice surface. $ClNO_2$ was observed as the product in these studies. These experiments were done at high HCl levels probably leading to a liquid water/acid surface solution (Abbatt et al.[1]). Indeed, Hanson and Ravishankara[2] point out that a pure ice surface is readily converted to one with a thin NAT coating even with low N_2O_5 partial pressures, making this reaction difficult to study on pure ice surfaces.

46. **N_2O_5 + NaCl.** This reaction has been studied on both solid NaCl and on aqueous solutions. The uptake of N_2O_5 on solid NaCl has been studied using Knudsen cells,[3,6] flow reactors,[8,9] annular reactors[11] and diffusion tubes.[7] The reaction has two possible channels if there is water available on the surface: $N_2O_5 + NaCl \rightarrow ClNO_2 + NaNO_3$ (1) and $N_2O_5 + H_2O/NaCl \rightarrow 2\ HNO_3$ (2). The presence of the two channels is supported by measured yields of $ClNO_2$ (relative to N_2O_5 lost) that vary from 60–100% [3,6,7,9] and by the observation of gaseous HCl as a reaction product.[6] Because hydrolysis on the surface occurs in addition to the reaction with Cl^-, the net uptake coefficient for N_2O_5 is particularly sensitive to the presence of surface-adsorbed water (SAW), with higher values for powders where there are more steps and edges that hold SAW. For example, Leu et al.[8] measured an upper limit of $\gamma < 1.0 \times 10^{-4}$ for salt powders that had been heated overnight in a vacuum, but ~4.5×10^{-4} for samples that were only pumped on for about an hour. Fenter et al.[3] reported a preferred value for the uptake coefficient of $(5 \pm 2) \times 10^{-4}$; however, the measured values varied from 2×10^{-3} for monodisperse powders (after correction for pore diffusion by factors of ~5 to 30) to $<1.0 \times 10^{-4}$ for a polished window face. Hoffman et al.[6] report a steady state value of $\gamma_{ss} = 3 \times 10^{-3}$ based on Knudsen cell studies of powders using less than a layer of salt where corrections to the available surface area due to diffusion into the salt are not necessary; the branching ratio for reaction (1) was measured to be 0.73 ± 0.28 (2σ).

The uptake of N_2O_5 on NaCl solutions or aqueous particles has been measured by a number of techniques.[1,2,4,5,12,16-18] Overall, the reported values of γ for relative humidities between 45 and 100% are between 1.5×10^{-2} to 5.0×10^{-2} and temperatures between 263 K and room temperature. Zetzsch and coworkers[1,2] used an aerosol chamber to measure the uptake of N_2O_5 on deliquesced NaCl particles from 71–94% RH, and obtained a value of $\gamma = 3.2 \times 10^{-2}$. Behnke et al.[1] measured $ClNO_2$ in a yield of 66 ± 7% from aerosol particle experiments. In a wetted wall flow tube, the yield was observed to increase to 100% at concentrations of NaCl of 1 M and above. Thornton and Abbatt[17] report a yield of at least 50% $ClNO_2$ at 50% RH, using an aerosol flow tube technique. It is proposed by both groups that a mechanism involving a competition between the reaction of NO_2^+ (or $H_2ONO_2^+$) with water to form HNO_3 or with Cl^- to form $ClNO_2$ determines the product yield. George et al.[5] used a droplet train and measured the formation of NO_3^- in the droplets; the value of γ decreased from 0.039 ± 0.013 at 263 K to 0.014 ± 0.008 at 278 K. Stewart et al.[16] measured the uptake of N_2O_5 on NaCl particles in a flow tube; after correction for diffusion/particle size effects, an uptake coefficient of 3×10^{-2} was derived at relative humidities 30% and above. The work of Gaston and Thornton[4] in which the uptake coefficients were independent of particle size indicates that the reactive process is occurring with a short reacto-diffusive length, close to the surface. This is consistent with facile reaction of the NO_2^+ intermediate with aqueous chloride. Shaloski et al.[15] have explored the surficial interactions of N_2O_5 with bromide, in the presence of a range of surfactants, finding that the nature of the intermolecular interactions can have a strong effect of the efficiency of bromide oxidation. Schweitzer et al.[14] used a droplet train apparatus to measure the uptake of N_2O_5 on water and on solutions of NaCl, NaBr and NaI with concentrations ranging from 0.1 to 1 M over a temperature range from 262 to 278 K. Within experimental error, all of the uptake coefficients were the same, with an average value of $\gamma = 0.018 \pm 0.003$. For 1 M NaCl, the $ClNO_2$ yield was 100%.

Note that the uptake kinetics can be suppressed by the presence of an organic monolayer on the aqueous particles.[10,17] Also, the product yield can change to Cl_2, when the acidity of the surface is taken below 2 and for chloride concentrations as low as 0.05 M (Roberts et al.[13]).

47. **N_2O_5 + KBr, NaBr, NaI.** Fenter et al.[1] and Koch et al.[3] measured the uptake coefficient for N_2O_5 on KBr at ambient temperature using a Knudsen cell and molecular diffusion tube respectively. The Knudsen cell experiments gave a value of $(4 \pm 2) \times 10^{-3}$ after correction (by factors of 6–16) for pore diffusion, and the molecular diffusion tube a value of $(2.5 \pm 1) \times 10^{-3}$. In the Knudsen cell studies, the uptake coefficient was larger for powders and a depolished window face (both 4×10^{-3}) than for a polished window face ($<1 \times 10^{-4}$), similar to the observations for the NaCl reaction (N_2O_5 + NaCl); this again suggests the importance of surface-adsorbed water and possibly surface defects created by roughening (which, however, also hold water) for the reaction. The initial product of the reaction is $BrNO_2$, identified by Finlayson-Pitts et al.[2] by FTIR but this can react further with the salt to generate Br_2, the product observed by Fenter et al.[1]

Schweitzer et al.[4] used a droplet train apparatus to measure the uptake of N_2O_5 on water and on solutions of NaBr and NaI, as well as NaCl, with concentrations ranging from 0.1 to 1 M over a temperature range from 262 to 278 K. Within experimental error, all of the uptake coefficients were the same, with an average value of $\gamma = 0.018 \pm 0.003$. For the NaBr reaction, the gas phase products were $BrNO_2$, Br_2, and HONO. For the NaI reaction, the only gas phase product observed was I_2.

48. **N_2O_5 + sea salt.** The uptake of N_2O_5 on solid synthetic sea salt was measured to be $\gamma = (3.4 \pm 0.8) \times 10^{-2}$ (2σ) by Hoffman et al.[1] This will be an upper limit as 1–2 layers of salt were used and no correction was made for diffusion into the bottom layer. However, it is clear that the reaction is at least an order of magnitude faster than that for NaCl; the yield of $ClNO_2$ is 100%.

Stewart and Cox[4] measured the uptake of N_2O_5 on submicron synthetic sea salt aerosols in a flow tube; after correction for diffusion/particle size effects, a value of $\gamma = 2.5 \times 10^{-2}$ was derived, independent of relative humidity above 30%. Similar results are reported for the same substrate by Thornton and Abbatt,[5] with the uptake coefficient changing from 0.02 to 0.03 from 43 to 70% RH. For partially crystallized artificial sea salt, the uptake coefficient was 0.005 at 30% RH. Employing sea spray particles generated using a process that mimics that which proceeds in the environment, and using either genuine seawater or artificial seawater, the uptake coefficient was measured by Ryder et al.[3] to be between 0.01 and 0.03 for relative humidities between 50 and 65%. Addition of trace organics to the artificial seawater, such as a sterol, sugar or polysaccharide, did not affect the overall update of N_2O_5. Thus, the organic constituents on the surfaces of these particles appear to not inhibit the reaction relative to the values measured on pure aqueous sodium chloride aerosol.

Experiments were conducted by Lopez-Hilfiker et al.[2] in a coated-wall flow tube on the uptake of N_2O_5 to frozen salt solutions containing variable ratios of Cl to Br, from temperatures of 258 to about 240 K. Br_2 and $ClNO_2$ products were observed with a total yield of unity, with their ratios dependent upon both temperature and the Cl/Br ratio of the frozen solution.

49. HONO + $H_2O(l)$. Bongartz et al.[1] present uptake measurements by two independent techniques, the liquid jet technique of Schurath and co-workers and the droplet train/flow tube technique of Mirabel and co-workers (Ponche et al.[4]). With a surface temperature of ~245 K the droplet train techniques yielded $0.045 < \gamma < 0.09$, while the liquid jet operating with a surface temperature of 297 K obtained $0.03 < \gamma < 0.15$. Mertes and Wahner[3] used a liquid jet technique to measure $4 \times 10^{-3} < \gamma < 4 \times 10^{-2}$ at 278 K. Harrison and Collins[2] performed aerosol flow reactor experiments on deliquescent sodium chloride and ammonium sulfate droplets at 279 K obtaining reactive uptake coefficients of 0.0028 ± 0.0015 and 0.0028 ± 0.0006, for 85% relative humidity conditions, respectively; these measurements are probably subject to significant surface saturation. Since HONO uptake by liquid water probably involves hydrolysis, an increase in Henry's law solubility with decreasing temperature may be offset by a decreasing hydrolysis rate constant, leaving the uptake coefficient's temperature trend uncertain. Measured uptake coefficients will not correspond to the mass accommodation coefficient.

50. **HONO + H_2SO_4•nH_2O(l).** Zhang et al.[4] measured uptake coefficients for HONO on sulfuric acid that increased from (1.6 ± 0.1) × 10^{-2} for 65.3 wt% H_2SO_4 (214 K) to (9.1 ± 1.6) × 10^{-2} for 73 wt% H_2SO_4 (226 K). Fenter and Rossi[3] measured uptake coefficients rising from 1.8 × 10^{-4} for 55 wt% H_2SO_4 (220 K) to 3.1 × 10^{-1} for 95 wt% H_2SO_4 (220 K and 273 K). Baker et al.[1] measured much smaller uptake coefficients for 60 wt% at 298 K. In general, the values measured by Zhang et al.[4] are a factor of 2 to 5 higher than those of Fenter et al.[3] for comparable acid concentrations. Since the reaction probably depends on both temperature and acid concentration and since the data scatter is high in both experiments, further independent data will be required to define γ as a function of acid concentration and temperature. These data are generally consistent with the effective Henry's law constant measurements of Becker et al.[2] who illustrate that HONO solubility decreases exponentially with H_2SO_4 concentration until ~53 wt%, at which point reaction to form nitrosyl sulfuric acid increases H* dramatically as H_2SO_4 concentration increases. Baker et al.[1] invoke surface decomposition of HONO to explain their room temperature data, since they separately determine that the bulk second-order disproportionation rate for HONO is too slow to account for even their small uptake coefficients. It is possible that surface formation of nitrosyl sulfuric acid and not HONO disproportionation is responsible for much of their measured uptake. The Zhang et al.[4] and Fenter and Rossi[3] data have been combined and fit with a four-term polynomial as a function of acid wt% (these data did not show an obvious temperature dependence):

$$\ln \gamma = a + b\,wt + c\,wt^2 + d\,wt^3$$

where wt is the H_2SO_4 wt%, and

$$a = -155.7 \pm 29.7$$

$$b = 5.663 \pm 1.232$$

$$c = -0.07061 \pm 0.01679$$

$$d = 0.000297 \pm 0.000076$$

This parameterization should be used only within the 55–95-wt% H_2SO_4 range and the 214 to 273 K temperature range.

51. **HONO + HCl + H_2O(s).** Knudsen cell uptake studies for HONO/HCl co-deposited on ice (180–200 K) and for HONO on 0.1 to 10 M HCl frozen solutions (~190 K) by Fenter and Rossi[3] showed HONO uptake coefficients in the 0.02 to 0.12 range as long as surface HCl concentrations significantly exceed HONO concentrations. ClNO was evolved quantitatively with HONO consumption. In a coated wall flow tube Diao and Chu[2] observed orders of magnitude lower uptake coefficients, even though low partial pressures of HONO were used. Some of the HCl partial pressures will have been large enough to melt the ice surface (Abbatt et al.[1]).

52. **HONO + HCl on H_2SO_4•nH_2O(l).** Fenter and Rossi[1] saw no reaction for acid wt% >65. They measured $\gamma = 2.0 \pm 0.7 \times 10^{-3}$ for 60 wt% acid saturated with HONO at 230 K. Zhang et al.[3] also measured the uptake of HCl after exposure to HONO, they observed HCl uptake with γs between 0.01–0.02 over an acid wt.% range of 60.8–71.3 (T = 207.9–222.6 K). The reaction was also studied by Longfellow et al.[2] using both HCl doped and HONO doped sulfuric acid aerosols. Their uptake measurements confirmed reaction at higher acid wt%, but by using lower HONO partial pressures they measured smaller γs. The reverse reaction, ClNO hydrolysis, was also studied in a wetted wall flow reactor and in the aerosol flow reactor by Longfellow et al.[2] and in a Knudsen cell reactor by Fenter and Rossi.[1] Data show clear evidence of both surface and bulk kinetics for the forward reaction. Longfellow et al.[2] report k^{II} values for the bulk reaction (in units of 10^4 M^{-1} s^{-1}) for 50 wt%: 81 at 250 K and 15 at 205 K; for 60 wt%: 9.4 at 250 K, 6.9 at 230 K and 5.0 at 219 K; for 67 wt%: 3.9 at 250 K; and for 70 wt%: 5.8 at 269 K and 0.35 at 215 K. The reaction is clearly complex and will require a comprehensive model of both the surface and bulk processes to arrive at an appropriate parameterization for γ.

53. **HONO + HBr + H_2O(s).** HONO reacts with HBr on ice films (Seisel and Rossi[2] and Diao and Chu[1]), but note that the HBr partial pressures used are generally higher than those prevalent in the atmosphere and so melting of the ice film may have occurred in these experiments. Diao and Chu observe BrNO as a product in a coated-wall flow tube.

54. **HONO + NaCl(s).** Diffuse reflectance experiments by Vogt and Finlayson-Pitt[3] on room temperature NaCl(s) and Knudsen cell uptake experiments by Fenter and Rossi on room temperature NaCl(s) and frozen 0.1 M NaCl aqueous solutions, all failed to show HONO uptake.[1] The latter results yield $\gamma < 1 \times 10^{-4}$. HONO + NaCl. Junkermann and Ibusuki[2] reported that HONO reacts with NaCl to form nitrite on the surface. However, subsequent studies[3] showed that the infrared bands assigned to NO_2^- were due to nitrate, likely from the reaction of gas phase NO_2 and perhaps HNO_3 present in the HONO. There is no evidence at the present time for a reaction between HONO and NaCl.

55. **HONO + Al_2O_3(s).** Romanias et al.[2] used a coated wall flow reactor with solid films of ~20 nm γ-alumina particles to measure HONO uptake coefficients over a RH range of 1.4×10^{-4} to 35.4% and a temperature range of 274–320 K, implementing mass spectrometric detection of HONO and its gaseous reaction products NO and NO_2.

The effect of near ultraviolet radiation (315–400 nm, $J_{NO2} = 0.002–0.012\ s^{-1}$) on uptake was also investigated. Reactive uptake was confirmed by a lack of HONO desorption and direct NOx product detection. Measured uptake coefficients are independent of [HONO] and T, but strongly dependent on RH. A moderate UV dependence that increased with RH and was linear in J_{NO2} was observed; neither significantly affected measured product branching ratios of (0.40 ± 0.06) for NO and (0.60 ± 0.09) for NO_2. Uptake coefficients were determined as a function of RH without and with UV radiation (J_{NO2} ~0.012 s^{-1}). The results were parameterized (estimated uncertainty of ± 30%):

$$\gamma(\text{dark}) = 4.8 \times 10^{-6}\,(\text{RH})^{-0.61} \quad (\text{RH} = 1.4 \times 10^{-4} \text{ to } 10.5\%)$$
$$\gamma(\text{UV}) = 1.7 \times 10^{-5}\,(\text{RH})^{-0.44} \quad (\text{RH} = 1.4 \times 10^{-4} \text{ to } 35.4\%)$$

The same authors published similar results for HONO reactive uptake on Fe_2O_3 and Arizona Test Dust.[1]

Given results from only one laboratory and no information on α-alumina surfaces, no uptake coefficient values are recommended.

56. **HNO_3 + NaCl(s) and NaCl(aq).** Recommendation is based on an average of the values of Hoffman et al.,[8] Ghosal and Hemminger,[6] the data of Davies and Cox[3] as revised by Ghosal and Hemminger[6] using their model for surface reactivation, and the single crystal data of Leu et al.[12] Hoffman et al.[8] used less than a single layer of particles so that diffusion into the underlying layers is not a factor to obtain an initial value of $\gamma_0 = (2.3 \pm 1.9) \times 10^{-3}$ (2σ). This is consistent within the combined experimental errors with a value of (1.3 ± 0.6) × 10^{-3} determined from the formation of nitrate on the surface of single crystal (100) NaCl by Ghosal and Hemminger,[6] and with a value of 1.1 × 10^{-3} from application of the Ghosal and Hemminger model to the Davis and Cox data.[3] Ghosal and Hemminger suggest that the value could be as high as 5 × 10^{-3} for NaCl powders that have more steps and edges that hold SAW.[7] At longer reaction times, the steady-state value[8] is a factor of two smaller, $\gamma = 1 \times 10^{-3}$. The reaction is hypothesized to occur both on dry terraces, which saturate rapidly, and on steps and edges that hold surface-adsorbed water. The water acts to recrystallize the product $NaNO_3$ so that the surface does not passivate during the reaction at atmospherically relevant HNO_3 pressures. This model, developed and modified by several research groups[2,3,6,8] brings together most of the seemingly disparate measurements of the reaction probability made using a variety of techniques including flow tubes,[3] Knudsen cells,[2,4,5,8] and XPS studies of nitrate formation on single crystals.[6,7,17] The only gas phase product observed is HCl, with a yield that is within experimental error of 100%. The higher value of (1.3 ± 0.4) × 10^{-2} of Leu et al.[12] was obtained by correcting even larger measured values using a pore diffusion model;[9,10] the corrections were typically in the range of a factor of 4–6. On single crystal NaCl where such corrections were not necessary, Leu et al.[12] measured a value of (2.4 ± 0.6) × 10^{-3}. A value of (4 ± 1) × 10^{-2} was measured using a molecular diffusion tube technique by Koch et al.[11] The corrected value of (8.7 ± 1.4) × 10^{-5} reported by Zangmeister and Pemberton[18,19] using Raman spectroscopy to follow the nitrate formed on the surface is lower than the other values likely because a much higher HNO_3 concentration was used (~ 10^{18} cm^{-3}), which would lead to a larger coverage of the surface by the recrystallized $NaNO_3$ product and passivation of much of the NaCl surface.

Abbatt and Waschewsky[1] measured the loss of gas-phase HNO_3 in a flow tube containing deliquesced 1–5 μm NaCl particles (75% RH) and obtained a lower limit to the uptake coefficient for HNO_3 of 0.2 on unbuffered NaCl. Stemmler et al.[15] report a value of 0.5 ± 0.2 for the initial uptake coefficient on deliquesced particles at 60% RH. Tolocka et al.[16] followed the reaction of HNO_3 with 100–220 nm NaCl particles at 80% RH using single particle MS to measure the Cl^-/NO_3^- ratio; the uptake coefficient for 100 nm particles was (4.9 ± 2.7) × 10^{-3} and increased with droplet size. Saul et al.[14] have extended the Tolocka et al. work, by studying the reaction over a wide range of relative humidities, both above and below the efflorescence point. Uptake coefficients on the mixed nitrate-chloride particles reach a maximum of 0.12 or so at 50% RH, decreasing at both higher and lower RHs. The presence of hygroscopic $MgCl_2$ increases the uptake coefficient at low RHs, where the particles may remain liquid. Liu et al.[13] using static particles probed spectroscopically determine the maximum uptake coefficients to be 0.2 (uncertainty a factor of three), also close to 50% RH, decreasing at higher and lower RHs. The combination of these studies shows that the initial uptake of HNO_3 into solution is fast, with γ_0 >0.2; as the solution becomes acidified, HCl is expelled as the gaseous product. The uptake coefficient may decrease when the reaction proceeds on processed particles, where a large amount of nitrate has built up. In such cases, the maximum reactivity is at close to 50% RH. Note that the Stemmler et al.[15] study illustrated that monolayer coverages of long-chain surfactants can reduce the initial uptake coefficient by over an order of magnitude.

57. **HNO_3 + NaBr and KBr.** Fenter et al.[1] reported that the value of γ for uptake of HNO_3 on NaCl, NaBr, KBr and KCl was the same, $(2.8 \pm 0.3) \times 10^{-2}$, independent of sample mass. Koch et al.[2] reported an uptake coefficient of HNO_3 on KBr of $(2 \pm 1) \times 10^{-2}$ using a molecular diffusion tube technique. As discussed in Note 7, integration of the results of an extensive series of studies in different laboratories using different techniques, uptake coefficients for HNO_3 on NaCl give a value for the HNO_3-NaCl reaction that is smaller than measured in the Fenter et al.[1] and Koch et al.[2] studies. These values for KBr may therefore be upper limits. Leu et al.[3] reported a value that is an order of magnitude smaller, $(2.8 \pm 0.5) \times 10^{-3}$ after applying large corrections (about an order of magnitude) for pore diffusion; the average uncorrected value using the geometric area was 0.027.

58. **HNO_3 + sea salt.** The uptake coefficient for HNO_3 on synthetic sea salt[1] is much larger than that on NaCl, which is attributed to the very hygroscopic nature of sea salt due to such components as the magnesium chloride and its hydrates (see Note on O_3 + sea salt). De Haan and Finlayson-Pitts[1] reported initial uptake coefficients of γ_0 in the range of 0.07 to 0.75 and steady state values in the range of 0.03 to 0.25; these were measured using salt layers from 2 layers to 10^3 layers. The initial uptake coefficient on $MgCl_2 \bullet 6H_2O$ was ≥ 0.4 and the steady-state value >0.1. At these high uptake values, the correction for diffusion into underlying layers is expected to be small. The large uptake coefficient on sea salt is consistent with the values measured for uptake on concentrated aqueous solutions of NaCl and the high water content of the surface of sea salt (see O_3 + sea salt Note above). The yield of HCl was within experimental error of 100%.

Guimbaud et al.[2] measured the uptake coefficient of HNO_3 on 70 nm supersaturated sea-salt particles (deliquesced particles held at 55% RH) to be 0.50 ± 0.20; they concluded that this was the mass accommodation coefficient.

59. **HNO_3 + Al_2O_3.** Börensen et al.[1] used diffuse reflectance FTIR observations to show that HNO_3 reacts with surface hydroxyl groups on γ-alumina at 299 K to produce surface bonded nitrate, while Goodman et al. reported similar observations for α-alumina at 296 K.[2] Goodman et al.[2] also observed that higher relative humidity lead to higher HNO_3 uptake. They integrated their nitrate absorbance feature to yield a time averaged uptake coefficient of $(4 \pm 1) \times 10^{-8}$.[2] Underwood et al.[5] report a linear mass dependent, BET corrected γ_o for α-alumina at 295 K of $(9.7 \pm 0.5) \times 10^{-5}$. Hanisch and Crowley also measured liner mass dependent γ_os on α-alumina (at 298 K) for four particle sizes, which yielded an average value of 0.133 ± 0.033.[3] They argue that the lack of variance of γ_os on a large range of particle sizes and masses indicate that the BET correction to the geometrical surface area is not required. They also measured γ_o for an unpolished single crystal of $(1.6 \pm 1.4) \times 10^{-3}$ and smaller values on polished single crystals, showing the higher density of surface defect sites on small amorphous particle are critical for their high reactive active uptake coefficients. The recommendation is based on the Hanisch and Crowley data and analyses for particulate samples.[3] Seisel et al.,[4] used Knudsen cell uptake experiments at 298 K to measure an initial uptake (γ_o) value of 0.13 ± 0.02 for γ–alumina with HNO_3 vapor concentrations of ~10^{11} cm^{-3}. Lower values of γ were

observed for higher nitric acid partial pressures; water vapor was observed as a product. They also performed DRIFTS experiments that yielded a mean uptake coefficient for surface nitrate formation of (7.7 ± 0.8) × 10^{-3} at 298 K.

60. **HO_2NO_2 + HCl on H_2SO_4•nH_2O(l).** Zhang et al.[1] performed wetted-wall flow-reactor studies with HCl and HO_2NO_2 partial pressures in the 10^{-6} to 10^{-7} Torr range. Using chemical ionization mass spectrometry (CIMS) to detect expected reaction products, no Cl_2 (using SF_4^- as an analyte ion) or HOCl (using F^-) was detected over a temperature range of 200–225 K and an acid concentration range of 50–70 wt% H_2SO_4. An upper limit for the reactive uptake coefficient for HO_2NO_2 reacting with HCl of $\gamma < 1 \times 10^{-4}$ was deduced.
Back to Table

61. **NH_3 + H_2SO_4•nH_2O.** Robbins and Cadle,[6] Huntzicker et al.,[4] McMurry et al.,[5] and Däumer et al.[1] all studied NH_3 uptake by sulfuric acid aerosols in near room temperature flow reactors (T = 281–300 K). Uptake coefficients varied between 0.1 and 0.5. Rubel and Gentry[7] used levitated H_3PO_4 acid droplets to show that heterogeneous reaction does control the initial NH_3 uptake on strong acid solutions. Both Rubel and Gentry and Däumer et al. also explored the effect of organic surface coatings. Swartz et al.[8] used a droplet train flow reactor to measure reactive uptake coefficients on 20 to 70 wt% acid over a temperature range from 248 to 288 K. Measured uptake coefficients varied from 1.0 at 55 wt% and above to 0.3 at 20 wt% and drop off smoothly to the pure water results reported by the same group, as well as other droplet train flow reactor and coaxial jet uptake studies.[9] Hanson and Kosciuch[2] used an aerosol flow reactor to measure reactive uptake coefficients at room temperature (287 to 297 K) from 15 to 65 wt%. While the data have a fair amount of scatter, taken as a whole they are consistent with $\gamma = 1$ over the whole range of acid concentrations. There is no obvious reason for the discrepancy between the 15 to ~45 wt% results from Swartz et al.[8] and Hanson and Kosciuch,[2] the two groups have discussed conceivable issues at length in print[9] and Hanson and Kosciuch.[3]

62. **$CO_2 + Al_2O_3(s)$.** Parkyns[1] and Szanyi and Kwak[2] each report FTIR studies of CO_2 chemisorbed on γ-alumina surfaces annealed at temperatures up to ~800 K. They report that CO_2 can react with the HO-Al surface sites of γ-alumina at room temperature to form adsorbed bicarbonate structures. They also show that the surface OH on γ-alumina can be eliminated by calcination of the alumina surfaces at temperatures near 800 K. Adsorbed CO_2 on the dehydroxylated γ-alumina forms weakly bound carbonate species. No kinetic uptake data are available for CO_2 uptake.

63. **$H_2CO + Al_2O_3(s)$.** Carlos-Cueller et al.[1] reported Knudsen cell studies that determined γ_o values for oxygenated volatile organic compounds (VOCs) at 295 K. They measured a γ_o on α-alumina for formaldehyde of $(7.7 \pm 0.3) \times 10^{-5}$, based on BET surface areas and the KML[2] correction for porosity; relatively “sticky” formaldehyde may not access the full BET surface and thus γ_o may be underestimated. Xu et al.[3] used a DRIFTS Reactor with γ-Al_2O_3 surfaces over a temperature range of 84–573 K and a RH range of 0–80%. BET and geometric surface areas were used to calculate initial uptake coefficients. Formaldehyde uptake was independent of gas phase O_2 over the studied range ($0.18–730 \times 10^{13}$ cm^{-3}); uptake was negatively correlated with RH. Surface analyses included FTIR, X-ray Diffraction and SEM. The initial surface product is dioxymethylene that is oxidized to formate, with reaction order of 0.74 ± 0.05. Polyoxymethylene is a secondary adsorbed product. Reactive uptake saturates active surface sites so initial γ_o values are reported for both geometric and BET surface areas. For T = 298 K, $\gamma_o(\text{Geo}) = (3.6 \pm 0.8) \times 10^{-4}$ and $\gamma_o(\text{BET}) = (1.4 \pm 0.31) \times 10^{-8}$ (T = 298 K, RH = 0); γ_o(BET, 298 K) deceases approximately a factor of 2 as RH increases from 0 to 80%; γ_o(BET, 0 RH) increases irregularly by approximately a factor of 3 as T increases from 273 to 373 K. The Xu et al. room temperature BET value for γ-Al_2O_3 is ~5000 lower than the Carlos-Cueller et al. value for α-alumina. It is unclear how much of this is due to systematic error in one or both experiments and how much is due to different surface properties for the two alumina phases. Given the available data an upper limit of $\gamma_o < 5 \times 10^{-4}$ over the temperature range of 270–300 K is estimated for both phases.

64. **$CH_3OH + H_2SO_4{\bullet}nH_2O(l)$ and $H_2SO_4{\bullet}mHNO_3{\bullet}nH_2O(l)$.** Van Loon and Allen[2] report spectroscopic observations at 293 K for 0 to 96.5 wt% H_2SO_4 exposed to methanol vapor. They observed rapid surface adsorption and saturation, followed by slower bulk absorption. For acid concentrations between 47.1 and 63.3 wt% they observed surface reaction between methanol and sulfuric acid that formed methyl hydrogen sulfate, CH_3SO_4H. Iraci et al.[1] used infrared spectroscopy to monitor the production of gas phase methyl nitrate, CH_3ONO_2, from the bulk reaction of ternary sulfuric acid/nitric acid/water solutions with 0.00005–0.005 M CH_3OH in 50.5 to 63.6 wt% H_2SO_4 with 0.03–0.21 M HNO_3 between 278.2 and 328.6 K. Within this range methyl nitrate production increased linearly with methanol and nitric acid concentration and exponentially with sulfuric acid concentration. At high acid concentrations nitric acid reacts with protons to form water and the nitronium ion, NO_2^+; methyl nitrate production was observed to be proportional to the NO_2^+ concentration indicating it was the nitrating agent.

65. $CH_3OH + Al_2O_3(s)$. Carlos-Cueller et al.[1] reported Knudsen cell studies that determined γ_o values for oxygenated volatile organic compounds (VOCs) at 295 K. They measured γ_o on α-alumina for methanol of $(1.0 \pm 0.7) \times 10^{-4}$, based on BET surface areas and the KML[2] correction for porosity. Since data is only available from a single laboratory using only a single method, an upper limit of $\gamma_o < 3 \times 10^{-4}$ is recommended for α-Al_2O_3.

Back to Table

Heterogeneous uptake kinetics of volatile organic compounds on oxide surfaces using a Knudsen cell reactor: Adsorption of acetic acid, formaldehyde, and methanol on α-Fe_2O_3, α-Al_2O_3, and SiO_2. *J. Phys. Chem. A* **2003**, *107*, 4250-4261, doi:10.1021/jp0267609.

(2) Keyser, L. F.; Leu, M.-T. Surface areas and porosities of ices used to simulate stratospheric clouds. *J. Colloid Interface Sci.* **1993**, *155*, 137-145, doi:10.1006/jcis.1993.1018.

66. $HC(O)OH + Al_2O_3(s)$. Tong and co-workers[3,4] used a DRIFTS reactor to investigate the uptake of formic acid on beds of α-Al_2O_3 particles; surface areas were estimated with BET measurements as well by geometric sample area. Their initial study[3] reported γ(BET) and γ(Geo) for formic, acetic and propionic acids on α-Al_2O_3 at 300 K over a RH range (0–90%). For RH(0) they reported:

Acid	γ (BET)	γ (Geo)
HC(O)OH	$(2.37 \pm 0.30) \times 10^{-7}$	$(2.07 \pm 0.26) \times 10^{-3}$
$CH_3C(O)OH$	$(5.99 \pm 0.78) \times 10^{-7}$	$(5.00 \pm 0.69) \times 10^{-3}$
$CH_3CH_2C(O)OH$	$(3.03 \pm 0.52) \times 10^{-7}$	$(3.04 \pm 0.63) \times 10^{-3}$

It is likely that γ(BET) underestimates the true uptake coefficient since organic acids adsorb and react before penetrating some pores and that γ(Geo) overestimates uptake rates. The effect of relative humidity on the HC(O)OH uptake co-efficients is modest, with a slight (~10%) rise between RH(0) and RH(20%) and then a gradual fall off (~33%) between RH(20%) and RH(95%). A second publication by Tong and co-workers[4] focused on the effects of temperature on uptake rate. For RH(0) they measured a modest increase (less than a factor of two) as T decreases from 298 to 240 K:

T (K)	γ(BET)	γ(Geo)
298	$(1.34 \pm 0.02) \times 10^{-6}$	$(2.35 \pm 0.03) \times 10^{-3}$
285	$(1.52 \pm 0.04) \times 10^{-6}$	$(2.65 \pm 0.07) \times 10^{-3}$
277	$(1.70 \pm 0.03) \times 10^{-6}$	$(2.98 \pm 0.03) \times 10^{-3}$
273	$(1.77 \pm 0.01) \times 10^{-6}$	$(3.09 \pm 0.03) \times 10^{-3}$
263	$(1.96 \pm 0.02) \times 10^{-6}$	$(3.43 \pm 0.04) \times 10^{-3}$
250	$(2.22 \pm 0.02) \times 10^{-6}$	$(3.89 \pm 0.03) \times 10^{-3}$
240	$(2.39 \pm 0.03) \times 10^{-6}$	$(4.18 \pm 0.05) \times 10^{-3}$

Note that their earlier γ(Geo) for room temperature and RH(0) of $(2.07 \pm 0.26) \times 10^{-3}$ [3] is in good agreement with the value of $(2.35 \pm 0.03) \times 10^{-3}$ reported in Wu et al.;[4] however, their later room temperature γ(BET) value is more than a factor of five larger than their earlier value, calling into question the reliability of BET surface area determinations. Infrared spectra indicated surface enhanced crystallization of HCOOH at lower temperatures as well reaction with surface hydroxyl groups to form formate. Based on these data only an upper limit of $\gamma_o < 0.01$ is recommended for α-Al_2O_3.

Rubasinghege et al.[2] used a Quartz Crystal Microbalance (QCM) and Attenuated Total Reflectance FTIR (ATR-FTIR) to characterize total HC(O)OH uptake and surface reactions on γ-Al_2O_3, SiO_2 and kaolinite surfaces at T (298 K) and RH (<1%); no kinetic data was presented. They observed both reversible and irreversible adsorption of HC(O)OH on γ-Al_2O_3. Adsorbed water, controlled by RH, increases the irreversible uptake of HC(O)OH. The resulting layer of adsorbed formate decreases the surface hydrophilicity, decreasing the amount of water uptake. Ruan et al.[1] report a density functional simulation of HC(O)OH interacting with an α-Al_2O_3 (0001) surface, presenting adsorbate dissociation pathways and estimating the energy barrier for dehydration reactions.

67. **$CH_3CH_2OH + H_2SO_4{\bullet}nH_2O$.** Timonen and Leu[2] used a trough flow reactor to measure uptake coefficients for ethanol on 41.1 to 79.3 wt% H_2SO_4, for selected temperatures between 193 to 273 K, but primarily for temperatures from 203 to 258 K. Uptake coefficients for 70.3–79.3 wt% acid showed little temperature variation, starting at ~0.07 for 203 K and falling to 0.05 to 0.06 above 250 K, while uptake coefficients for 41.1 to 64.1 wt% started at ~0.07 at 203 K and decreased to about 0.02 at 233 K for 41.1 wt% 1, to ~0.03 at 243 K for 54.4 wt% and ~0.035 at 253 K for 64.1 wt%. Uptake was only partially reversible, so it was attributed to both physical and reactive processes, making the reported uptake coefficients as upper limits for γ. The authors attributed the reactive portion of the uptake to esterification reactions, forming ethyl hydrogen sulfate and diethyl sulfate, and saw some mass spectral evidence for these products when they mixed ethanol with 80 wt% acid in their reactor at 296 K. Michelsen et al.[1] found no evidence for ethyl hydrogen sulfate in Knudsen cell ethanol uptake experiments for 39–76 wt% H_2SO_4 over a 209–237K temperature range, so the extent of reaction for low temperature acid solutions remains uncertain. Timonen and Leu suggest that at low ethanol vapor fluxes surface reactivity may be important.

69. **$CH_3CHO + H_2SO_4•nH_2O$.** Knudsen cell uptake measurements are reported by Michelsen et al.[3] for 38.5–76.2 wt% H_2SO_4 over a temperature range of 211–241 K, with evidence of reactive uptake for some temperatures in the 38.5–66.3 wt% H_2SO_4 range. Using a rotating wetted-wall flow reactor Esteve and Nozière[2] measured small, probably solubility constrained, uptake coefficients at 298 ± 3 K for 96 wt% and 89.4 wt% of 9.4×10^{-6} and 4.2×10^{-7}, respectively. Michelsen et al. found uptake over the 211–241 K temperature range was controlled by Henry's law solubility, and had a complex dependence on acid concentration due to competition among the reversible bulk phase processes of physical dissolution, hydration to form the gem diol, protonation and enolization, all of which affect H*. They also saw evidence for aldol condensation at some temperatures for acid concentrations of 66.3 wt% and below. Drawing on the complex aldol condensation mechanism presented to explain the bulk kinetic studies of Baigrie et al.,[1] Michelsen et al. present plausible arguments why non-reversible condensation reactions might have the complex dependence on acid concentrations and temperature that they observed. Given its relatively small rate constant, they suggest that aldol condensation bulk reactions will play a negligible role for typical aldehyde concentrations in the atmosphere.

70. **CH_3CHO, CH_3CH_2CHO and $CH_3C(O)CH_3 + Al_2O_3(s)$.** Li et al.[1] reported Knudsen cell studies that determined γ_o values for oxygenated volatile organic compounds (VOCs) at 298 K. They reported very similar BET corrected γ_os values on α-alumina for acetaldehyde (3.2×10^{-5}), propionaldehyde (4.7×10^{-5}), and acetone (2.0×10^{-5}). For molecules this large BET surface area may not be assessable and derived γ_os may be underestimated. Since data are from a single laboratory using only one technique, only conservative lower limits are recommended.

Geophys. Res.* **2001**, *106*, 5517-5529, doi:10.1029/2000JD900573.

71. **$CH_3C(O)CH_3 + H_2SO_4•nH_2O$.** Duncan et al.[1,2] used IR spectra of thin sulfuric acid films to establish that acetone is absorbed as the protonated species. Above 70 wt.% protonated acetone undergoes a self-condensation/dehydration reaction to form protonated mesityl oxide, which can, in turn, react with an additional protonated acetone to form trimethyl benzene. Kane et al.[4] Henry's law uptake measurements diverged above 80 wt%, which they attribute to reactive uptake as suggested by Duncan et al. Using a rotating wetted-wall flow reactor Esteve and Nozière[3] measured small, probably solubility constrained, uptake coefficients at 298 ± 3 K for 89.4, 85, 80.8 and 73.9 wt% H_2SO_4 of 5.2×10^{-5}, 5.6×10^{-6}, 4.7×10^{-6} and 1.6×10^{-6}, respectively.

72. **$CH_3C(O)O_2$ + $H_2O(l)$ and H_2SO_4•nH_2O.** Villalta et al.[1] used wetted-wall flow tube techniques to measure $\gamma = 4.3\ (+2.4/-1.5) \times 10^{-3}$ for water at 274 ± 3K. They also measured uptake for 34 wt% H_2SO_4 at 246 K ($\gamma = (2.7 \pm 1.5) \times 10^{-3}$), 51 wt% at 273 K ($\gamma = (0.9 \pm 0.5) \times 10^{-3}$), and 71 wt% at 298 K ($\gamma = (1.4 \pm 0.7) \times 10^{-3}$). They suggest that products subsequent to hydrolysis are HO_2 and $CH_3C(O)OH$.

73. **$H_2C{=}C(CH_3)CHO$** and **$H_2C{=}CHC(O)CH_3$ + $Al_2O_3(s)$.** Zhao et al.[1] report a coated wall flow reactor study with Transmission FTIR measurements of adsorption and reaction of both methacrolein (MAC) and methyl vinyl ketone (MVK) on α-Al_2O_3 at T~300 K and relative humidity values of RH <1%, 20% and 60%. They reported RH = 0 γ_o values based on BET surface areas of: γ_o(MAC) = $(2.0 \pm 0.5) \times 10^{-8}$ and γ_o(MVK) = $(3.8 \pm 0.8) \times 10^{-8}$. They measured significantly lower γ_os for RH = 20 and 60% indicating that water vapor blocks reactive surface sites. Major products (>0.03) were CH_3CH_2CHO, HCHO and HCOOH for MAC and isomerization of MVK to $CH_3CH{=}CHCHO$ (crotonaldehyde) that then reacted to produce CHOCHO, CH_3CHO and $CH_3C(O)OH$. For molecules this large some BET surface area may not be accessible and derived γ_os may be underestimated. Given the strong impact of relative humidity and uncertainty in effective surface area no recommendations for γ_os are made.

74. **$CH_3C(O)O_2NO_2$ + HCl, Cl, ClO, and OClO on H_2SO_4•$nH_2O(l)$.** Zhang and Leu[1] performed wetted wall flow reactor studies with Cl species partial pressures in the 10^{-6} to 10^{-7} Torr range and $CH_3C(O)O_2NO_2$ at 3×10^{-6} Torr after equilibrating the acid surfaces (42, 51, and 69 wt% at 202 and 224 K) with $CH_3C(O)O_2NO_2$. Also uptake studies with 5×10^{-7} Torr $CH_3C(O)O_2NO_2$ were performed after exposing the acid surface to the Cl species. No Cl species or $CH_3C(O)O_2NO_2$ uptake enhancements were observed under either condition and an upper limit for the reactive uptake coefficient of $\gamma < 1 \times 10^{-4}$ of $CH_3C(O)O_2NO_2$ was deduced. No gas phase reaction products were observed using CIMS after 42 wt% H_2SO_4 at 210 K was exposed to $CH_3C(O)O_2NO_2$ and each Cl species for 20 minutes.

75. **IEPOX + Sulfate Aerosol.** Isoprene-derived epoxides (IEPOX) are important oxidation products of isoprene that are involved in the formation of secondary organic aerosol. Specifically, the reactive uptake of trans-beta-isoprene epoxydiol to aerosol particles was studied by Riedel et al.[2] and Gaston et al.[1] in an aerosol flow tube at room temperature using chemical ionization monitoring of the gas phase reactant. The uptake coefficient was studied as a function of aerosol acidity, composition and relative humidity. It was found that acidic particles (i.e. ammonium bisulfate vs. ammonium sulfate) were much more reactive, consistent with an acid-catalyzed nucleophilic attack mechanism. For example, the uptake coefficient varied between

roughly 0.01 to 0.1 on ammonium bisulfate to values two orders of magnitude lower on ammonium sulfate, at 50% relative humidity. There was a weak negative dependence of the uptake coefficient on relative humidity with ammonium sulfate particles.

77. **Cl + NaCl(s).** Ciuraru et al.[1] have measured the uptake coefficients for Cl atoms onto pure NaCl and artificial sea-salt in a coated-wall flow tube. The surface area of the substrates is not easily estimated. Uptake coefficients are on the order of 10^{-2} for dry NaCl, with evidence for Cl_2 as a reaction product probably arising from surface recombination.

79. **Cl_2 + NaCl.** Mochida et al.[2] used salt powders and spray-deposited films of NaCl and reported an initial uptake coefficient of 1.0×10^{-3}. Aguzzi and Rossi[1] reported no measurable uptake of Cl_2 on NaCl.
Back to Table

80. **Cl_2 + NaBr and NaI.** Mochida et al.[5] used salt powders and spray-deposited films to obtain a value for the initial uptake coefficient of 2×10^{-2}. The measured uptake coefficients for the salt powders were a factor of six larger, but application of the pore diffusion model of Keyser et al.[3,4] gave this value, which is in agreement with that for a spray-deposited film. Br_2 was generated in a yield of 100%, within experimental error.

Hu et al.[1] measured the uptake of Cl_2 on aqueous solutions of NaBr and NaI over the temperature range of 263–293 K using a droplet train flow reactor. Measured values of the uptake coefficients on NaBr solutions ranged from 0.16 at 263 K to 0.05 at 293 K, and there was evidence of a surface reaction between Cl_2 and Br^- at the air-particle interface. Similarly, the uptake coefficients for Cl_2 on NaI solutions ranged from 0.20 to 0.07 over the same temperature range, again with evidence for a contribution from an interface reaction. Huff and Abbatt[2] have studied the reaction of Cl_2 with films formed by freezing NaBr solutions at 233 K,

observing Br_2 as the reaction product and that the maximum reaction probability is 0.1 when the surface is saturated with bromide ions.

81. **Cl_2 + KBr.** Mochida et al.[2] used salt powders and spray-deposited films to obtain a value for the initial uptake coefficients. The value measured for salt powders was 0.176, but after correction for pore diffusion, this became 3.7×10^{-2}, similar to a value of 2.3×10^{-2} measured for spray-deposited films. Br_2 was generated in a yield of 100%, within experimental error. Aguzzi and Rossi[1] measured a similar value, 2.7×10^{-2}, using a Knudsen cell. Santschi and Rossi[3] reported an initial value of $\gamma_0 = 0.11$ for the uptake of Cl_2 on thin spray-deposited films of KBr that had not been extensively pumped on; this initial value was 4×10^{-2} for films that had been pumped on for hours. They attributed the difference to the removal of surface-adsorbed water (SAW) by extensive pumping.

82. **Cl_2 + sea salt.** Mochida et al.[1] used a synthetic sea salt and a "natural" seasoning sea salt in Knudsen cell studies of the uptake of Cl_2. The synthetic sea salt value of $(2.2 \pm 0.3) \times 10^{-2}$ is the value reported after correction of the measured value of 0.138 using the pore diffusion model. For the “natural” seasoning salt, the measured value was 0.11 which after correction for diffusion into the underlying layers became $(3.1 \pm 1.1) \times 10^{-2}$. Br_2 was the major gas phase product, with small mass spectrometric signals also seen for BrCl.

83. **ClO + H_2O(s) and HNO_3•nH_2O(s).** Proposed reaction (Leu[3]) is 2 ClO → $Cl_2 + O_2$; reactive uptake may depend on ClO surface coverage, which in turn may depend on gas phase ClO concentrations. Kenner et al.[2] measured reaction probabilities of $(8 \pm 2) \times 10^{-5}$ for ice at 183 K which is far lower than the limit of $>1 \times 10^{-3}$ obtained by Leu.[3] Abbatt,[1] using nearly the same low levels of ClO as Kenner et al., obtained $\gamma < 1 \times 10^{-5}$ at 213 K. The difference may lie in the level of ClO or other adsorbable reactive species present. The lower value of Abbatt is probably closer to the expected reactivity under stratospheric conditions. Using high concentrations of ClO radicals ($>10^{12}$ molecules/cm^3) exposed to ice surfaces at 225 K, McKeachie et al.[4] infer an uptake coefficient of 0.001, which increases with ClO exposure. Formation of higher chlorine oxides, notably OClO, is observed mass spectrometrically and by UV-VIS spectroscopy, upon warming the ice. It is likely that the high ClO concentrations drive self-reactions on the ice surface. Kenner et al. also measured a reaction probability limit of < (8 ± 4) × 10^{-5} for NAT at 183 K.

84. **ClO + H_2SO_4•nH_2O.** Measured reaction probability (Martin et al.[2]) varies between 2 × 10^{-5} and 2 × 10^{-4} as H_2O content is varied by changing wall temperature. Reaction product is claimed to be HCl, not Cl_2. Abbatt[1] measured $\gamma < 1 \times 10^{-5}$ for 60 and 70 wt% H_2SO_4 at 213 K.

Back to Table

(1) Abbatt, J. P. D. Heterogeneous interactions of BrO and ClO: Evidence for BrO surface recombination and reaction with HSO_3^-/SO_3^{2-}. *Geophys. Res. Lett.* **1996**, *23*, 1681-1684, doi:10.1029/96GL01430.

85. **HCl + HNO_3 on H_2SO_4•mHNO_3•nH_2O(l).** Two studies have noted HCl activation in concentrated ternary $H_2SO_4/HNO_3/H_2O$ solutions or ice slurries. Luick et al.[2] saw only gas phase HCl in 64.6 wt% H_2SO_4/ 4.8 wt% HNO_3 at 200 K, but saw a vapor phase Cl partitioning of 50% HCl and 50% ClNO/$ClNO_2$ for a 76.6/20.1 wt% solution (an ice slurry) at 200 K. Cappa et al.[1] saw substantial yields of ClNO, $ClNO_2$, and Cl_2 at 273 K for a range of solution compositions; e.g. 32.6%, 9.8%, and 44.4% respectively for a total HCl conversion of 86.9% in a 35% H_2SO_4 /45% HNO_3 solution and 20.2%, 6.9%, 27.9% for a 60/25 wt% solution. While no kinetic coefficients or detailed mechanisms are available, these studies do show the potential for HCl activation in strong $H_2SO_4/HNO_3/H_2O$ solutions.

86. **HOCl + HCl + H_2O(s) and HNO_3•3H_2O(s).** Hanson and Ravishankara[5] and Abbatt and Molina[1] have investigated the HOCl + HCl reaction on water ice and NAT-like surfaces, and Chu et al.[3,4] studied the reaction on water ice. Product yield measurements support the identification of Cl_2 and H_2O as the sole products. The measured yield of product Cl_2 is 0.87 ± 0.20 and was stated to be similar on both surfaces according to Abbatt and Molina. Within the accuracy of the experiments, the reaction probability does not depend on the gas phase HCl and HOCl densities. Only Abbatt and Molina investigated at more than one temperature, their data indicates that γ increases at lower temperatures. A plot of data from the three studies does show a weak temperature trend, with γ increasing about a factor of two as the temperature drops from 202 to 188 K. However, the data are too sparse to assign a definitive temperature dependence. The average of all three studies yields $\gamma = 0.26 \pm 0.08$ for data based on the geometrical area of the flow tube surfaces. Chu et al.[3] indicate that a porosity correction for their data would reduce their value by a factor of 3 to 4. The real uncertainty would appear to be dominated by systematic uncertainties in porosity corrections and a potential temperature dependence. Given the fact that any porosity correction must reduce the value, a central value of 0.2 is adopted with an uncertainty factor of 2. The high reaction probabilities measured for water ice indicate that this reaction may play a significant role in release of reactive chlorine from the HCl reservoir.

Two studies (Hanson and Ravishankara[5] and Abbatt and Molina[1]) have measured the reaction probability of HOCl + HCl on NAT surfaces. These data show γ increases as the ambient water pressure increases and then reaches a plateau. At relatively high water pressure, the two studies averaged $\gamma = 0.135 \pm 0.049$, with no porosity correction. The reaction probability on water-poor NAT-like surfaces falls off dramatically (a factor of 10). A recommendation of 0.1 with an uncertainty factor of 2 is shown in Table 5-2. Carslaw and Peter[2] have published a model of this reaction and its dependence on HCl uptake.

87. **$HOCl + HCl + H_2SO_4{\bullet}nH_2O(l)$.** This process has been studied in coated flow tubes over ~200–260 K by Zhang et al.,[7] Hanson and Ravishankara,[3] Donaldson et al.,[1] and Hanson and Lovejoy.[2] Hanson and Lovejoy also made measurements in an aerosol flow tube from 251 to 276 K. A model of this and related sulfuric acid aerosol reactions tailored to stratospheric conditions has been published by Hanson et al.[4] Zhang et al. held the water vapor partial pressure at 3.8×10^{-4} Torr and showed γ increased by a factor of 50 as the temperature was lowered from 209 to 198 K increasing the water mole fraction, showing that the reaction rate is strongly dependent on water activity.
A detailed kinetic uptake model has been developed to fit the experimental data.[6] The formulation for γ is given as:

$$\frac{1}{\gamma} = \frac{1}{\alpha} + \frac{1}{\Gamma_{HOCl}^{rxn}}$$

where

$$\Gamma_{HOCl}^{rxn} = \frac{4H_{HOCl}RT}{\bar{c}}\left(D_{HOCl}k_{HOCl\_HCl}\right)^{1/2}$$

At the low temperatures of interest, α for HOCl was assumed to be unity consistent with the value for HCl measured at 240 K and below (Robinson et al.[5]). The individual formulations for H_{HOCl}, D_{HOCl} and $k_{HOCl\text{-}HCl}$ are given in Table A-4 in Shi et al.[6] Reaction of HOCl with HCl is considered to be acid catalyzed. It is known that the reaction rate for HOCl + HCl in pure water is low (Donaldson et al.[1]). Experimental data noted above indicated that the reaction rate of HOCl + HCl increases with acidity of H_2SO_4 solution. The data from the experimental studies noted above were fit to the model without bias. Using the same error analysis discussed in the note for N_2O_5 uptake on sulfuric acid, a detailed kinetic model yields a 33.4% error (one sigma fit to the available data set, with $\sigma_m = 33.3\%$ and $\sigma_d = 3.0\%$).

In the cold stratosphere where T<190 K, the reaction of $ClONO_2$ + HCl is so fast that HCl is depleted which slows down the reaction of HOCl + HCl. As shown in Table A-4 in Shi et al., the effect of HCl depletion on the HOCl reactive uptake coefficient (due to reaction with $ClONO_2$ inside/on the surface of particles) is taken into account via the factor F_{HCl} (also see the note on chlorine nitrate/hydrochloric acid reactive uptake on sulfuric acid surfaces).

88. HOCl + HBr on $H_2O(s)$. Chu and Chu[1] measured γ at 189 K to be in the range from 0.06 to 0.38 for HBr partial pressures ranging from 1.1×10^{-7} to 6.6×10^{-5} Torr. At 220 K they measured γ in the range from 0.01 to 0.07 for HBr partial pressures in the range from 7.2×10^{-7} to 1.3×10^{-5} Torr. These γ values were estimated assuming the area of the ice surface to be equal to the geometric area of the cylindrical flow reactor; corrections for surface porosity effects range from a factor of 3 to 10 lower.

89. HOCl + HBr on $H_2SO_4 \bullet nH_2O(l)$. Abbatt and Nowak[1] measured uptake of HOCl in the presence of excess HBr on a 69.3 wt% sulfuric acid solution in a wetted wall flow reactor at 228 K. A second order bulk reaction rate constant, k^{II}, of 2×10^6 M^{-1} s^{-1} was derived; this is a factor of ~10 faster than HOBr + HCl under the same conditions. Since HOCl and HBr have variable solubilities under stratospheric conditions, characterizing this reaction with a simple uptake coefficient is not appropriate. A full reaction/solubility/liquid phase diffusion model will require further data.

90. HOCl + NaBr and KBr. Rossi[2] reported studies of the uptake of HOCl in a Knudsen cell using KBr powders and spray-deposited thin films. Values for the initial uptake coefficients covered a wide range, from 5×10^{-3} to 0.2, due to changes in the surface from adsorbed reaction products. The major product initially was Br_2, and subsequently BrCl and HOBr, with much smaller amounts of BrOCl and Br_2O. The mechanism was interpreted as the formation of small amounts of HBr on the surface from hydrolysis of KBr, followed by the reaction of HOCl with adsorbed HBr to form BrCl which then reacts with KBr to form Br_2. On frozen solutions of NaBr, Huff and Abbatt[1]observe reactivity of HOCl with uptake coefficients between 0.02 and 0.04 at 233 K in a coated-wall flow tube. Br_2 is the gas-phase product, thought to arise from the intermediate BrCl reacting with the bromide film. Although the kinetics are faster on the most acidic films (pH 2), there is no dependence of the acidity of the solution from pH 4 to 10.

91. ClNO + $H_2O(l)$. Scheer et al.[1] used droplet train and wetted wall flow reactor measurements to determine reactive uptake coefficients for ClNO over a temperature range of 273–293 K. Measured values show a weak negative temperature dependence ranging from 0.12 at 273 K to 0.0058 at 293 K. The reaction was shown to be base catalyzed producing HONO.

92. ClNO + NaCl(s). Using a Knudsen cell technique Beichart and Finlayson-Pitts[1] set upper limits of $\gamma <\sim 10^{-5}$ for reactive uptake of ClNO on NaCl(s) powders at 298 K.

93. $ClNO_2$ + H_2O(l). Behnke, George and co-workers have used droplet train and wetted wall flow reactor techniques to investigate the reactive uptake of $ClNO_2$ on aqueous solutions.[1-4] Droplet train flow reactor experiments from 268–279 K demonstrated that the reactive uptake coefficient on pure water is $<1 \times 10^{-5}$.[3] Wetted wall flow reactor studies from 279 to 292 K on pure water and very low concentration sodium halide solutions all yielded reactive uptake coefficients in the 10^{-6} range, with typical values of $(4.84 \pm 0.13) \times 10^{-6}$ at 291 K,[1] and 3.41×10^{-6} at 276.6 K, 4.27×10^{-6} at 282.2 K, and 4.48×10^{-6} at 287.4 K.[2] There is apparently no significant temperature dependence.

94. $ClNO_2$ + KBr, NaBr, NaI and NaCl. Caloz et al.[3] measured the uptake of $ClNO_2$ on solid KBr at room temperature using a Knudsen cell and salt samples in the form of powders, spray-deposited films, polished windows and depolished windows. The uptake coefficient increased with the number of layers of salt powders; correction of the uptake coefficients using the pore diffusion model gave initial uptake coefficients of $(1.0–1.3) \times 10^{-4}$, in agreement with values measured for the spray-deposited film (1.0×10^{-4}) and depolished window (1.0×10^{-4}). The value for the polished window was an order of magnitude smaller, as expected since this has much less surface-adsorbed water (SAW) that assists in keeping the surface from becoming passivated. The yield of Br_2 relative to $ClNO_2$ lost was 0.55 ± 0.2. Using a diffusion tube method, Koch and Rossi[7] measured an uptake coefficient of 2.0×10^{-4}, in reasonable agreement with the Knudsen cell results.

The uptake of $ClNO_2$ on aqueous solutions of NaBr has been shown to increase with the concentration of NaBr. Frenzel et al.[5] measured the uptake of $ClNO_2$ on $(0.5–5) \times 10^{-3}$ M NaBr solutions from 275–291 K using a wetted wall flow tube apparatus; the values of γ increased from 1.2×10^{-5} to 4.0×10^{-5} over this range of NaBr concentrations. Schweitzer et al.[9] used a droplet train apparatus from 275–288 K; γ increased from 8.6×10^{-6} to 9.4×10^{-4} as the NaBr concentration increased from 10^{-4} to 1.0 M. The main product was Br_2, with traces of $BrNO_2$ and BrCl. In a subsequent study,[10] they applied a wetted wall flow tube method from 275–293 K and reported uptake coefficients that were independent of temperature over this range, but again increased with the concentration of NaBr: γ increased from 7.1×10^{-6} at 10^{-4} M NaBr to 9.2×10^{-4} at 1.0 M. Fickert et al.[4] used a wetted wall flow tube at 274 K and measured an uptake coefficient of 1.1×10^{-5} for 10^{-4} M NaBr, increasing to 1.1×10^{-4} for 10^{-2} M NaBr. The major gas phase products were Br_2 and $BrNO_2$, with the yield of $BrNO_2$ decreasing as the initial bromide ion concentration in solution increased. The mass accommodation coefficient for $ClNO_2$ on aqueous solutions at 275 K was measured to be $(9 \pm 4) \times 10^{-3}$. A Knudsen cell study by Beichart and Finlayson-Pitts[2] found $\gamma <\sim 10^{-5}$ on NaCl powders at 298 K.

The uptake of $ClNO_2$ on solutions of NaI was studied by George et al.[6] and by Schweitzer et al.[9,10] The uptake coefficient increases with the concentration of NaI. For example, George et al.[6] reported that γ_0 increased from 1.1×10^{-3} to 6.6×10^{-3} as the iodide concentration increased from 10^{-3} M to 10^{-2} M at 280 K. This is consistent with the results of Schweitzer et al.[9,10] who reported that γ_0 increased from 3.1×10^{-5} to 4.5×10^{-3} as the iodide concentration increased from 10^{-4} M to 10^{-2} M at 275 K.

The uptake of $ClNO_2$ on solutions of NaCl is much slower than on NaBr or NaI solutions. Behnke et al.[1] reported uptake of $ClNO_2$ at 291 K using a wetted wall flow tube, with uptake coefficients decreasing as the NaCl concentration increased. At 0.1 M NaCl, $\gamma_0 = (3.1 \pm 0.3) \times 10^{-6}$ but at 4.6 M NaCl, the value was about an order of magnitude smaller, $\gamma_0 = (0.27 \pm 0.02) \times 10^{-6}$. They proposed that this was due to the common ion effect owing to the reversible hydrolysis of $ClNO_2$ to $Cl^- + NO_2^+$.

Roberts et al.[8] report that $ClNO_2$ produces Cl_2 when exposed to solutions of chloride with concentrations as low as 0.05 M, when the pH is less than 2.

95. **$ClONO_2 + H_2O(s)$.** Measurement of $\gamma = 0.3$ (+0.7, –0.1) (Hanson and Ravishankara[5]) significantly exceeds early measurements of Molina et al.,[11] Tolbert et al.,[14] Leu,[9] and Moore et al.[12] but agrees reasonably well with subsequent measurements by Chu et al.,[2] Zhang et al.,[15] and Fernandez et al.[3] when geometrical surface areas are assumed for analysis. Previous measurements were probably complicated by NAT formation on the surface (Hanson and Ravishankara[6] and Chu et al.[2]). Lower levels of $ClONO_2(g)$ used by Hanson and Ravishankara[5] minimized this surface saturation problem. Also, using lower $ClONO_2$ concentrations, Zhang et al. obtained a reaction probability of 0.08 ± 0.02 at 195 K, Fernandez et al. measured 0.1, and values were 0.03 to 0.13 from Chu et al. Subsequent Knudsen cell measurements at 180 and 200 K by Oppliger et al.[13] showed initial uptake γs in the 0.2 to 0.4 range. Measured reaction products were HNO_3 and HOCl. All of the HNO_3 and much of the HOCl is retained on the surface under polar stratospheric conditions (Hanson and Ravishankara[5,6]). Hanson[4] deposited $ClONO_2$ on $H_2{}^{18}O$ enriched ice and detected $H^{18}OCl$ showing the Cl–ONO_2 bond is broken at 191 K.

Data plots confirm a trend showing that at a high density of $ClONO_2$, the product HNO_3 covers the ice surface preventing the further reaction of $ClONO_2$ with H_2O molecules on the surface. Therefore, data obtained at high $ClONO_2$ densities (>10^{14} molecules/cm^3) are excluded from further evaluation. An experiment (Berland et al.[1]) using a laser-induced thermal desorption technique yielded a much lower value of $ClONO_2$ reaction probability at 190 K (about 3 orders of magnitude lower) after extrapolating the results obtained at temperatures of 140 K and below. We also exclude this point in the averaging of data since the physical characteristics of ice surfaces at these very low temperatures may not be very representative of those found at stratospheric temperatures. Selected data show no temperature dependence between T = 180 and 200 K and averaged $\gamma_o = 0.28 \pm 0.25$. Again, within the experimental accuracy, the Hanson and Ravishankara[6,7] and Chu et al.[2] data show that uptake measurements are nearly independent of ice substrate thickness. See Henson et al.[8] for discussion of a model which accounts for the effect of HNO_3 on the reaction $ClONO_2$ on water and nitric acid ice surfaces. The reactivity of $ClONO_2$ on ice, as modeled with high level ab initio methods and simulations with four water molecules is consistent with the above laboratory results, i.e., the uptake coefficient is modeled to be close to 0.1 at 180 K with a strong negative temperature dependence (Loerting et al.[10]).

Zondlo et al.[16] report the formation of a supercooled H_2O/HNO_3 liquid layer at 185 K as a reaction product, forming NAT or NAD only after decreasing the relative humidity below the ice frost point. This effect is similar to that resulting from the interaction of gaseous HNO_3 or N_2O_5 with the ice surface. These authors measured $\gamma = (3 \pm 2) \times 10^{-3}$ at 185 K for the reaction of $ClONO_2$ with this supercooled liquid layer.

97. $ClONO_2 + HNO_3•nH_2O(s)$. Hanson and Ravishankara[3] report a γ value of 0.006 at 201 K for the $ClONO_2$ reaction with the water on NAT ($HNO_3•nH_2O$). However, these authors present re-analyzed and additional data with $\gamma \approx 0.001$ at 191 K in Hanson and Ravishankara.[4,5] Similar experiments (Moore et al.[8] and Leu et al.[7]) report a larger value of 0.02 ± 0.01 which falls very rapidly as slight excesses of H_2O above the 3/1 H_2O/HNO_3 ratio for NAT are removed. In general, it is difficult to know that only NAT is formed when freezing from solution; it is likely that the high value reflects the reactivity on water ice that will form when the solution stoichiometry is water rich. They measured γ of less than 1×10^{-6} for slightly water-poor NAT surfaces. Abbatt and Molina[1] report γ values reaching 0.002 at 202 K and high RH. Hanson and Ravishankara[4] reported that γ for this reaction increases by a factor of 4 as the surface temperature increases from 191 to 211 K. However, Knudsen cell measurements at 185 K by Barone et al.[2] reported $\gamma = 0.004$ at a relative humidity (RH) of 100%, rising to 0.007 near RH = 120%, indicating a possible mild negative temperature dependence when high RH values from this and other studies are compared. Excluding the JPL data,[7,8] the other data obtained at high RH (~90%) were averaged, assuming no temperature dependence, to yield $\gamma = 0.0043 \pm 0.0021$. The strong dependence on RH and the possible temperature dependence suggest that systematic error probably exceeds the calculated statistical error. Within the experimental accuracy, the data of Hanson and Ravishankara[4,5] show that measured uptake coefficients are independent of ice substrate thickness. Barone et al. report very similar uptake coefficients for nitric acid dihydrate (NAD) as for NAT as a function of RH at 202 K. See Henson et al.[6] for discussion of a model which accounts for the effect of HNO_3 on the reaction of $ClONO_2$ on water and nitric acid ice surfaces.

98. $ClONO_2 + H_2SO_4•nH_2O(l)$. Results from wetted-wall flow tube (Hanson and Ravishankara[5]) Knudsen cell reactor (Manion et al.[6]), aerosol flow tube (Hanson and Lovejoy[3]), and droplet train uptake (Robinson et al.[7])

experiments supplement older wetted-wall flow tube (Hanson and Ravishankara[4]) and Knudsen cell measurements (Rossi et al.[8] and Tolbert et al.[10]). Although earlier Knudsen cell measurements probably suffered from surface saturation, more recent results compare well with those from other techniques. Saturation free results, available over a temperature range of 200–265 K and a H_2SO_4 concentration range of 39 to 75 wt%, were fit to a phenomenological model developed by Robinson et al.[7] Measured γ values depend strongly on H_2SO_4 concentration and vary modestly with temperature, with a trend to somewhat higher values for the 210–220 K temperature range. The temperature-dependent uptake model takes into account the temperature and composition dependence of the effective Henry's Law constant, liquid phase diffusion coefficient, and the liquid phase hydrolysis rate constant. The hydrolysis reaction was treated by modeling two reaction channels, a direct hydrolysis process dominating reaction at low H_2SO_4 concentrations with a reaction rate proportional to water activity and a proton-catalyzed reaction with a rate proportional to H^+ activity, which dominates at higher acid concentrations.

The data fit to the original Robinson et al. model have been supplemented by additional wetted-wall flow tube and aerosol flow tube data from Hanson[2] and aerosol flow tube data from Ball et al.[1] A revised kinetic model (Shi et al.[9]) incorporating these data has been developed that is based on the earlier work of Robinson et al.[7] In this model, γ is calculated using the expression

$$\frac{1}{\gamma} = \frac{1}{\alpha} + \frac{1}{\Gamma_b^{H_2O}}$$

where,

$$\Gamma_b^{H_2O} = \frac{4H_{ClONO_2}RT}{\bar{c}}\left(D_{ClONO_2}k_{hydr}\right)^{1/2}$$

The detailed parameterizations for H_{ClONO_2}, D_{ClONO_2}, and k_{hydr} are given in the Appendix in Shi et al.[9] As was the case for N_2O_5 hydrolysis k_{hydr} is seen to have a direct and an acid catalyzed channel. Using the same error analysis approach as in the note on N_2O_5 uptake, the model error is about 32.4% (1σ), with $\sigma_m = 32.2\%$ and $\sigma_d = 4.0\%$.

In the calculation of the chlorine activation (Cl_2 production) rate under stratospheric conditions, one needs to take into account the competition between the reactions of $ClONO_2 + H_2O$ and $ClONO_2 + HCl$. The presence of HCl will depress the reaction probability of $ClONO_2$ with H_2O.

99. **$ClONO_2 + H_2SO_4 \bullet H_2O(s)$ and $H_2SO_4 \bullet 4H_2O(s)$.** Measurements by Hanson and Ravishankara[1] and Zhang et al.[2] demonstrate that the reaction probability on the tetrahydrate is a strong function of both temperature and relative humidity, both of which affect the level of adsorbed H_2O. Both groups covered the temperature range of 192–205 K. The reaction is slowest at higher temperatures and lower relative humidities. Zhang et al.[2] have parameterized their data in the form of $\log \gamma = a_1 + a_2 \log x + a_3 \log^2 x$; for 195 K and x = water partial pressure in Torr: $a_1 = 10.12$, $a_2 = 5.75$ and $a_3 = 0.62$; for a water partial pressure of 3.4×10^{-4} Torr and x = T(K) between 182 and 206: $a_1 = 318.67$, $a_2 = -3.13$ and $a_3 = 0.0076$. Zhang et al.[3] have also measured a low value of $\gamma \sim 2 \times 10^{-4}$ on sulfuric acid monohydrate at 195 K.

100. **$ClONO_2 + HCl + H_2O(s)$.** Reaction probabilities of 0.27 (+0.73, –0.13) (Leu [6]) and 0.05 to 0.1 (Molina et al.[8]) were reported at 195 and 185 K, respectively. Abbatt and Molina[1] and Hanson and Ravishankara[4] report that a portion of the reaction may be due to $HOCl + HCl \rightarrow Cl_2 + H_2O$, with HOCl formed from $ClONO_2 + H_2O(s) \rightarrow HOCl + HNO_3(s)$. Hanson and Ravishankara[5] saw no enhancement of the $ClONO_2$ reaction probability when $H_2O(s)$ is doped with HCl. Their preferred value at 192 K is $\gamma = 0.3$, but this is consistent with $\gamma = 1$. Chu et al.[2] also report a value of 0.27 (±0.19) at 188 K, assuming no correction for porosity, but suggest the true value is 0.10 (±0.08). Using a Knudsen cell technique and looking at initial uptake, Oppliger et al.[9] measured $\gamma = 0.7$ at 180 K and 0.2 at 200 K with HCl in excess, and both Fernandez et al.[3] and McNeil et al.[7] report a value of >0.1 at close to 200 K. McNeil et al. report that this value is substantially smaller at 218 K. Eliminating the Molina et al. points, which were taken at much higher $ClONO_2$ concentrations than the others, plots of the remaining data show no obvious bias when plotted as a function of reactant concentration or temperature (180–200 K). Their average value $\gamma = 0.26 \pm 0.06$. The Oppliger et al. data were presented for two HCl concentrations, differing by a factor of three. All points from both HCl concentrations were included since all the data were generally consistent with previous measurements, although the higher HCl concentrations did tend to produce modestly higher uptake coefficients. Until a fuller model is available, a single temperature independent value with a moderate uncertainty due to surface porosity seems appropriate.

101. **$ClONO_2$ + HCl + HNO_3•$3H_2O$.** Measurements by Hanson and Ravishankara,[3,4] Leu and co-workers in Moore et al.[6] and Leu et al.,[5] and Abbatt and Molina[1] all report high γ values (>0.1) on NAT for temperatures between 192 and 202 K on water-rich NAT. Hanson and Ravishankara indicate that reaction probabilities on NAD are similar to those on NAT. The most recent NAT studies (Abbatt and Molina[1]) show a strong fall-off with relative humidity from γ >0.2 at 90% RH to 0.002 at 20% RH, indicating the necessity of sufficient water to solvate reactants. Within the limited measurements, data plots show no indication that the reaction probability of $ClONO_2$ + HCl depends on HCl and $ClONO_2$ gas phase concentrations or temperature between 191 and 202 K for water-rich NAT, but for nitric acid-rich NAT, there is a strong dependence on the partial pressure of HCl indicating that HCl is a limiting reagent on the surface under those conditions (Abbatt and Molina[1]). Averaged data yield $\gamma = 0.23 \pm 0.10$ for the water-rich case. Carslaw and Peter[2] have published a model of this reaction and its dependence on HCl uptake.

102. **$ClONO_2$ + HCl + H_2SO_4•$nH_2O(l)$.** Early work by Tolbert et al.[10] and Hanson and Ravishankara[4] indicated that the presence of HCl had little effect on the reaction of $ClONO_2$ with concentrated sulfuric acid (>65 wt% H_2SO_4). Subsequent realization that HCl would be more soluble, and therefore a more potent reactant, in the colder, more dilute sulfuric acid aerosols characteristic of the polar stratosphere led to additional investigations by Hanson and Ravishankara,[5] Zhang et al.,[11] Elrod et al.,[1] and Hanson.[2] All these measurements show a strong dependence of reactivity on HCl solubility, which in turn depends on water activity. The solubility of HCl in a wide range of sulfuric acid solutions has been experimentally determined by a range of techniques that agree well with current thermodynamic models. See Robinson et al.[8] for a review. Hanson and Lovejoy[3] measured a reacto-diffusive length, l, of only 0.009 ± 0.005 µm for 60 wt% H_2SO_4 in an aerosol flow reactor. (See Hanson et al.[6] for a definition of l) This is a factor of four lower than the value for the hydrolysis reaction of $ClONO_2$ showing the significant enhancement of $ClONO_2$ uptake due to HCl.

The $ClONO_2$ + HCl reaction on/in sulfuric acid has been modeled in Shi et al.[9] using the same phenomenological model for $ClONO_2$ hydrolysis driven uptake by sulfuric acid. Since the effect of HCl on the $ClONO_2$ uptake is to increase the $ClONO_2$ pseudo-first-order reaction rate, the model of $ClONO_2$ uptake (see note on $ClONO_2$ uptake on sulfuric acid) should include the pseudo first order reaction rate, k_{HCl}. The formulation of k_{HCl} is found in the appendix in Shi et al.[9] It is likely that the $ClONO_2$ reaction with HCl, like the $ClONO_2$ hydrolysis reaction, is acid catalyzed via protonated $HClONO_2^+$, where Cl^+ is activated as in the case of HOCl + HCl. For the $ClONO_2$ + HCl reaction, there is also a surface reaction (Hanson[2]). Hanson proposed that Γ_s, the effective uptake rate due to surface reactions, is linearly proportional to water activity; however, the calculated value of γ_o at 250 K and 60 wt% H_2SO_4 using his formulation is 0.02 (here $\gamma_o \sim \Gamma_s$), which is contradictory to his aerosol flow reactor result, which yielded $\gamma_o = 0.0079$ (here $\gamma_o \sim \Gamma_b$) (Hanson and Lovejoy[3]). In the model presented in the Shi et al. appendix, it is assumed that that Γ_s is linearly proportional to Henry's law constant of $ClONO_2$, rather than the water activity. The temperature dependence of Γ_s is determined, based on two measured values of Γ_s at 203 K (Hanson[2]) and 250 K (Hanson and Lovejoy[3]). The model yields a value of $\gamma_o \sim 0.011$ (here $\gamma_o \sim \Gamma_s$), which is close to the measured value.

In the stratosphere, when the reaction rate of $ClONO_2$ with HCl exceeds the flux of HCl to the particle surface, HCl is depleted. This, in turn, will depress the rate of both the $ClONO_2$ and HOCl + HCl reactions, and increase the $ClONO_2$ hydrolysis rate. Shi et al.[9] have proposed a model in which this effect is taken into account by including a factor F_{HCl} (see Table A–3 in Shi et al.). The formulation of F_{HCl} is based on scaling HCl reaction and accommodation fluxes. This flux correction is not exact (i.e., it does not rigorously calculate the HCl surface or bulk concentration) but provides a good approximation to the expected reduction in HCl + $ClONO_2$/HOCl reactivity and, just as importantly, the effective increase in $ClONO_2 + H_2O$ reactivity when $p_{ClONO_2} > p_{HCl}$. This is particularly relevant during cold Cl activation events when HCl can be removed almost completely (i.e., see Jaegle et al.[7]).

Using the same error analysis approach as in the note on N_2O_5 uptake by sulfuric acid, the error of using the model in the Appendix is about 40.0% (one sigma), with $\sigma_m = 39.8\%$ and $\sigma_d = 4.0\%$.

103. $ClONO_2$+HCl + H_2SO_4•H_2O(s) and H_2SO_4•4H_2O(s). This reaction has been studied by Hanson and Ravishankara[1] and Zhang et al.[2] The reaction probability is strongly dependent on the thermodynamic state of the SAT surface, which is controlled by the temperature and the water vapor partial pressure. At a water vapor pressure of 5.6×10^{-4} Torr the measured γ drops by over two orders of magnitude as the SAT surface temperature rises from 195 to 206 K. The results from the two groups are in qualitative agreement, but

sample different H_2O and HCl partial pressures. Zhang et al. have parameterized their data as a function of water partial pressure (at 195 K) and temperature (both at an HCl partial pressure of 4 to 8 × 10^{-7} Torr) in the form $\log \gamma = a_1 + a_2 \log x + a_3 (\log x)^2$. For H_2O partial pressure, $a_1 = 5.25$, $a_2 = 1.91$, and $a_3 = 0.0$; for T(K), $a_1 = 175.74$, $a_2 = -1.59$, and $a_3 = 0.0035$. Care must be taken in extrapolating either data set to lower HCl concentrations. Zhang et al.[3] measured no enhancement of $ClONO_2$ uptake on sulfuric acid monohydrate at 195 K with (2–8) × 10^{-7} Torr of HCl present, implying $\gamma < 1 \times 10^{-4}$.

104. $ClONO_2$ + HCl + Al_2O_3(s). Molina et al.[1] used flow tube techniques to measure $\gamma = 0.020 \pm 0.005$ on α–alumina at 195–230 K with stratospheric (5 ppmV) water vapor levels. Measured γ was independent of T and was affected very little by 5 ppbv HNO_3 vapor. The same γ was measured for a Pyrex surface, indicating the absorbed water and not the inorganic substrate hosted the reaction.

105. $ClONO_2$ + NaCl. Timonen et al.[10] studied the uptake of $ClONO_2$ on NaCl powders at 296 K and 225 K using a flow tube. Complete deactivation of the surface was observed at 225 K but not at 296 K. The uptake coefficients, after correction (typically by an order of magnitude) using the pore diffusion model of Keyser et al.[7,8] were $\gamma_0 = (4.6 \pm 3.1) \times 10^{-3}$ (1σ) at 296 K and $\gamma_0 = (6.7 \pm 3.2) \times 10^{-3}$ (1σ) at 225 K. Similarly low values for the uptake coefficient are reported by Zelenov et al.[11] using a flow tube approach. On the other hand, Caloz et al.[2] used a Knudsen cell and found that the initial uptake coefficient was 0.23 ± 0.06, independent of the type of salt used (powders, single crystals, deposited salt films) and without applying a correction for pore diffusion since no mass dependence for γ was observed; in similar studies. Aguzzi and Rossi[1] measured a value of $\gamma_0 = 0.10 \pm 0.05$ for the uptake of $ClONO_2$ on NaCl and 0.27 ± 0.10 for uptake on the unreactive $NaNO_3$ and Na_2SO_4 salts. The Cl_2 yield was 100% for NaCl, in agreement with the earlier studies[2,10] but 27 ± 7 % on the unreactive salts. Koch and Rossi[9] used a diffusion tube technique to measure a value of 0.1 for the uptake coefficient. Gebel and Finlayson-Pitts[5] used a Knudsen cell and measured an initial value of $\gamma_0 = 0.14 \pm 0.11$ (2σ) and a steady-state value of $\gamma = (3.9 \pm 1.8) \times 10^{-2}$, but concluded that approximately two layers of salt were sampled in these multi-layer experiments. The use of a single or sub-single layer of NaCl gave a steady state value corrected using the model of Hoffman et al. of $\gamma = (2.4 \pm 1.2) \times 10^{-2}$.[6] The source of the very disparate results from the different groups and techniques is not clear. All studies agree that the yield of Cl_2 is 100%, consistent with $ClONO_2 + NaCl \rightarrow Cl_2 + NaNO_3$ as observed earlier,[4] with small amounts of HOCl from hydrolysis of $ClONO_2$ on the surface being observed in the presence of water.

Deiber et al.[3] studied the uptake of $ClONO_2$ on water, NaCl and NaBr solutions using a droplet train flow reactor. The uptake coefficient was the same on water and 0.1 M NaCl, and Cl_2 was observed as the gas phase product.

106. $ClONO_2$ + KBr and NaBr. Caloz et al.[2] and Aguzzi and Rossi[1] report a rapid uptake of $ClONO_2$ on KBr solid salts at room temperature, $\gamma_0 = 0.35 \pm 0.06$ and $\gamma_0 = 0.18 \pm 0.07$ respectively; corrections for pore diffusion were not applied but are not expected to be large at these high uptake coefficients (see Introduction). This is consistent with a value of 0.1 measured by Koch and Rossi[4] using a diffusion tube technique. The reaction products are BrCl, Br_2 and Cl_2. BrCl is the initial reaction product formed from $ClONO_2 + KBr \rightarrow BrCl + KNO_3$. Br_2 is generated in a secondary reaction of BrCl with KBr: $BrCl + KBr \rightarrow Br_2 + KCl$. Cl_2 is then formed as the surface KBr is converted to KCl, which then reacts with $ClONO_2$.

Deiber et al.[3] studied the uptake of $ClONO_2$ on water, NaCl and NaBr solutions using a droplet train flow reactor. On NaBr, the uptake increased from 0.041 at 0.01 M NaBr to 0.073 at 1 M NaBr. From the dependence on the NaBr concentration, a value for the mass accommodation coefficient for $ClONO_2$ of 0.108 ± 0.033 (2σ) was obtained. The gas phase products were BrCl and Br_2, the latter formed by secondary reactions of BrCl with Br^-.Back to Table

107. $ClONO_2$ + sea salt. Gebel and Finlayson-Pitts[1] reported a rapid reaction between $ClONO_2$ and synthetic sea salt, with initial values based on the geometric sample area of $\gamma_0 = 0.42$ and steady-state values of $\gamma = 0.16$ (2σ). These were measured with multiple salt layers (3–236) but corrections for diffusion into underlying layers for such high uptake coefficients are relatively small, less than a factor of three. The yield of Cl_2 was 78 ± 13%; small amounts of HCl and HOCl were also observed as products. The recommended lower limit is based on these studies and the rapid uptake of other reactive species such as HNO_3 and N_2O_5. Back to Table

108. $ClONO_2$ + HBr + H_2O(s) and HNO_3•nH_2O(s). This reaction was studied by Hanson and Ravishankara[2] on water ice and NAT near 200 K. A diffusion-limited reaction probability of >0.3 was observed. Allanic et al.[1] measured $\gamma = 0.56 \pm 0.11$ at 200 K on water ice, observing Cl_2 and Br_2 to be formed in yields of 100% and 66 to 80%, respectively, in the range 180 to 200 K.

110. $CF_xCl_{(4-x)}$ (x=0–3) and CF_2Br_2 + Al_2O_3(s). Robinson et al.[3] reported steady-state dissociative uptake of CF_2Cl_2 and CF_2Br_2 on α-alumina surfaces at 210 and 315 K. Reaction probabilities of about 1×10^{-3} at 210 K were measured by monitoring the amounts of surface species bonded to the Al_2O_3 substrate. A re-analysis (Robinson et al.[4]) lowered this value by about a factor of 50. Moderate surface dosage with water vapor did not quench the reaction. In addition, Dai et al.[1] and Robinson et al.[2] studied dissociative chemisorption of CF_3Cl, CF_2Cl_2, $CFCl_3$, and CCl_4 on dehydroxylated γ-alumina powders. The obtained reactive uptake probabilities ranging from 0.4×10^{-5} for $CFCl_3$ to 1.0×10^{-5} for $CFCl_3$ over a temperature range of 120 to 300 K. HCl and halomethyl radicals were observed as desorption products. Loss of these products may point to somewhat higher γs, since they were measured by integrating halogen bound to Al_2O_3 substrates.

111. BrCl + NaCl, NaBr, KBr and NaI. The uptake of BrCl on solid NaCl and KBr using a Knudsen cell has been reported by Aguzzi and Rossi,[1] yielding 298 K values of 6×10^{-2} for NaCl and 0.14 on KBr. An earlier preliminary study from the same group reported a value at $\gamma > 0.1$ on KBr.[2] Insufficient data are available to make a recommendation.

Katrib et al.[4] measured the uptake of BrCl on aqueous solutions of NaI over the temperature range from 273 to 288 K; the uptake coefficient increased from 0.37×10^{-2} to 0.7 as the I^- concentration increased from 1×10^{-4} to 0.5 M NaI. The complex dependence on the I^- concentration indicated that a surface reaction was occurring at the air-solution interface.

Huff and Abbatt[3] studied the loss of BrCl on frozen bromide salt solutions at 233 K, finding that the uptake coefficients vary between 0.02 and 0.04 depending on the bromide concentration, independent of solution acidity.

112. Br_2 + NaCl, KBr and NaI. Only one report of the uptake of Br_2 on solid NaCl and KBr using a Knudsen cell is available[1] as part of a study of $BrONO_2$ uptake on salts. The uptake coefficient for Br_2 was 4×10^{-3} on NaCl and 3×10^{-3} on KBr. Insufficient data are available to make a recommendation.

Hu et al.[2] measured the uptake of Br_2 on aqueous solutions of NaI using a droplet train flow reactor over the temperature range of 263 to 293 K. The measured uptake coefficients decreased from 0.33 at 263 K to 0.08 at 293 K, with evidence for a significant contribution from a reaction at the interface between Br_2 and I^-.

Chem.* **1995**, *99*, 8768-8776, doi:10.1021/j100021a050.

113. BrO + H_2O(s), H_2SO_4•nH_2O(l) and NaCl(aq). Abbatt[1] used a coated flow tube technique to measure heterogeneous uptake on water ice, 60 and 70 wt% H_2SO_4 at 213 K, and 23 wt% aqueous NaCl at 253 K. He obtained $\gamma(\text{ice}) = (1.0 \pm 0.4) \times 10^{-3}$, γ (60 wt% H_2SO_4) = $(7 \pm 2) \times 10^{-4}$, γ (70 wt% H_2SO_4) = $(5 \pm 2) \times 10^{-4}$ and γ (23 wt% NaCl) $<3 \times 10^{-3}$. He observed product Br_2, indicating BrO self-reaction on both water ice and sulfuric acid solutions. Since reaction rate will depend on BrO concentrations, no recommendation is made for an atmospheric rate.

114. HOBr + H_2SO_4•nH_2O. Hanson[1] reported that uptake of HOBr on 80 wt.% H_2SO_4, producing Br_2. Br_2 and Br_2O production was also observed by Iraci et al.[2] during Knudsen cell studied of HOBr uptake on 70 wt% uptake for temperatures below 228 K. These products probably arise from HOBr self-reaction, although impurities in the acid solution might also play a role. Iraci et al. discuss methods to correct HOBr uptake data for the effects of self-reaction and secondary reactions with its products. The bulk phase self-reaction of HOBr noted above is not likely to be significant over the expected range of atmospheric concentrations.

Back to Table

115. HOBr + HCl + H_2O(s). Abbatt[1] measured $\gamma = 0.25$ (+0.10/-0.05) for this reaction on ice at 228 K. Chaix et al.[3] measured $\gamma = 0.3$ on ice from 180 to 195 K, dropping to ~0.15 at 205 K. The BrCl product was observed by mass spectrometry. Allanic et al.[2] report a faster rate for this reaction than for HOBr uptake on pure ice (which had an uptake coefficient of 0.15 at 200 K). Mössinger et al.[4] report a lower limit for γ of 0.1, under conditions with HCl concentration in excess of the HOBr concentration. No data on NAT surfaces is available.

(4) Mössinger, J. C.; Hynes, R. G.; Cox, R. A. Interaction of HOBr and HCl on ice surfaces in the temperature range 205–227 K. *J. Geophys. Res.* **2002**, *107*, 4740, doi:10.1029/2002JD002151.

116. HOBr + HCl + H_2SO_4•nH_2O. For the sulfuric acid reaction, Abbatt[1] measured γs of ~ 0.1 to 0.2 for [HCl] >1 × 10^{12} cm^{-3} over 68.8 wt% H_2SO_4 at 228 K; yielding an estimated $k^{II}_{HCl+HOBr} = 1.4 \times 10^5$ M^{-1} s^{-1} with a factor of 2 uncertainty. Hanson and Ravishankara[3] also measured $\gamma \leq 0.2$ (+0.2, – 0.1) for 60 wt% H_2SO_4 at 210 K. However, both of these measurements were based on significant underestimation of the solubility of HOBr in the relevant sulfuric acid solutions. More recent measurements by Waschewsky and Abbatt[5] indicate that the Henry's law constant for HOBr varies slightly with acidity between 60 to 70 wt% H_2SO_4 and more strongly with temperature between 208 and 238 K. (For 59.7 wt% H_2SO_4, H (M atm^{-1}) = 1.2 × 10^6 at 208 K and 2.2 × 10^5 at 228 K.) The HOBr + HCl second order liquid phase rate constant, $k^{II}_{HCl+HOBr}$, varies between 2 × 10^5 and 3 × 10^8 (M^{-1} s^{-1}) between 213 and 238 K over the same composition range (60–70 wt% H_2SO_4). Such a strong dependence on acid composition for the reaction rate of HOBr + HCl and the very small acid composition dependence for HOBr solubility in H_2SO_4 solution might be partially due to the formation of H_2OBr^+ in the acidic solution as discussed in their paper. However, this acid catalyzed reaction, i.e. H_2OBr^+ + HCl, alone does not completely account for measured reaction rates over the acid composition range studied.

Using the Henry's Law data for HOBr reported by Waschewsky and Abbatt,[5] the limiting reagent will vary depending on atmospheric temperature (H_2SO_4 wt%) and the concentrations of HOBr and HCl. For stratospheric conditions where [HOBr] is 10 pptv and [HCl] 1 ppbv, they predict dissolved HOBr will be in excess above 204 K and HCl in excess below 204 K for a H_2O vapor partial pressure of 3 × 10^{-7} atm. From their coated wall flow reactor uptake measurements, Waschewsky and Abbatt[5] derived expressions for $k^{II}_{HCl+HOBr}$ and predicted uptake coefficients. For temperature between 204 and 218 K where HOBr is likely to be in excess, they calculated HCl uptake coefficients, γ_{HCl}, which range between 7 × 10^{-5} and 9 × 10^{-5}. For temperatures in the 202–198 K range, where dissolved HCl is likely to be excess, the calculated uptake coefficients for HOBr, γ_{HOBr}, of ~1 × 10^{-2}. Hanson has reported Henry's law solubility data for 58–70 wt.% sulfuric acid and reactive uptake coefficients for HCl on HOBr doped sulfuric acid surfaces using a wetted wall flow reactor.[2] Hanson's reported that H_{HOBr} was independent of acid concentration at 250 K, however, the heat of solvation for HOBr derived is significantly lower (-12.5 ± 3.7 versus -9 ± 1 kcal/mol reported at lower temperatures by Waschewsky and Abbatt) that the values of H* based on Hanson's data, taken from 250 to 270 K, are much higher than the prior study's when extrapolated to their lower temperatures. Hanson's reported γ_{HCl} are strongly dependent on HOBr partial pressure and drop almost three orders of magnitude as the sulfuric acid concentration is raised from 58 to 95 wt%, possibly because HCl may be reacting with sulfuric acid at higher acid concentrations. The higher temperature $k^{II}_{HCl+HOBr}$ values computed by Hanson for his data disagree, when extrapolated to lower temperatures with the values reported by Waschewsky and Abbatt as well as a prior lower temperature value reported by Hanson and Ravishankara.[3] Better agreement can be obtained if the solvation enthalpy reported by Hanson is used to adjust the H_{HOBr} values used in the earlier, lower temperature studies. Clearly, the HOBr + HCl reaction will be difficult to parameterize in a simple manner. Potential inconsistencies in their $k^{II}_{HCl+HOBr}$ values, as discussed by Waschewsky and Abbatt[5] and Hanson[2] indicate that further measurements are required before this reaction can be definitively modeled. Iraci et al.[4] subsequently measured HOBr uptake over both of the temperature ranges covered in the prior

experiments. Their derived H* values agreed well with data from Waschewsky and Abbatt[5] at lower temperatures but fell far below Hanson's higher temperature measurements. Thus, it appears that HOBr + HCl kinetic parameters developed from analyses based on the Hanson[2] data may need to be reanalyzed.

117. HOBr + HBr + $H_2O(s)$ and H_2SO_4•nH_2O. Abbatt[1] measured $\gamma = 0.12 \pm (0.03)$ on ice at 228 K. Chaix et al.[3] measured γ_o values ranging from 0.44 at 180 K to 0.15 at 205 K. The Br_2 product was observed by mass spectrometry. The HBr concentrations were such that the ice surface had probably melted. Abbatt[2] measured $\gamma = 0.25$ for [HBr] = 1×10^{12} cm^{-3} over 68.8 wt% H_2SO_4 at 228 K; yielding an estimated $k_{II} > 5 \times 10^4$ M^{-1} s^{-1}.

118. HOBr + NaCl. Studies have been done on solid salts and aqueous surfaces. On solids, Mochida et al.[4] studied the uptake of HOBr on NaCl using multi-layer powders (10–500 μm) in a Knudsen cell at room temperature. After correction (by about an order of magnitude) for diffusion into the underlying layers, they obtained values for the initial uptake coefficient in the range of $(0.97\text{–}6.5) \times 10^{-3}$, with the corrected values decreasing with increasing concentrations of HOBr. They attributed this to competition between the reaction of HOBr with NaCl and a self-reaction of HOBr on the surface: $2\ HOBr \rightarrow Br_2 + H_2O + ½\ O_2$. Their final value of $\leq 6.5 \times 10^{-3}$ is based on their extrapolation back to very low HOBr concentrations. Both Br_2 and BrCl were observed as products. Chu et al.[2] measured the uptake of HOBr on NaCl at 250 K over a range of RH from 1.5 to 22.5%. After correcting the measured loss of HOBr by a factor of ~30 for diffusion into the underlying salt layers using the pore diffusion model, they obtained a value $\gamma_o = 5 \times 10^{-5}$. The smaller value compared to the Knudsen cell results of Mochida et al.[4] may be due to the much lower temperature they used; BrCl was the only gas phase product observed. Huff and Abbatt[3] report reactivity with frozen NaCl solutions in a coated-wall flow tube at 233 K. Uptake coefficients were dependent on the chloride concentration of the solution and on the acidity, with faster kinetics on the more acidic surfaces. BrCl was the only product observed.

Abbatt and Waschewsky[1] measured the uptake of HOBr on deliquesced 1–5 μm NaCl particles (75% RH); for particles at pH values of 0.3 and 7.2, a lower limit to the uptake coefficient of $\gamma_o > 0.2$ was measured. On unbuffered particles, the upper limit for the uptake coefficient was $\gamma_o < 1.5 \times 10^{-3}$ due to the limited availability of H^+ for the reaction between HOBr and Cl^- to form BrCl. Somewhat smaller values have been measured by Pratte and Rossi[5] in another aerosol flow tube experiment, using acidified NaCl particles. Acidification was necessary for the reaction to be observable. In general, the uptake coefficients varied from 1 to 10×10^{-3} from 70 to 90% relative humidity. The particles were acidified with quite large amounts of H_2SO_4, and the authors show that the reactivity on pure H_2SO_4 is less than that on the acidified salts. This could be a reason for the disagreement between the lower limit of Abbatt and Waschewsky and the Pratte and Rossi results.

119. HOBr + NaBr and KBr. Mochida et al.[6] studied the uptake of HOBr on solid KBr using multi-layer powders and spray-deposited films in a Knudsen cell. After correction (by factors of ~4–5) for diffusion into the underlying layers for the powders, they obtained values for the initial uptake coefficient in the range of $(1.3–8.4) \times 10^{-2}$, with the corrected values again decreasing with increasing concentrations of HOBr due to the self-reaction of HOBr on the surface: $2\ HOBr \rightarrow Br_2 + H_2O + \frac{1}{2}\ O_2$. On spray-deposited films where correction for diffusion into the underlying layers is not necessary, a value of 0.18 ± 0.04 was measured. The recommended upper limit is based on their extrapolation back to very low HOBr concentrations for the powders, and the spray-deposited film results. Br_2 was the only product observed.

Chu et al.[2] measured the uptake of HOBr on NaBr at 250 K in a flow tube at RH from 0.5 to 12 %. After correction by approximately an order of magnitude for diffusion of HOBr into the underlying salt layers using a pore diffusion model, a value for γ_0 of 2.5×10^{-3} was obtained; the smaller value may be due to the much lower temperature at which these studies were carried out. Again, Br_2 was the only product observed.

The uptake of HOBr on aqueous solutions of NaBr has been measured by Wachsmuth et al.[7] and by Fickert et al.[3] Wachsmuth et al.[7] report a rapid rate of uptake that is limited by mass accommodation; the mass accommodation coefficient was calculated to be 0.6 ± 0.2. This is consistent with the studies of Fickert et al.[3] who reported a lower limit for the mass accommodation coefficient of 1×10^{-2} at 274 K and observed that Br_2 was released at 100% yield at pH <6.5. The yield of Br_2 decreased rapidly with pH at higher pH values due to the declining ratio of HOBr to BrO^-. Fickert et al.[3] also measured the uptake of HOBr on aqueous solutions containing mixtures of NaCl and NaBr. BrCl was the major product at small Br^- concentrations while Br_2 dominated as the bromide ion concentration in solution increased.

Finally, there have been a number of coated-wall flow tube studies of HOBr reactivity on frozen salt solutions containing both NaCl and NaBr (Kirchner et al.,[5] Huff and Abbatt,[4] and Adams et al.[1]). HOBr uptake coefficients are in the 10^{-2} to 10^{-3} range at roughly 233 K. A general finding is that if the HOBr concentrations are too high, then only BrCl is seen as a gas-phase product from films composed of the (low) seawater ratios of bromide to chloride. The reason for this is that the small concentrations of bromide at the surface are rapidly depleted, leaving only chloride available for reaction. However, for low HOBr concentrations (10^9 to 10^{10} molecules/cm^3), as used by Adams et al., Br_2 is observed as the initial product.

120. $BrNO_2$ + H_2O(l). Behnke, George and co-workers have used wetted wall flow reactor techniques to investigate the reactive uptake of $BrNO_2$ on aqueous solutions from 276 to 298 K.[1,2] Measured reactive uptake coefficients range from 1 to 3.5×10^{-6} with a small positive temperature dependence.

121. $BrNO_2$ + KCl and NaCl. Caloz et al.[1] measured an uptake coefficient for $BrNO_2$ on KCl of 5×10^{-2}, but concluded that it was due only to reaction with a small bromide impurity in the KCl; as expected if this is the case, only Br_2 was generated in the reaction.

The uptake of $BrNO_2$ on aqueous solutions of 0.5 M NaCl has been measured using a droplet train flow reactor by Schweitzer et al.[3] from 277–293 K yielding $\gamma_0 \sim 1 \times 10^{-5}$. Frenzel et al.[2] used a wetted wall flow tube to obtain a lower limit for the uptake coefficient of 3.8×10^{-5} at 291 K.

122. $BrNO_2$ + KBr, NaBr and NaI. Caloz et al.[1] used a Knudsen cell to study the uptake of $BrNO_2$ on solid KBr powders. The uptake was fast, $\gamma_0 \geq 0.3$, with production of Br_2 as the gas phase product.

On aqueous solutions of NaBr, the uptake coefficient increases as the concentration of NaBr increases.[2-4] For example, at 278 K, γ_0 increased from 8.6×10^{-6} to 1.1×10^{-4} as the NaBr concentration increased from 5×10^{-4} to 5×10^{-2}, but was independent of temperature over the range from 275–293 K.[4] The major gas phase product is Br_2, with smaller amounts of $BrNO_2$ and only at the smaller concentrations of NaBr.[3,4]

The uptake of $BrNO_2$ on aqueous NaI solutions has been determined using a droplet train flow reactor[3] and a wetted wall flow tube;[4] the uptake coefficient from 4.4×10^{-5} to 4.4×10^{-4} as the iodide concentration increased from 10^{-4} M to 5×10^{-3} M.[4]

123. $BrONO_2$ and $BrONO_2$ + HCl + H_2O(s). Hanson and Ravishankara[3] investigated these reactions in an ice-coated flow reactor at 200 (±10) K. The reaction of $BrONO_2$ with H_2O(s) proceeded at a rate indistinguishable from the gas phase diffusion limit, implying that the reaction probability may be as high as one; the product BrNO(g) was observed. Allanic et al.[2] used a Knudsen cell reactor to measure $BrONO_2$ uptake between 190–200 K. Values of initial γ's in the 0.2–0.3 range were observed. An average $\gamma = 0.26 \pm 0.05$ was obtained from all of the appropriate data from both experiments**.** Aguzzi and Rossi[1] studied the hydrolysis reaction on various types of ices, obtaining $\gamma = 0.34 \pm 0.03$ at 180 K and $\gamma = 0.15 \pm 0.01$ at 210 K. They observed HOBr as the main product and Br_2O as a secondary product. Hanson and Ravishankara[3] also codeposited HCl with $BrONO_2$ observing rapid production of BrCl. It is unclear whether BrCl is produced directly from $BrONO_2$ + HCl or via HOBr (from $BrONO_2$ hydrolysis) reacting with HCl.

124. $BrONO_2$ + H_2O(l). Deiber et al.[1] used a droplet train rector to measure to uptake of $BrONO_2$ on pure water between 272 and 280 K. An apparent positive temperature dependence was observed with measured reactive uptake measurements ranging from 0.024 ± 0.0008 at 272.5 K to 0.039 ± 0.0012 at 279.7 K.
Back to Table

(1) Deiber, G.; George, C.; Le Calve, S.; Schweitzer, F.; Mirabel, P. Uptake study of $ClONO_2$ and $BrONO_2$ by halide containing droplets. *Atmos. Chem. Phys.* **2004**, *4*, 1291-1299, doi:10.5194/acp-4-1291-2004.

125. $BrONO_2$ and $BrONO_2$ + HCl + $H_2SO_4{\bullet}nH_2O$(l). Hanson and co-workers used both coated flow tube and aerosol flow tube techniques to show that the reaction of $BrONO_2$ with 45–70 wt% H_2SO_4 is extremely facile at temperatures from 210 to 298 K. Hanson and Ravishankara[2] measured γs of 0.5 (+0.5, –0.25) (45 wt% H_2SO_4, 210 K, 0.4 (+0.6, –0.2) (60 wt%, 210 K), and 0.3 (+0.7, –0.1) (70 wt%, 220 K) in a coated-wall flow tube experiment. Hanson et al.,[3] measured γ ~0.8 (20 to 40% error) for submicron aerosols at temperatures between 249 and 298 K and H_2SO_4 concentrations of 45 to 70 wt%; there was a sharp falloff in γ for H_2SO_4 concentrations between 73 and 83 wt%. Hanson also reported additional temperature dependent (230–295 K) coated flow reactor and room temperature (295–300 K) aerosol flow reactor studies extending measurements to higher acid wt% values.[1] Hanson has analyzed these combined data sets, the data indicated that γ is a function of sulfuric acid concentration, but independent of temperature. After eliminating one previously reported anomalously low 83 wt% data point Hanson has fit an empirical expression for measured γs for $BrONO_2$ + H_2O in the form of: $1/\gamma = 1/\alpha + 1/\gamma_{rxn}$, where $\gamma_{rxn} = \exp(a+b*wt.)$ and $\alpha = 0.80$, and a = 29.2, b = –0.40.[1] Using the same approach as detailed in the note for N_2O_5 uptake on sulfuric acid, the error for $BrONO_2$ + H_2O is 27.3% (1σ), with γ_m = 26.6% and γ_d = 6.3%. Addition of excess HCl to 229 K, 40 and 60 wt% H_2SO_4 aerosols caused an increase in γ to 1.0 and 0.9, respectively.[3]

126. **$BrONO_2$ + HBr.** Aguzzi and Rossi[1] measured γ over the 180–210 K temperature range, with $\gamma = 0.3$ at 180 K and an activation energy of –1.2 ± 0.2 kcal/mol.
Back to Table

(1) Aguzzi, A.; Rossi, M. J. Heterogeneous hydrolysis and reaction of $BrONO_2$ and Br_2O on pure ice and ice doped with HBr. *J. Phys. Chem. A* **2002**, *106*, 5891-5901, doi:10.1021/jp014383e.

127. **$BrONO_2$ + NaCl.** Aguzzi and Rossi[1] used a Knudsen cell and three types of NaCl samples (powders, spray-deposited and single crystal) to measure the uptake of $BrONO_2$ and obtained consistent results with $\gamma_0 = 0.31 \pm 0.12$. No correction for diffusion into the powders was made because of the high uptake coefficient (see Subsection 5.6). BrCl was the major product, 80 ± 20%, with smaller amounts (~10%) of Br_2 and some HCl. Rapid uptake of $BrONO_2$ of the same magnitude was observed on the unreactive salts $NaNO_3$ and Na_2SO_4, with a Br_2 yield of 45 ± 10%; this uptake and reaction was attributed to the self-reaction of $BrONO_2$ on the surface to generate Br_2O which decomposed to Br_2.

Deiber et al.[2] studied the uptake of $BrONO_2$ on water, NaCl and NaBr solutions using a droplet train apparatus from 272–280 K. The uptake coefficient was the same on water and 0.1 M NaCl, where BrCl was observed as the gas phase product. On NaBr, the uptake increased with the square root of the NaBr concentration, from which a value for the mass accommodation coefficient for $BrONO_2$ of 0.063 ± 0.021 (2σ) was obtained.
Back to Table

(2) Deiber, G.; George, C.; Le Calve, S.; Schweitzer, F.; Mirabel, P. Uptake study of $ClONO_2$ and $BrONO_2$ by halide containing droplets. *Atmos. Chem. Phys.* **2004**, *4*, 1291-1299, doi:10.5194/acp-4-1291-2004.

128. **$BrONO_2$ + KBr and NaBr.** Aguzzi and Rossi[1] used a Knudsen cell and three types of KBr samples (powders, spray-deposited and single crystal) to measure the uptake of $BrONO_2$ and obtained consistent results with $\gamma_0 = 0.33 \pm 0.12$. No correction for diffusion into the powders was made because of the high uptake coefficient (see Subsection 5.6). Br_2 was the major product, with its yield decreasing as the concentration of $BrONO_2$ increased; this was attributed to a competition between the reaction of $BrONO_2$ with KBr and the self-reaction of $BrONO_2$ on the surface.

Deiber et al.[2] studied the uptake of $BrONO_2$ on water, NaCl and NaBr solutions using a droplet train flow reactor from 272–280 K. The uptake coefficient was the same on water and 0.1 M NaCl. On NaBr, the uptake increased with the square root of the NaBr concentration, from which a value for the mass accommodation coefficient for $BrONO_2$ of 0.063 ± 0.021 (2σ) was obtained. The gas phase product on the NaBr solution was Br_2.

129. **ICl on NaCl/NaBr.** ICl uptake onto acidified and neutral NaCl/NaBr solutions at 274 to 298 K was studied in coated–wall flow tubes. The initial uptake coefficients were in the 0.6 to 3×10^{-3} range depending on the experimental system used, for solutions containing bromide; IBr was the gas-phase product observed. In an aerosol flow tube, uptake of ICl onto concentrated NaBr solutions showed uptake coefficients of 1 to 2×10^{-2}, which dropped to values of 10^{-4} on sea-salt solution aerosols. IBr was the product of the reaction on NaBr particles, with a yield of 0.6 (Braban et al.[1]).

130. HOI on NaCl/NaBr. HOI uptake on acidified and neutral NaCl/NaBr solutions at 274 K in a wetted-wall flow tube indicate a lower limit for the uptake coefficient of 2.2×10^{-3} (Braban et al.[1]). IBr is identified as the major gas-phase product when the solutions contain bromide to chloride ratios of 1:200, whereas ICl is the product from pure NaCl solutions. HOI uptake on dry and frozen solutions of NaCl and NaBr with chloride to bromide ratios equal to that of seawater were also studied in a coated wall-flow tube. The product ICl is only formed when the surface is depleted of bromide, otherwise IBr forms. Uptake coefficients measured in a flow reactor by Holmes et al.[2] are >0.01 at 243 K on the frozen films and >0.01 at 243 K and 298 K on dry salts. Mössinger and Cox[3] report uptake of HOI onto dry films of NaCl, NaBr and sea salt from 278 to 298 K and measured uptake coefficients of 0.016, 0.034 and 0.061 respectively. The products are ICl, IBr and IC//IBr, respectively.

131. $CF_3OH + H_2O + H_2O(l)$ and H_2SO_4•$nH_2O(l)$. Lovejoy et al.[1] used both wetted-wall and aerosol flow tube techniques to measure reactive uptake of CF_3OH on water at 274 K and 39–60 wt% H_2SO_4 at various temperatures between 206 and 250 K. γ's showed a strong dependence on water activity. Aerosol uptake studies yielded reacto-diffusive lengths of >0.4 µm for 40 wt% H_2SO_4 and 1.0 µm for 50 wt% H_2SO_4, both at 250 K. Recommended γ's were estimated by averaging bulk uptake measurements at similar H_2SO_4 concentrations and ignoring temperature effects on water activity.

132. $SO_2 + O_3 + Al_2O_3(s)$. Usher et al.[1] present Knudsen cell data showing that pretreatment of α-alumina with SO_2 increases γ_o values for O_3 uptake by 30%; FTIR observations by the same group show that O_3 oxidized surface sulfite and bisulfite formed by SO_2 absorption to sulfate and bisulfate.

133. SO_2 on H_2O_2/ice. SO_2 loss on ice surfaces has been observed to proceed when H_2O_2 is present, making the reaction of potential significance in ice clouds. Clegg and Abbatt[2] have observed this reaction when both SO_2 and H_2O_2 are delivered from the gas phase in a coated-wall flow tube at 228 K, with H_2O_2 in excess. For both SO_2 and H_2O_2 only small fractions of a monolayer are present on the surface during the reaction. It is inferred that the reaction proceeds through the HSO_3^- intermediate because the reaction rate declines as acidity builds up on the surface from the sulphuric acid product, i.e., because dissociation of adsorbed SO_2 to form HSO_3^- is becoming inhibited. At about 200 K, relative to the uptake on pure ice, Chu et al.[1] observe enhanced loss of SO_2 on ice films that have been doped with 3% H_2O_2 and they detect sulphate as a product. Uptake coefficients are reported in Clegg and Abbatt that are dependent on both the H_2O_2 and SO_2 partial pressure, so no single value prevails for atmospheric conditions.

(2) Clegg, S. M.; Abbatt, J. P. D. Oxidation of SO_2 by H_2O_2 on ice surfaces at 228 K: A sink for SO_2 in ice clouds. *Atmos. Chem. Phys.* **2001**, *1*, 73-78, doi:10.5194/acp-1-73-2001.

134. SO_2 + H_2O_2, O_3, HONO, NO_2, HNO_3 + H_2SO_4•nH_2O(l). Rattigan et al.[2] used a bubble train reactor to measure the uptake of SO_2 in the presence of solvated oxidants at 293 K. For H_2O_2 the second order rate constant at 1 wt% H_2SO_4 agreed well with previous bulk kinetics measurements and with previous droplet train/flow reactor measurements. Measurements at 20, 40, and 60 wt% H_2SO_4 are the first reported for concentrated acid. Reaction rate data were fit to a two term (acid catalyzed and water catalyzed) bulk second order rate expression, which, in the limit of high acid activity ($a_{H^+} = \alpha_{H+}[H^+]$, where α_{H+} is the H^+ activity coefficient) reduces to: $k^{II}_{H_2O_2} = 8.3 \times 10^4 (\alpha_{H_2O}/ a_{H^+})$, where α_{H_2O} is the water activity coefficient. Both α_{H+} and α_{H_2O} can be obtained from the sulfuric acid thermodynamic model of Carslaw et al.[1] The high a_{H^+} approximation for $k^{II}_{H_2O_2}$ should be accurate to a factor of two between 40 and 70 wt%.

Uptake of SO_2 in the presence of solvated O_3 was measured for 1–70 wt% acid; the Henry's law expression for O_3 was determined in separate experiments. Measured second order rates agree reasonably well with previous results measured below 18 wt%. A three-term fit for reaction with SO_2(aq), HSO_3^-, and $SO_4^=$ was fit to the data: $k^{ii}_{O_3} = 6.6 \times 10^3 [SO_2(aq)] + 3.2 \times 10^5 [HSO_3^-] + 1 \times 10^9 [SO_4^=]$. This expression should be accurate to a factor of two between 20 and 70 wt.%.

The HONO reaction was studied by adding nitrosyl sulfuric acid to 20, 40, 60, and 70 wt% acid. Measured second order rate constants were moderately consistent with previous measurements below 10 wt%. A $k^{II}_{HONO} = 142[H^+]$ was fit to the full data set; it should be accurate to a factor of two for acid concentrations between 10 and 70 wt%.

No enhanced SO_2 uptake was observed with added gas phase NO, NO_2, or with 20 wt% HNO_3 added to 50–60 wt% sulfuric acid.

135. SO_2 + Al_2O_3. Goodman et al.[2] used FTIR observations of SO_2 absorption on α-alumina to show that surface bound sulfite and bisulfite products are produced, they integrated these surface feature absorbencies to estimate a γ_o of $(9.5 \pm 0.3) \times 10^{-5}$. Usher et al.[8] performed BET corrected room temperature studies on four α-alumina samples reporting an average γ_o of $(1.6 \pm 0.5) \times 10^{-4}$. Seisel et al.[7] measured $\gamma_0 = (7.4 \pm 0.9) \times 10^{-3}$ on γ-alumina at 298 K using a pulsed Knudsen cell method. FTIR studies of SO_2 uptake on commercial γ-alumina catalyst samples also show sulfite formation on non-hydroxylated surfaces.[1,3] Ma et al.[6] co-deposited SO_2 and NO_2 on γ-alumina surfaces, using FTIR to observe that rather than forming adsorbed nitrite or nitrate, NO_2 dimerized and the dimer oxidized SO_2 to sulfate. Ma and coworkers[4] extended their studies of NO_2/N_2O_4 interactions with adsorbed SO_2 on α-Al_2O_3, CaO, α-Fe_2O_3, ZNO_3, MgO, TiO_2 and SiO_2. Lo et al.[5] published a density functional theory study of SO_2 interactions with hydrated and dehydrated γ-alumina surfaces calculating the thermochemistry of SO_2 adsorption and conversion to SO_3/HSO_3.

136. SO_2 + NaCl and sea salt. Gebel et al.[1] reported no measurable uptake of SO_2 on NaCl, yielding an upper limit of 1×10^{-4} for the uptake coefficient. The same was true for synthetic sea salt that had been heated while pumping. However, sea salt that had not been heated or pumped on extensively had a rapid uptake of SO_2, with initial uptake coefficients as large as 0.09. The time dependence of the uptake coefficient was consistent with uptake of SO_2 into a liquid layer, likely due to large amounts of water adsorbed on the hygroscopic components of sea salt such as magnesium hydrate. No gas phase products were observed but sulfite formation in the salt was seen by FTIR, indicating that uptake was due to dissolution of SO_2 into the water film on the salt surface.

137. SO_3 + $H_2SO_4 \cdot nH_2O(l)$. Jayne et al.[1] measured the uptake coefficient in a wetted wall-flow reactor at 300 K over a composition range of 78–92 H_2SO_4 wt%. The measured γ was indistinguishable from 1.0. Higher water concentrations and lower temperatures probably tend to increase γ, so a value near 1.0 probably holds for all atmospheric conditions.

138. OCS + Al_2O_3. Liu and co-workers have measured OCS uptake on both α-alumina and γ-alumina surfaces at 298 K using Knudsen cell techniques[3] and on α-alumina surfaces with controlled water vapor levels using both a Knudsen cell and a reaction chamber equipped with diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS).[4] The DRIFTS technique was also used to investigate heterogeneous reaction mechanisms, revealing that surface Al-OH plays a major role in oxidizing adsorbed OCS to CO_2 and that a number of surface adsorbed reactive intermediate anions, including $HSCO_2^-$, are formed. The overall reaction is essentially a surface catalyzed hydrolysis reaction producing both CO_2 and H_2S.[1,2,4] Liu et al.[3] report uptake of relatively dry OCS yielding rather small $\gamma_0 = (4.9 \pm 0.5) \times 10^{-7}$ and $\gamma_{ss} = (6.5 \pm 2.4) \times 10^{-8}$ values for α-alumina and $\gamma_0 = (1.0 \pm 0.2) \times 10^{-7}$ and $\gamma_{ss} = (1.8 \pm 0.4) \times 10^{-8}$ values for γ-alumina at 298 K. The low steady-state uptake coefficients are probably due to consumption of most of the surface Al-OH sites and a low regeneration rate due to limited water vapor. OCS uptake experiments that provide controlled water vapor fluxes to α-alumina surfaces produce somewhat higher γ_{ss} values in the Knudsen apparatus, and the values obtained by integrating the DRIFTS spectra for RH values between 7 and 47% fall in the range of 7.4 × 10^{-6} to 3.3 × 10^{-6}.[4] Interestingly, the highest uptake values are not obtained for the highest RH values because water vapor can also occupy reactive alumina surface sites and block OCS adsorption.

5.4 Table 5-3. Soot Surface Uptake Coefficients

Gaseous Species	Uptake Coefficient (γ)	Notes
SO_2	See Note	1, 2
NH_3	0, See Note	1, 3
O_3	See Note	1, 4
HNO_3	See Note	1, 5
N_2O_5	See Note	1, 6
NO_2	See Note	1, 7
NO_3	See Note	1, 8
HO_2	See Note	1, 9
HO_2NO_2	See Note	1, 10
H_2O	See Note	1, 11

5.4.1 Notes for Table 5-3

1. See the discussions on soot presented in the introductory discussions of "Surface Types" and "Parameter Definitions" for descriptions of some of the factors affecting the uptake and reaction of gases on soot surfaces. In most cases, the available reactive surface area rather than the geometric areas have been used in obtaining the uptake coefficients; in those cases where the geometric area was used but a higher available surface area was involved in the measured uptake, the uptake coefficient is given as an upper limit. Most data are available at room temperature or there are very limited data at lower temperatures characteristic of the upper troposphere.
Back to Table

2. **SO_2 + soot.** $\gamma \leq 3 \times 10^{-3}$ measured using Degussa FW2 carbon black by Rogaski et al.[7] This is an upper limit since it is based on the geometric surface area. Koehler et al.[5] measured an average value of $(2 \pm 1) \times 10^{-3}$ over the first 10–30 s on n-hexane soot at –100° C (the initial uptake may be larger), but indicate that taking into account surface roughness would reduce this value. A number of studies[1-7] suggest that uptake is primarily due to physisorption on the surface; oxidation occurs in the presence of water, oxidants and metals.

3. **NH_3 + soot.** Chughtai et al.[1] and Muenter and Koehler[2] measured the uptake of NH_3 on soot. Based on Muenter and Koehler[2] where conditions are closest to atmospheric, NH_3 is not taken up by soot particles at temperatures above 173 K.

4. **O_3 + soot.** Many studies report a rapid, initial loss of O_3 followed by a slower loss that also occurs on aged soot or soot pre-exposed to ozone[2,4-10,13,14,17,18]. Initial, rapid O_3 loss may be most applicable for soot as it comes out of aircraft exhaust, with γ^{init} ~10^{-3} from most studies using both carbon black and organic combustion soots.[6-8,13,18] The second stage of the reaction is probably more applicable to soot dispersed in air; γ^{aged} ~10^{-4}–10^{-6} using both carbon black and organic combustion soots,[6-10,12,18] but in the range of 10^{-4} to 10^{-5} based on organic combustion soot data alone.[8,10] A few studies have been carried out at temperatures below room temperature;[2,8-10] given the wide ranges measured even at room temperature, these values generally fall in the same range. Il'in et al.[8] report a temperature dependence for the initial uptake on fresh soot of $\gamma^{fresh} = 1.9 \times 10^{-3}\exp(-780/T)$ and for aged soots, $\gamma^{aged} = 1.8 \times 10^{-4}\exp(-1000/T)$. Both physisorption and reaction of ozone with the surface appear to take place. The studies of Fendel et al.[6] suggest that lower particle growth in size below 40 ppb O_3 is due to less than a monolayer of O_3 on the surface. Stephens et al.[18] proposed a Langmuir-type reversible adsorption of O_3, followed by a slower reaction with the surface. Pöschl et al.[12] proposed a similar scheme for uptake of ozone on spark-generated graphite soot coated with benzo[*a*]pyrene. Initial reversible physisorption occurred with γ ~10^{-3}, and "apparent reaction probabilities" for O_3 with BaP on soot of γ ~10^{-5}–10^{-6} were reported. The presence of water inhibited the reaction, which was postulated to be due to competitive adsorption between water and ozone on the surface; this is in contrast to the report of Chughtai et al.[1] in which the rate of ozone loss increased with RH. Pöschl et al.[12] report Langmuir adsorption equilibrium constants for O_3 and H_2O, and a second order surface reaction rate constant for the O_3-BaP reaction of $(2.6 \pm 0.8) \times 10^{-17}$ cm^{-2} s^{-1}. Three possible paths have been proposed: (1) chemisorption of O_3; (2) catalytic decomposition of O_3: $2O_3 \rightarrow 3O_2$; (3) surface oxidation and formation of gas-phase carbon oxides. The studies of Fendel et al.[6] suggest that lower particle growth in size below 40 ppb O_3 is due to less than a monolayer of O_3. Studies of Smith et al.[17] and Smith and Chughtai[14] suggest that catalytic decomposition occurs to some extent over the entire reaction sequence. CO_2 and H_2O are the major gas phase and surface oxidized functional groups on the surface such as carboxylic acids are observed.[1-3,5,6,9,11,14-16,18]

5. **HNO_3 + soot.** Studies of the uptake of HNO_3 on soot have been carried out over a range of nitric acid pressures.[1-8] Measured values of γ at room temperature are typically in the range 10^{-1}–10^{-5}, with smaller uptake coefficients measured at longer reaction times. Saathoff et al.[7] report an upper limit of 3×10^{-7} as a time-averaged value over two days. At lower concentrations characteristic of the atmosphere, uptake appears to be primarily due to physisorption while at higher concentrations, $>2 \times 10^{12}$ molecule cm^{-3}, a surface reaction occurs. At 220 K, γ ~0.1 with irreversible uptake attributed to reaction with surface groups.[1] Reaction of HNO_3 at concentrations from $(1–9) \times 10^{12}$ molecule cm^{-3} with "grey" soot from a rich flame using hexane has been reported[8] to generate HONO as the major gaseous product with initial and steady-state reaction probabilities of $\gamma_o = 4.6 \times 10^{-3}$ and $\gamma_{ss} = 5.2 \times 10^{-4}$, respectively; reaction with "black" soot from a lean flame gave NO as the major gaseous product, with initial and steady-state reaction probabilities of $\gamma_o = 2.0 \times 10^{-2}$ and $\gamma_{ss} = 4.6 \times 10^{-3}$, respectively (based on geometric surface area of sample holder). The NO was hypothesized to result from secondary reactions of an initial HONO product.

6. **N_2O_5 + soot.** Brouwer et al.,[1] Longfellow et al.,[2] and Saathoff et al.[3] studied the uptake of N_2O_5 at room temperature on a ground charcoal (carbon black) sample, on propane soot and on spark-generated graphite soot, respectively. Brouwer et al. and Longfellow et al. report uptake coefficients based on the geometric sample surface area, and therefore give upper limits. An upper limit of $\gamma \leq 0.02$ can be derived based on the larger value of 0.016 reported by Longfellow et al. As discussed below, much smaller values are reported by Saathoff et al.: 4×10^{-5} under dry conditions and 2×10^{-4} at 50% RH. Three possible reactions may occur: (1) decomposition of N_2O_5 on the surface to generate $NO_2 + NO_3$; (2) reaction of N_2O_5 with the soot; (3) hydrolysis of N_2O_5 with water on the surface to generate HNO_3. The studies of Longfellow et al. support the decomposition reaction, with yields of NO_2 within experimental error of 100%; the generation of NO_3 on the surface followed by its decomposition to NO_2, may contribute to the observed production of NO_2. The studies of Brouwer et al. suggest that a redox reaction with the soot surface to generate NO occurs in parallel with hydrolysis of N_2O_5 to generate HNO_3. Saathoff et al. propose two independent, parallel reactions: (1) hydrolysis generating HNO_3, $N_2O_5 + \text{soot} \rightarrow 2\ HNO_3$ with $\gamma = (4 \pm 2) \times 10^{-5}$ under dry conditions (<10 ppm H_2O) which increases to $(2 \pm 1) \times 10^{-4}$ at 50% RH. (2) decomposition to NO and NO_2: $N_2O_5 + \text{soot} \rightarrow NO + NO_2 + \text{products}$, with $\gamma = (4 \pm 2) \times 10^{-6}$ under dry conditions.

(3) Saathoff, H.; Naumann, K.-H.; Riemer, N.; Kamm, S.; Möhler, O.; Schurath, U.; Vogel, H.; Vogel, B. The loss of NO_2, HNO_3, NO_3/N_2O_5, and $HO_2/HOONO_2$ on soot aerosol: A chamber and modeling study. *Geophys. Res. Lett.* **2001**, *28*, 1957-1960, doi:10.1029/2000GL012619.

7. **NO_2 + soot.** A fast initial uptake of NO_2 is observed on fresh soots[1-3,8-12,15,17,19,20,24-26] with the initial uptake coefficient in studies involving both carbon blacks and organic combustion soots in the range of $\gamma^{init} \cong 10^{-1}$ to 10^{-4}. For longer reaction times on carbon black soots, $\gamma^{aged} \sim 10^{-4}$ based on studies by Kalberer et al.[16] and Ammann et al.[3,4] However, Kleffmann et al.[18] report a lower uptake coefficient of $\sim 10^{-7}$ on carbon black over the first 5 minutes of reaction and Saathoff et al.[21] report an upper limit of $< 4 \times 10^{-8}$ averaged over 5 days under dry conditions (<10 ppm H_2O) on spark-generated graphite. On organic combustion soots, γ^{aged} has been reported to be in the range of $\sim 10^{-4}$–10^{-6}.[1,4,5,19,22,24] All studies were done at room temperature except those of Longfellow et al.[19] which were carried out at 262 K. The surface deactivates on continued exposure to NO_2, suggesting a maximum amount of HONO that can be formed per cm^2 of soot area or mg of soot; this has been reported to be in the range of 10^{16} to 10^{18} HONO per mg of soot.[5,12,14,15,18,24] However, reactivation on heating of the surface, exposure to water vapor and/or with time after the exposure is stopped has been observed.[12,19,24-26] A small portion (~10–20%) of the NO_2 taken up appears to be chemisorbed to the surface.[1,5,9,14,15,17,18,24-26] Infrared studies[1,17,23] show that surface C–ONO, C–N–NO_2, and C–NO_2 groups are formed. The remainder of NO_2 reacted appears as gaseous HONO and NO; Salgado and Rossi[22] report HONO as the major product for hexane soot from a flame at near stoichiometric ratio but NO as the major product for soot from an extremely lean flame. In addition, N_2O, CO, and CO_2 have been observed as products at higher temperatures.[6,7] At lower NO_2 concentrations, the HONO yield can approach 100%; production of NO may be due to the bimolecular reaction of HONO on the surface at higher concentrations to give $NO + NO_2 + H_2O$. The HONO yield at 262 K appears to be smaller than at room temperature.[19] Formation of HONO is due to reaction with a reduced surface site and not to NO_2 surface-catalyzed hydrolysis. The formation of HONO from the reaction of NO_2 with unspecified semi-volatile organics in diesel exhaust has been reported [13] and proposed to be a much larger source of HONO than the reaction with the soot itself.

11. **H_2O + soot.** Alcala–Jornod et al.[1] report an upper limit to the initial uptake coefficient of $\gamma < 2 \times 10^{-3}$, consistent with the earlier measurements of Rogaski et al.[8] The uptake is most likely a reversible physisorption[1,7] although based on water uptake isotherms, Chughtai et al.[2,3,5,6] propose that at low relative humidities (<25%) chemisorption occurs. While prior exposure of Degussa FW-2 to NO_2 and SO_2 was not found to increase the uptake coefficient for water, treatment with HNO_3 increased the measured uptake coefficient by a factor of 28 and with H_2SO_4 by a factor of 68.[8] Water adsorption isotherms on soot have been measured in a number of studies, e.g.[2-6] and the amount of water taken up found to increase with the air/fuel ratio used to generate the soot, with the sulfur content, with aging and oxidation of the surface (e.g. by O_3) and with the presence of metals.[2-6,9]

a. $\ln H = A + B/T + C \ln(T)$ [M atm^{-1}]

b. Uncertainty Classes:

- I—Better than 10%
- II—10% to 50%
- III—50% to 100%
- IV—Factor of 2 to factor of 10
- V—Factor of 10 to factor of 100
- VI—Greater than a factor of 100

c. $h_{G,0}$ and h_T are the gas-specific Sechenov coefficients. See the Introduction: Parameter Definitions section, for more information.

5.5.1 Notes for Table 5-4

Note 1: *Simple O, H Species* Back to Table

O_2 The recommendation was taken from the studies of Benson et al.[1] and Rettich et al.[9] The data show clear curvature in a plot of ln (K_h) v. 1/T. A two-parameter fit gives A = –13.26 and B = 1950 K for the temperature range 273–285 K. The salt effect parameter $h_{G,o}$ is set to zero (see discussion in the text preceding this Table). The temperature dependent salt effect parameter is from the optimization of Weisenberger and Schumpe.[16]

O_3 The recommendation of Rischbieter et al.[10] was accepted and refitted. Salt effect parameters were obtained from the effect of NaCl, KCl, Na_2SO_4, and $Ca(NO_3)_2$ on H, combined with specific ion parameters.

H An average of estimates of the solubility of H based on two approaches: One is simply the assumption that the solubility of H is the same as the solubility of H_2.[8] The second assumes that the solubility of H is what would be expected for a rare gas atom of the same radius.[11] The average value from 273 K to 298 K is 2.6×10^{-4}, with very small variation with temperature. Above room temperature the solubility increases.

OH Calculated from the reduction potential of the OH radial, $E^o(OH/OH^-) = (1.90 \pm 0.02)$ V, derived from an equilibrium with Tl^+.[13] This was combined with the Gibbs energy of the anion and the gas-phase radical to obtain the free energy of solution.

HO_2 The recommendation was based on a calculation by Schwartz[12] based on the gas phase constituents HO_2, H^+, and O_2^-. Thermodynamic values were updated to those in our Thermodynamic tables, to $pK_a = (4.8 \pm 0.1)$, and to a reduction potential $E^o(O_2/O_2^-) = -(0.35 \pm 0.01)$ V. The reduction potential, referenced to one atmosphere O_2, is based primarily on equilibria reported by Meisel and Czapski,[6] corrected for a revised duroquinone potential.[15]

H_2O_2 The data of Lind and Kok[4] (corrected),[5] Hwang and Dasgupta,[3] Yoshizumi et al.,[17] Staffelback and Kok,[14] O'Sullivan et al.,[7] and Huang and Chen[2] are all in good agreement. The recommendation is from a two-parameter fit to all the results (Kok, et al. and Hwang and Dasgupta are represented by calculated endpoints; Huang and Chen by calculated points at the experimental temperatures). Previous recommendations were A = −14.16 and B = 760.

Note 2: *Simple Inorganic Nitrogen Species*

Back to Table

N_2 The recommendation of Battino[3] was accepted and refitted to three-parameter equations. A two-parameter fit gives A = 12.81 and B = 1625 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[20]

NH_3 Based on the recommendation by Edwards et al.,[10] refit to a two-parameter equation. Over the temperature range 273–348 K, there appears to be little curvature in the data. The more recent work of Dasgupta and Dong[9] are in quite good agreement with this recommendation, whereas the results of Hales and Drewes[11] are somewhat higher and those of Shi et al.[18] (an uptake study) are significantly lower. The Hales and Drewes paper also included studies of the effect of dissolved CO_2 on the solubility of NH_3. The solubility of NH_3 in solutions containing a wide variety of ions is discussed by Clegg and Brimblecombe.[8] Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[20]

NF_3, N_2F_4 Refit to three- parameter equation from the recommendation of Wilhelm et al.[21]

Chloramines

Derived from flash off studies with glass sparging columns at 20° C and 40° C.[12] Data point for ammonia at 20°C in exact agreement with recommended value in Table.

NO Three-parameter refit from the recommendation of Battino.[2] Two-parameter fit gives A = -12.27 and B = 1790 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[20]

NO_2 Based on NO_2 uptake studies and an analysis of literature values.[7] A value of 0.014 was obtained from an analysis of studies of reactive dissolution of NO_2 by Schwartz and White.[17]

NO_3 From the reduction potential $E^o(NO_3/NO_3^-)$ = (2.46 ± 0.02) V, which is an average based on determinations of equilibria with Cl^-,[6,13] combined with the Gibbs energy for the anion and the gas-phase radical. The derived solubility value is in good agreement with that calculated from the uptake of NO_3 into a wetted-wall flow reactor containing Cl^-.[15] It is in very poor agreement with the much higher value derived from a study of the uptake of NO_3 by a series of wetted denuders.[19]

N_2O Three-parameter refit to the recommendation of Battino.[1] Two parameter fit gives A = 13.40 and B = 2880 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[20]

NOCl Uptake kinetics measured as function of temperature into water and solutions containing HCl, NaCl, and NaOH. Only the latter had an effect. The kinetics were consistent with an uptake coefficient of 0.03.[16]

HN_3 Measured using a packed column technique at pH 1.8 ($\mu = 0.02$ mol L^{-1}). The effective Henry's law constant can be calculated using $K_H^* = K_H(1 + K_a/[H^+])$, with $pK_a = 4.65$[4]

HNCO, isocyanic acid

The recommended value is the apparent Henry's Law constant and includes a contribution from hydrolysis, $H^* = H/(1 = K_{hyd})$.[5] Measurements were made on a bubbler column with HNCO measurement through chemical-ionization mass spectrometry. The temperature dependence of H* was determined over 273–298 K, leading to an enthalpy change of −34 ± 2 kJ mol^{-1}. An investigation as a function of pH was carried out at 298 K, leading to a value of H = 26 ± 2 M atm^{-1} and a dissociation constant of $K_a = 2.1 \pm 0.2 \times 10^{-4}$ M. Note that the value of A in the Table was not given in the paper but was calculated from the values of H*(298) and ΔH. An earlier study at pH 3, also employing chemical-ionization mass spectrometry, led to a value of H(298) = 21 M atm^{-1}.[14]

Note 3: *Simple Inorganic Carbon Species* Back to Table

CO The recommendation is based on smoothed data from Rettich et al.[2] and refit to three-parameter equation. A two-parameter fit gives A = –12.72 and B = 1720 K for the temperature range 273–293 K.

CO_2 Refit to three- parameter equation from the recommendation of Carroll et al.[1] Two parameter fit gives A = −11.92 and B = 2550 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[3]

Note 4: *Hydrocarbons* Back to Table

CH_4 The recommendation is a three-parameter fit to the smoothed recommendation of Battino.[1] There is very good agreement with the more recent data of Ben-Naim and Battino.[2] A two-parameter fit gives A = –13.45 and B = 2040 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[5]

C_2H_6 The recommendation is a three-parameter fit to the smoothed recommendation of Battino.[1] There is very good agreement with the more recent data of Ben-Naim and Battino.[2] Two parameter fit gives A = –15.95 and B = 2875 K for the temperature range 273−293 K.

C_3H_8 The recommendation is a three-parameter fit to the smoothed recommendation of Battino.[1] There is very good agreement with the more recent data of Ben-Naim and Battino.[2] A two parameter fit gives A = 17.52 and B = 3275 K for the temperature range 273–293 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[5]

***n*-C_4H_{10}** The recommendation is a three-parameter fit to the smoothed recommendation of Battino.[1] There is very good agreement with the more recent data of Ben-Naim and Battino.[2] A two parameter fit gives A = –19.28 and B = 3740 K for the temperature range 273–288 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[5]

$CH_3CH(CH_3)CH_3$

The recommendation is from a three-parameter fit to the smoothed recommendation of Battino.[1] A two-parameter fit gives A = 18.22 and B = 3340 K for the temperature range 278–293 K.

C_2H_4 The recommendation is from a three-parameter fit to the smoothed recommendation of Wilhelm.[6] A two parameter fit gives A = –12.40 and B = 2170 K for the temperature range 288–313 K. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[5]

C_2H_2 Converted from the evaluation of Fogg et al.[4] A two parameter fit gives A = –10.70 and B = 2230 for the temperature range 272–298 K. Previous recommendation was from a three-parameter fit to the recommendation of Wilhelm et al.[6] The recommendation of Yaws et al.[7] generates identical results.

Note 5: *C1 Haloalkanes*

Back to Table

CH_3F A fit to the transformed recommended values of Staudinger and Roberts[6] and Brockbank.[2] The values are very close at lower temperatures, but diverge 16% at 273 K. A two-parameter fit yields: Ln H = −10.08 + 2180/T M atm^{-1}. The previous recommendation, Ln H = −9.48 + 1990/T M atm^{-1} from Staudinger and Roberts,[6] was essentially the same.

CH_3Cl A refit to the recommendation of Brockbank.[2] A two-parameter fit over the temperature range 293 to 318 K results in Ln H = −12.13 + 2942/T M atm^{-1}. The recommendation is slightly lower than the previous recommendations from the reviews of Warneck[7] and Staudinger and Roberts.[6] This probably reflects the more recent study over the temperature range 281–364 K, which deviates somewhat from the earlier studies at the lowest temperature.[4]

CH_3Br A fit to the transformed recommended values of Staudinger and Roberts[6] and Brockbank.[2] The values are very close at lower temperatures, but diverge up to 20% at 303 K. The earlier recommended value was Ln H = −12.16 + 3100/T M atm^{-1} from Staudinger and Roberts.[6]

CH_3I A fit to the transformed recommended values of Staudinger and Roberts[6] and Brockbank.[2] The values are very close at lower temperatures, but diverge 12% at 313 K. A two-parameter fit yields: Ln H = −13.51 + 3550/T M atm^{-1}. The previous recommendation, from Staudinger and Roberts, was essentially the same.

CH_2Cl_2 From the review of Warneck.[7] The review cited previously,[6] gave somewhat different parameters, but a similar value at 298 K. The uncertainties quoted are ±0.78 in A and ±231 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.401 vs. 0.485 M atm^{-1} at 293 K.[4]

CH_2Br_2 A refit to the recommendation of Brockbank.[2] A two-parameter fit over the temperature range 293 to 313 K results in Ln H = −14.50 + 4389/T M atm^{-1}.

$CHCl_3$ From the review of Warneck.[7] The review cited previously,[6] gave somewhat different parameters, but a similar value at 298 K. The uncertainties quoted are ±0.38 in A and ±112 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.313 vs. 0.334 M atm^{-1} at 293 K.[4] A more recent review by Brockbank[2] results in Ln H = −213.32 + 12980/T + 29.53 Ln T M atm^{-1} for the temperature range 273–366 K or Ln H = −13.51 + 3550/T M atm^{-1} for the temperature range 273–323 K, falling about 20% below these other values.

$CHCl_2Br$, $CHClBr_2$, $CHBr_3$, CF_2Cl_2, $CFCl_3$

A refit to the evaluation of Staudinger and Roberts.[6]

CHF_3 Calculated values from the evaluation of Welhelm[8] were combined with results from Zheng et al.,[9] double weighted. The latter study, gas solubilities measured at 278, 308, and 338 K and at NaCl concentrations from 0 to 0.0564 mole/mole (0 to 174‰) with a gas absorption unit. Calculated values for 0‰ NaCl taken at each temperature and fitted to a two-parameter equation.

CHF_2Cl A linear fit to the data of Zheng et al.,[9] Boggs and Buck,[1] and Kutsuna and Hori.[5] The data of Chang and Criddle[3] were significantly lower than these results and not included in the fit. The review by Wilhelm, et al.[8] gave a three-parameter fit that indicated curvature, but this does not appear to be supported by these more recent data.

CF_3Cl, CF_4

A refit to the evaluation of Welhelm et al.[8]

CCl_4 From the review of Warneck[7] and in good agreement with the review cited previously.[6] The uncertainties quoted are ±0.40 in A and ±119 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.040 vs. 0.046 M atm^{-1} at 293 K.[4] A more recent study over the temperature range 281–364 K is also in close agreement, with K_h = 0.040 vs. 0.046 M atm^{-1} at 293 K.[4] A more recent review by Brockbank[2] results in Ln H = −359.12 + 19390/T + 29.53 Ln T M atm^{-1} for the temperature range 273-366 K or Ln H = −16.73 + 4020/T M atm^{-1} for the temperature range 273–323 K, in close agreement.[2]

Note 6: *C2 Haloalkanes*

Back to Table

Chloroethanes

Unless otherwise stated all recommended values are taken from the review of Warneck.[4]

C_2H_5Cl A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 283 to 318 K results in Ln H = −12.21 + 2900/T M atm^{-1}. The results are essentially identical to the previous recommendation taken from Warneck,[4] but cover a wider temperature range, showing slight curvature. The uncertainties quoted by Warneck are ±1.04 and ±305 in B.

1,1-$C_2H_4Cl_2$

A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 283 to 318 K results in Ln H = −15.84 + 4214/T M atm^{-1}. The results are essentially identical to the previous recommendation taken from Warneck, with a slight deviation above 310 K. This probably reflects the more recent study of Chen, et al. over the temperature range 8–91°C. Note that the lowest temperature point of Chen, et al., is above both recommendations.

1,2-$C_2H_4Cl_2$

Recommended values taken from the review of Warneck.[4] The uncertainties quoted are ±0.56 in A and ±165 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 1.33 vs. 1.16 M atm^{-1} at 293 K.[2]

1,1,1-$C_2H_3Cl_3$

Recommended values taken from the review of Warneck.[4] The uncertainties quoted are ±0.32 in A and ±96 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.070 vs. 0.076 M atm^{-1} at 293 K.[2]

1,1,2-$C_2H_3Cl_3$

Recommended values taken from the review of Warneck.[4] The uncertainties quoted are ±0.40 in A and ±118 in B.

1,1,1,2-$C_2H_2Cl_4$

Recommended values taken from the review of Warneck.[4] The uncertainties quoted are ±1.30 in A and ±394 in B.

1,1,2,2-$C_2H_2Cl_4$

Recommended values taken from the review of Warneck.[4] The uncertainties quoted are ±0.94 in A and ±281 in B.

C_2HCl_5 A refit to the recommendation of Brockbank[1] at 293 and 298 K.

1,1,2-$C_2F_3Cl_3$ (CFC-113)

A refit to the evaluation of Staudinger and Roberts.[3]

C_2Cl_6 A refit to the evaluation of Staudinger and Roberts.[3] Warneck[4] did not make a recommendation for this substance.

Chloroethenes

All recommended values are taken from the review of Warneck.[4]

C_2H_3Cl The uncertainties quoted are ±0.66 and ±194 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.048 vs. 0.047 M atm^{-1} at 293 K.[3]

1,1-$C_2H_2Cl_2$

The uncertainties quoted are ±0.61 in A and ±182 in B.

***cis*-1,2-$C_2H_2Cl_2$**

The uncertainties quoted are ±0.34 in A and ±104 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with K_h = 0.313 vs. 0.320 M atm^{-1} at 293 K.[2]

***trans*-1,2-$C_2H_2Cl_2$**

The uncertainties quoted are ±0.28 in A and ±86 in B.

C_2HCl_3 The uncertainties quoted are ±0.40 in A and ±120 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with $K_h = 0.131$ vs. 0.142 M atm^{-1} at 293 K.[2]

C_2Cl_4 The uncertainties quoted are ±0.25 in A and ±74 in B. A more recent study over the temperature range 8–91°C is also in close agreement, with $K_h = 0.080$ vs. 0.081 M atm^{-1} at 293 K.[2]

C_2H_5Br A refit to the recommendation of Brockbank.[1]

1,2-$C_2H_4Br_2$

A refit to the recommendation of Brockbank.[1] The previous value, $\text{Ln } H = -17.97 + 5890/T$ M atm^{-1} ($H_{298} = 3.4$), was a refit to the evaluation of Staudinger and Roberts for T = 283–303 K.[3]

1,1,2,2-$C_2H_2Br_4$

A refit to the recommendation of Brockbank.[1]

Note 8: *Alcohols*

Back to Table

CH_3OH The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants.[4] A two-parameter fit up to 298 K gives A = −13.61 and B = 5640, whereas a two-parameter fit up to 373 K gave A = −12.16 and B = 5215. An evaluation by Warneck[10] for the temperature range 273 to 353 K resulted in recommended parameters of A = −12.45 and B = 5310. The previous recommendation was A = −12.08 and B = 5210, which was based on the two data points of Snider and Dawson.[8] The 298 K result of Butler et al.[3] and a calculation based on the NBS Thermodynamic tables,[9] are in very good agreement. The 298 K result of Altschuh et al.[1] is about 40% lower.

C_2H_5OH The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants.[4] A two-parameter fit up to 298 K gives A = −17.14 and = 6660, whereas a two-parameter fit up to 373 K gave A = −14.57 and B = 5908. An evaluation by Warneck[10] for the temperature range 273 to 353 K resulted in recommended parameters of A = −15.87 and B = 6274. The previous recommendation was A = −16.98 and B = 6630, which was based on the two data points of Snider and Dawson,[8] the 298 K results of Butler, et al.[3] and Rohrschneider,[7] and a calculation based on the NBS Thermodynamic tables,[9] are in very good agreement. The 298 K result of Altschuh, et al.[1] is about 50% lower.

***n*-C_3H_7OH** The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants.[4] A two-parameter fit up to 298 K gives A = −19.80 and B = 7370. The previous recommendation was A = −20.16 and B = 7470, which was based on two data points from Snider and Dawson.[8] Room temperature data from other studies[1-3] support these results.

***iso*-C_3H_7OH, 2-propanol**

The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants.[5] A two-parameter fit up to 298 K gives A = −18.95 and B = 7100. The previous recommendation was A = −20.5 and B = 7450, which was based on the two data points of Snider and Dawson[8] supported by room temperature data from other studies.[1,3]

***n*-C_4H_9OH** The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants.[4] A two-parameter fit up to 298 K gives A = −17.68 and B = 6725. The previous recommendation was A = −19.34 and B = 72.10, which was based on two data points from Snider and Dawson.[8] Room temperature data from other studies[1,2] support these results.

***iso*-C_4H_9OH, 2-methyl-1-propanol**

The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants, over the temperature range 298−372 K.[5] A two-parameter fit up to 298 K gives A = −21.56 and B = 7720. Extrapolated values are in very good agreement with the results of Snider and Dawson[8] at 273 and 298 K and room temperature data from other studies.[3,1] A room temperature value of 22.2 M atm^{-1} from a thermal desorption-GC/MS study is about 40% lower than this recommendation.[6]

***sec*-C_4H_9OH, 2-butanol**

The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants, over the temperature range 298−372 K.[5] A two-parameter fit up to 298 K gives A = −22.60 and B = 7095. Extrapolated values are in very good agreement with the results of Snider and Dawson[8] at 273 and 298 K and room temperature data from Butler et al.[3]

***tert*-C_4H_9OH, 2-methyl-2-propanol**

The recommendation is from a three-parameter fit to the values derived through a comprehensive analysis of limiting activity coefficients, infinite-dilution partial molar excess enthalpies and heat capacities, and measured Henry's law constants, over the temperature range 298−372 K.[5] Extrapolated values are in very good agreement with the results of Snider and Dawson[8] at 273 and 298 K and room temperature data from Butler et al.[3] The two data points of Snider and Dawson yield A = −23.63 and B = 8310.

Note 9: *Diols*

Back to Table

Alkyl diols The vapor pressure of the pure liquid and the activity coefficient of the dilute solution were determined from an analysis of literature data. These were then used to obtain the Henry's law values.[1]

(1) Compernolle, S.; Müller, J. F. Henry's law constants of polyols. *Atmos. Chem. Phys.* **2014**, *14*, 12815-12837, doi:10.5194/acpd-14-13529-2014.

Note 10: *Polyols*

Back to Table

$HOCH_2CH(OH)CH_2OH$, glycerol

The vapor pressure of the pure liquid and the activity coefficient of the dilute solution were determined from an analysis of literature data. These were then used to obtain the Henry's law value.[1]

$HOCH_2(CH(OH))_2CH_2OH$, erythritol

Determined from the solubility, water activity, obtained by a review of the literature, and solid vapor pressure of the polyol.[1]

$C_5H_8(OH)_4$, pentaerythritol

Determined from the solubility, water activity, obtained by a review of the literature, and solid vapor pressure of the polyol.[1]

$C_5H_7(OH)_5$, xylitol, adonitol, arabitol

Determined from the solubility, water activity, obtained by a review of the literature, and solid vapor pressure of the polyols steroisomers.[1] These values, xylitol (4.0×10^{13}), adonitol (4.7×10^{13}), and arabitol (6.8×10^{13}) were averaged to get the value in the Table.

$C_6H_8(OH)_6$, sorbitol, mannitol, glactitol

Determined from the solubility, water activity, obtained by a review of the literature, and solid vapor pressure of the polyols steroisomers.[1] These values, sorbitol (6.7×10^{16}), mannitol (1.8×10^{17}), and glactitol (9.1×10^{16}) were averaged to get the value in the Table.

Note 11: *Ethers* Back to Table

$(C_2H_5)_2O$, diethyl ether

A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 293 to 313 K results in Ln H = −20.91 + 6234/T M atm^{-1}. The previous value, Ln H = −1867 + 5774/T M atm^{-1} (H_{298} = 2.0), was from a refit to the recommendation of Staudinger and Roberts.[2]

Note 12: *Hydroperoxides* Back to Table

CH_3OOH The data of Lind and Kok[1,2] and O'Sullivan et al.[4] are in excellent agreement and were fit to a two-parameter expression. A lower limit value of 700 M atm^{-1} at 281 K was estimated from an uptake study, in agreement with the present recommendation.[3]

$HOCH_2OOH$

The results of O'Sullivan et al.[4] and Staffelbach and Kok[5] are very close and were fit to obtain the recommended values. The results of Zhou and Lee[6] are much lower and were not included.

$CH_3C(O)OOH$ and C_2H_5OOH

Experimental results of O'Sullivan et al.[4]

Note 13: *Aldehydes* Back to Table

HCHO The recommended value is the apparent Henry's law constant and includes a contribution due to hydrolysis $H^* = H(1 + K_{hyd})$. Data from Betterton and Hoffmann[3] and Zhou and Mopper[10] are in substantial agreement and were fit to a two-parameter expression. The more recent results of Allou et al.[1] are in complete agreement. Betterton and Hoffmann have calculated H = 2.5 M atm^{-1} at 298 K for the physical solubility. A gas-stripping study over the temperature range 5–50 C agreed at room temperature, but was lower below and higher above room temperature.[8] Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured H.[10] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M. Additional studies of the effect of NaCl as a function of temperature have been carried out by Allou et al.[1]

CH_3CHO The recommended value is the apparent Henry's law constant and includes a contribution due to hydrolysis $H^* = H(1 + K_{hyd})$. The results of Snider and Dawson,[9] Benkelberg et al.,[2] and Betterton and Hoffmann[3] are in excellent agreement and have been fit to a two-parameter expression for the recommendation. The results of Zhou and Mopper[10] curve off at higher temperatures and were not included in the fit. (Note the similar situation for acetone.) Betterton and Hoffmann[3] have calculated $H = 4.8$ M atm^{-1} at 298 K for the physical solubility. Brockbank[4] recommends $\ln H = -16.761 + 5560/T$ M atm^{-1} over T = 293-318K ($H_{298} = 14.8$ M atm^{-1}). Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured H.[10] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M.

C_2H_5CHO Results of Zhou and Mopper[10] and Snider and Dawson[9] agree only to within about a factor of two. The two points from the former were weighted by 3 and combined with the five points of the latter to generate the recommendation. A room temperature value of 9.26 M atm^{-1} from a thermal desorption-GC/MS study is in good agreement with this recommendation.[7] Brockbank[4] recommends $\ln H = -266.9 + 16740/T + 37.45 \ln(T)$ M atm^{-1} over T = 293-318K ($H_{298} = 13.5$ M atm^{-1}). Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured H.[10] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M.

C_3H_7CHO The results from Zhou and Mopper[10] were fit to a two-parameter expression. A room temperature value of 6.19 M atm^{-1} from a thermal desorption-GC/MS study is about 40% lower than this recommendation.[7] Brockbank[4] recommends $\ln H = -18.1085 + 6060/T$ M atm^{-1} over T = 293−318 K (H(298) = 9.24 M atm^{-1}). Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured H.[10] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M.

$H(CH_3)CHO$, 2-Methyl propanol, isobutyraldehyde

Taken from the recommendation of Brockbank.[4]

$CHOCHO$, glyoxal

Measured using a bubble-column method.[5] Validation measurements on formaldehyde and acetic acid gave results of 4.8×10^3 and 5.0×10^3, slightly higher than the recommendations here. The recommended value is the apparent Henry's law constant and includes a contribution due to hydrolysis $H^* = H(1 + K_{hyd})$. An intrinsic $K_h = 1.90$ M atm^{-1} was calculated at 298 K. The solubility increased by about a factor of three at 0.05 M NaCl, but dropped by ~50% when the concentration was increased to 5 M. Na_2SO_3 concentrations of 0.0003 M to 0.03 M increased the solubility, up to a factor of ~50. Even higher sulfate concentrations led to values too high to measure. An earlier study reported only limiting values of $\geq 3 \times 10^5$.[3]

$HOCH_2CHO$, hydroxyacetaldehyde

Apparent Henry's law measurements by a bubble-column technique at 25 and 45°C.[3] An intrinsic Henry's law constant of 4.1×10^3 M atm^{-1} at 298 K was calculated.

$CH_3C(O)CHO$, methyl glyoxal

Apparent Henry's Law constant measured by a bubble-column technique.[3] An intrinsic Henry's law constant of 1.4 M atm^{-1} at 298 K was calculated.

CH_2CHO, 2-Propenal, acrolein

Taken from the recommendation of Brockbank.[4]

$CH_2C(CH_3)CHO$, methacrolein

Taken from the recommendation of Brockbank.[4] Previous value, $H_{298} = 6.5$ M atm^{-1}, was measured using a static technique with daily instrument calibrations and absolute determinations of partial pressures.[6] An uncertainty of ±0.7 M atm^{-1} was reported.

$CH_3CHCHCHO$, Crotonaldehyde, 2-butenal

A refit to the recommendation of Brockbank.[4] Two-parameter fit over the temperature range 273 to 308 K results in $\ln H = -14.452 + 5505/T$ M atm^{-1}.

Note 14: *Ketones*

Back to Table

$CH_3C(O)CH_3$

The recommendation is from a fit to the data of Snider and Dawson,[10] Benkelberg et al.,[1] Betterton,[2] and Strekowski and George.[11] Room temperature data points of Nozière and Riemer,[8] Hoff et al.,[5] Burnett,[3] and Vitenberg et al.[12] are in very good agreement. Results of Zhou and Mopper[13] are somewhat higher, particularly at room temperature and above. The situation is similar for acetaldehyde. Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured *H*.[13] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M. The K_S values from this work are somewhat different than those obtained by Benkelberg et al.,[1] 0.089 vs 0.17 at 298 K and 0.17 vs 0.085 at 273 K. The magnitude of this difference is not too great, but the two studies predict a different sign for h_T.

$C_2H_5C(O)CH_3$, butanone, methyl ethyl ketone

The recommendation is from the two points of Snider and Dawson.[10] The room temperature points of Vitenberg et al.[12] and Rohrschneider[9] are in good agreement, while a room temperature value of 10.5 M atm^{-1} from a thermal desorption-GC/MS study[7] is about 80% lower. The higher temperature data of Zhou and Mopper[13] are somewhat higher and those of Friant and Suffet[4] are lower than the recommendation. Salt effect parameters derived from data on the effect of seawater concentration (0 to 100%) on the measured *H*.[13] For these calculations, the seawater was assumed to be a solution of pure NaCl, with 35‰ salinity equal to 0.6 M.

$CH_3C(O)C(O)CH_3$, 2,3-butanedione

Measured by a bubble-column technique.[2]

$CH_2CHC(O)CH_3$, methyl vinyl ketone

Measured using a static technique with daily instrument calibrations and absolute determinations of partial pressures.[6] An uncertainty of ±7 M atm^{-1} was reported.

Note 15: *C1 and C2 Organic Acids*

Back to Table

HC(O)OH The results of Johnson et al.[3] are accepted. The 298 K result of Khan et al.[4] is about 75% lower.

$CH_3C(O)OH$

The results of Johnson et al.[3] are accepted. A value calculated from the NBS Thermodynamic tables[6] is about a factor of two higher.

HC(OH)C(O)OH, glycolic acid

Measured using a bubble-column method with no pH control (measured ~3–3.1).[2] Validation measurements on formaldehyde and acetic acid gave results of 4.8 × 10^3 and 5.0 × 10^3, slightly higher than the recommendations in the Table. An intrinsic $K_h = 2.37 \times 10^4$ M atm^{-1} was calculated at 298 K.

$HC(O)C(O)OH$, glyoxylic acid

Measured using a bubble-column method with no pH control (measured ~2.6–2.8).[2] Validation measurements on formaldehyde and acetic acid gave results of 4.8×10^3 and 5.0×10^3, slightly higher than the recommendations in the Table. An intrinsic $K_h = 28.67$ M atm^{-1} was calculated at 298 K.

$HOC(O)C(O)OH$, oxalic acid

Determined from the solubility, water activity, obtained by a review of the literature, and solution vapor pressure of the acid.[1] The first two were obtained by a review of the literature; the vapor pressure was from evaporation measurements on levitated particles.[5]

$CH_3C(O)C(O)OH$, pyruvic acid

Taken from Khan et al.[4] Salt effect derived from effect of NaCl ($k_s = 0.236$ M^{-1}) and KCl ($k_s = 0.235$ M^{-1}) on the partial pressure over 1.5 M solution of pyruvic acid at various salt concentrations. Much different values derived when other salts were used, suggesting complications due to specific interactions and, possibly, to the weakly buffered nature of the solution.

Note 16: *C3 and Higher Organic Acids*

Back to Table

$HOC(O)CH_2C(O)OH$, malonic acid

The solubility and water activity for the acid were obtained through a review of the literature. These were combined with solid vapor pressure[1] or solution vapor pressure[4] data to derive Henry's law values of 0.94×10^{10} and 3.9×10^{10} M atm^{-1}.[2]

$HOC(O)CH_2CH_2C(O)OH$, succinic acid

The solubility and water activity for the acid were obtained through a review of the literature. These were combined with solid vapor pressure[1] or solution vapor pressure[4] data to derive Henry's law values of 2.0×10^9 and 4.2×10^9 M atm^{-1}.[2]

$HOC(O)(CHOH)_2C(O)OH$, tartaric acid

Determined from the solubility, water activity, obtained by a review of the literature, and liquid vapor pressure of the acid.[2] The first two were obtained by a review of the literature; the vapor pressure was obtained from the evaporation rate of levitated, supersaturated liquid particles.[3] The value listed is the midpoint of the range ($0.7–9.3 \times 10^{17}$) from the uncertainty in the vapor pressure data.

$HOC(O)C_3H_6C(O)OH$, glutaric acid

The solubility and water activity for the acid were obtained through a review of the literature. These were combined with solid vapor pressure[1] or solution vapor pressure[4] data to derive Henry's law values of 2.4×10^9 and 5.2×10^9 M atm^{-1}.[2]

$HOC(O)C_4H_8C(O)OH$, adipic acid

Determined from the solubility, water activity, obtained by a review of the literature, and solid vapor pressure of the acid.[2] The first two were obtained by a review of the literature; the vapor pressure was from evaporation rates of aerosol samples.[1]

$(CH_2C(O)OH)_2C(OH)C(O)OH$, citric acid

Determined from the solubility, water activity, obtained by a review of the literature, and liquid vapor pressure of the acid.[2] The first two were obtained by a review of the literature; the vapor pressure was obtained from the evaporation rate of levitated, supersaturated liquid particles.[3] The value listed is the midpoint of the range ($0.2–6 \times 10^{17}$) from the uncertainty in the vapor pressure data.

Note 17: *Formates and Acetates*

Back to Table

$CH_3OC(O)H$ Methyl formate, $C_2H_5OC(O)H$ ethyl formate, n-$C_3H_7OC(O)H$ n-propyl formate

Measured using a column-stripping method.[2]

$CH_3C(O)OCH_3$, methyl acetate

A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 293 to 313 K results in $\text{Ln H} = -16.596 + 5590/T$ M atm^{-1}. The previous value, $\text{Ln H} = -14.745 + 5008/T$ M atm^{-1} ($H_{298} = 4.2$), was a refit to the evaluation of Staudinger and Roberts.[3]

$CH_3C(O)OC_2H_5$, ethyl acetate

A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 293 to 308 K results in $\text{Ln H} = -16.761 + 5560/T$ M atm^{-1}. The previous value, $\text{Ln H} = -17.97 + 5890/T$ M atm^{-1} ($H_{298} = 3.4$), was from a study utilizing a column-stripping method over temperature range 272−298 K.[2]

$CH_3C(O)C_3H_8$, n-propyl Acetate.

A refit to the recommendation of Brockbank.[1] A two-parameter fit over the temperature range 293 to 308 K results in $\text{Ln H} = -18.418 + 5970/T$ M atm^{-1}.

Note 18: *Carbonates* Back to Table

$(CH_3O)_2CO$, dimethyl carbonate; $(C_2H_5O)_2CO$, diethyl carbonate; $CH_2CHOC(O)CH_3$,, vinyl acetate; $CH_2C(CH_3)C(O)OCH_3$, methyl methacrylate

Infinite dilution activity coefficients were determined and combined with vapor pressure values to yield Henry's law constants. These were presented as a three-parameter equation. The values showed only slight curvature and are given here as fit to a two-parameter equation.[1]

Note 19: *Peroxyacyl Species* Back to Table

$CH_3C(O)O_2$, peroxyacetyl radical

Villalta et al.[1] measured an upper limit for H of 0.2 M atm^{-1} in a coated-wall flow tube uptake experiment on aqueous sodium ascorbate solutions.

(1) Villalta, P. W.; Lovejoy, E. R.; Hanson, D. R. Reaction probability of peroxyacetyl radical on aqueous surfaces. *Geophys. Res. Lett.* **1996**, *23*, 1765-1768, doi:10.1029/96GL01286.

Note 20: *Amines* Back to Table

Aliphatic amines

Water-saturated air was bubbled through a 0.01 N NaOH solutions containing the amines and the amine removed from the air stream by passing through a 0.01 N HCl solution. The concentration of the uncharged amine in the original solution was adjusted for the percentage of ionized amine.[1]

CH_3NCl_2 Determined by using a static method with a variable headspace and measuring the dichloromethylamine concentration in the liquid phase by UV spectroscopy.[2]

$(CH_3)_2NNO$ N-nitrosodimethylamine

Determined from the rate of loss of ^{14}C labeled NDMA from a stirred aqueous solution.[3]

Note 22: *Cyano compounds* Back to Table

HCN Determined in a 0.1 mol L^{-1} sodium phosphate buffer (pH = 9.00 ± 0.03) by air equilibrium of aqueous cyanide partitioned by a microporous membrane. The error limits were estimated to be ±1.44 on A and ±342 on B.[3]

CH_3CN The values reported by Benkelberg et al.,[1] Snider and Dawson,[4] Hamm et al.[2] are all in good agreement and have been fit to a two-parameter expression for the recommendation. The Hamm et al.[2] paper includes a measurement with artificial seawater at 293 K. Salt effect derived from the effect of 0.6 mol L^{-1} NaCl on solubility at 293 K.[1]

Note 23: *Nitro compounds* Back to Table

Nitroalkanes (CH_3NO_2, $C_2H_5NO_2$, $C_3H_7NO_2$, and $CH_3CH(NO_2)CH_3$)

The recommended values are all taken from the work of Benes and Dohnal.[1] For nitromethane, the 298 K value from Rohrschneider[9] is about 30% higher.

Alkyl nitrates (CH_3ONO_2, $C_2H_5ONO_2$, 1-$C_3H_7ONO_2$, 2-$C_3H_7ONO_2$, 1-$C_4H_9ONO_2$, 2-$C_4H_9ONO_2$)

The recommended values are all taken from the work of Kames and Schurath.[7] The results of Luke et al.[8] are in very good agreement for 1-butyl and 2- butyl nitrates, but the values reported by Hauff[4] for 1- and 2-propyl and butyl nitrates by head-space chromatography are significantly (~50%) lower.

$CH_3C(O)O_2NO_2$ (PAN)

The results of Kames and Schurath[7] and Frenzel et al.[3] are close and were used for the recommendation. They are somewhat higher (~60%) than the single temperature point of Holdren et al.[5] Kames and Schurath[7] and Holdren et al.[5] also measured hydrolysis rate constants. $K_s = 0.0807\ M^{-1}$ for NaCl at 293.2 K based on solubility in artificial sea water (~0.7 M).[7]

Bifunctional alkyl nitrates ($ONO_2C_2H_4ONO_2$, $HOC_2H_4ONO_2$, $HOCH_2CH(ONO_2)CH_3$, $CH_3CH(OH)CH_2ONO_2$, $CH_3C(O)CH_2ONO_2$)

The recommended values (at 293 K) are taken from the work of Kames and Schurath.[6]

$CH_3CH(ONO_2)CH_2ONO_2$, 1,2-propane dinitrate

Direct measurement at 293 K.[6] A much lower value of 33 $atm^{-1}\ L^{-1}$ mol was calculated from vapor pressure and solubility measurements.[2]

$O_2NO_2CH_2CH_2CH_2ONO_2$, 1,3-propane dinitrate

Calculated from vapor pressure and solubility measurements.[2] Note that the value for 1,2-propane dinitrate was much lower than that directly measured.

CCl_3NO_2, chloromethylnitrate (chloropicrin)

Measured by a stripping technique in water, 0.1 M and 0.2 M NaCl, and at pH 4.0 and 8.0 (buffered). All values were within the stated margin of error (±0.3).[10]

Note 26: *Haloaldehydes*

Back to Table

CCl_3CHO 1,1,1-trichloroacetaldehyde (chloral). Apparent Henry's law constant measured by head-space analysis.[1] An intrinsic Henry's law constant of 14 mol L^{-1} atm^{-1} at 25°C was derived. Listed parameters from a refit to the data.

(1) Betterton, E. A.; Hoffmann, M. R. Henry's law constants of some environmentally important aldehydes. *Environ. Sci. Technol.* **1988**, *22*, 1415-1418, doi:10.1021/es00177a004.

Note 27: *Haloacids*

Back to Table

$CFH_2C(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.15 mol kg^{-1} HBr to suppress dissociation. Reported values corrected for the effect on the activity of the solution.[1] Due to high toxicity, only a single determination was made for this acid.

$CF_2HC(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.15 to 6.0 mol kg^{-1} HBr to suppress dissociation.[1] Reported values corrected for the effect on the activity of the solution.

$CF_3C(O)OH$, trifluoroacetic acid

Values derived at 178, 288, and 298 K from the simultaneous measurement of the equilibrium partial pressures of TFA over aqueous solutions and the concentration of undissociated TFA in solution using total reflection IR spectroscopy.[2] The previous recommended value from the equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing HBr to suppress dissociation, assuming a pK_a value of 0.47 at 298 K.[1] The results of Kutsuna and Hori suggest a pK_a value of 0.2. It has been pointed out that are large discrepancies in reported pK_a values for TFA, which are not fully understood.[3]

$CClH_2C(O)OH$ and $CCl_2HC(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.15 to 6.0 mol kg^{-1} HBr to suppress dissociation. Reported values corrected for the effect on the activity of the solution.[1]

$CCl_3C(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.25 to 6.0 mol kg^{-1} HBr to suppress dissociation. Reported values corrected for the effect on the activity of the solution.[1]

$CClF_2C(O)OH$, $CH_2BrC(O)OH$, and $CHBr_2C(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.15 to 6.0 mol kg^{-1} HBr to suppress dissociation. Reported values corrected for the effect on the activity of the solution.[1]

$CBr_3C(O)OH$

Equilibrium partial pressure of the acid obtained using a stripping technique over a solution containing 0.15 to 6.0 mol kg^{-1} HBr to suppress dissociation. Reported values corrected for the effect on the activity of the solution.[1] Only a few measurements at 308 K and one at 298 K were made. The reported value of B is the mean of those for $CF_3C(O)OOH$ and $CCl_3C(O)OOH$.[1]

Note 28: *Haloacetates*

Back to Table

$CF_3C(O)OCH_3$, methyl trifluoroacetate

Parameters derived from a linear fit to the reported data from a column-stripping study. A hydrolysis rate constant of $10^{5.3\pm2.0}\exp[-(5.07 \pm 1.27) \times 10^3/T$ s^{-1} was also obtained.[2]

$CF_3CH_2OC(O)H$, 2,2,2-trifluoroethyl acetate

Value measured using a column-stripping method.[1]

$CH_3C(O)OCH_2CF_3$, 2,2,2-trifluoroethyl acetate

Parameters derived from a linear fit to the reported data from a column-stripping study. The hydrolysis rate constant was too slow to measure.[2]

$C_2H_5OC(O)CF_3$, ethyl trifluoroacetate

Value measured using a column-stripping method[1]

(1) Kutsuna, S.; Chen, L.; Abe, T.; Mizukado, J.; Uchimaru, T.; Tokuhashi, K.; Sekiya, A. Henry's Law constant of 2,2,2-trifluoroethyl formate, ethyl trifluoroacetate, and non-fluroinated analogous esters. *Atmos. Environ.* **2005**, *39*, 5884-5892, doi:10.1016/j.atmosenv.2005.06.021.

Note 29: *Halogens*

Back to Table

Cl From the reduction potential $E^o(Cl/Cl^-) = (2.43 \pm 0.03)$ V, together with the Gibbs energy for the anion and the gas-phase atom. The potential was derived from an analysis of the reaction of OH with Cl^-, yielding the equilibrium constant for $OH + Cl^- + H^+ \leftrightarrow H_2O + Cl$ ($K_{eq} = 1.1 \times 10^5$ M^{-2}, corrected to a standard state of water at unit activity),[8] and the reduction potential $E^o(OH^-,H^+/H_2O) = (2.73 \pm 0.02)$ V.[7]

Cl_2 Three-parameter refit to the recommendation of Battino.[3] Two parameter fit gives A = 9.38 and B = 2090 K for the temperature range 283–313 K. A more recent study in which the chlorine solubility was determined by measuring the total molecular chlorine concentration in contact with pure chlorine gas resulted in values of 0.11 mol L^{-1} atm^{-1} at 10°C, 0.074 at 20°C, and 0.052 at 30°C.[1]

Br_2 The results of Kelley and Tartar[6] and Jenkins and King[5] agree well below about 313 K, and with the 298 K point of Hill et al.[4] Recommendation based on a two-parameter fit to all data at and below 308 K.

BrCl The recommendation is from the work of Barlett and Margerum.[2]

Note 30: *Inorganic Halogen Species*

Back to Table

ClO From the reduction potential $E(ClO/ClO^-) = (1.41 \pm 0.02)V$, which is based on an equilibrium with carbonate at high pH and ionic strength.[5] This was combined with the Gibbs energy of the anion and the gas-phase radical to obtain the free energy of solution. Due to the high ionic strength, 3 M, it was not possible to correct the potential value and obtain a reduction potential for the standard state. Thus, the derived Henry's law constant must be considered uncertain.

Cl_2O Fit to recommendation of Wilhelm et al.[7] Data appear somewhat uncertain.

ClO_2 Two-parameter fit to the recommendation of Battino.[1]

HOCl Huthwelker et al.[6] analyzed the limited data for pure water from Blatchley et al.,[2] Holzwarth et al.,[4] and the more extensive data for uptake by sulfuric acid from Hanson and Ravishankara,[3] along with thermodynamic information, and obtained a consistent expression for the solubility of HOCl.

HOBr The Henry's law constant was estimated to be more than twice that of HOCl based on a study of the effective Henry's law constant for free bromine from a stripping column.[2]

Back to Table

SO_2 The recommendation of Battino[1] was accepted and refit to a three-parameter equation. The earlier recommendation of Edwards et al.[3] is slightly lower. A two-parameter fit gives A = –9.53 and B = 2930 K for the temperature range 278–298 K. New value of $h_{SO2,0}$ from absorption equilibria studies in aqueous HCl and NaCl solutions.[8] Temperature dependence, h_T, from the optimization of Weisenberger and Schumpe.[10]

H_2S In the recommendation of Fogg,[5] two expressions were given, representing the results above and below 283 K. The predicted values from these expressions were calculated, with the points at 283 K averaged, converted to the desired units, and then fit with the two- and three-parameter expressions. These are the recommended values. More recent results of Rinker and Sandall[7] and Munder et al.[6] are slightly lower; in these studies, the physical solubility of H_2S was determined through measurements involving aqueous solutions of glycols or amines, neutralized with HCl. The reported values of De Bruyn et al.[2] are significantly (~30%) lower. The earlier recommendation of Edwards et al.[3] is very close to the recommendation of Fogg[5] as is the recommendation of Yaws et al.[12] The room temperature point calculated from the NBS Thermodynamic tables Wagman et al.[9] is also slightly lower. The work of De Bruyn et al.[2] covered also a wide range of NaCl and $(NH_4)_2SO_4$ concentration and of pH. Salt effect parameters taken from the optimization of Weisenberger and Schumpe.[10]

CS_2 The recommendation is from a fit to data of Elliott,[4] who also present data in 0.5 mol L^{-1} NaCl. The results of De Bruyn et al.[2] are significantly (50%) lower. The work of De Bruyn et al.[2] covered also a wide range of NaCl and $(NH_4)_2SO_4$ concentration and of pH. Salt effect parameters derived from the ratio of the solubility of CS_2 in water and 0.5 M NaCl.[1] At 278 K, $k_s = 0.184\ M^{-1}$, compared to 0.150 M^{-1} from the results of De Bruyn, et al. Note also De Bruyn, et al.[2] obtained $K_s = 0.410\ M^{-1}$ for $(NH_4)_2SO_4$, whereas these parameters would predict 0.261 M^{-1}.

COS The reviews by Wilhelm et al.[11] and Yaws et al[12] result in identical values over the low temperature range (<303 K) and are combined to generate the recommendation. The results of De Bruyn et al[2] are somewhat (~25%) lower at the lower temperature range. The work of De Bruyn et al[2] covered also a wide range of NaCl and $(NH_4)_2SO_4$ concentration and of pH.

Note 32: *Organic Sulfur Species*

Back to Table

CH_3SH The recommendation is based on the data of Przyjazny et al.[4] Results of De Bruyn et al.[3] are about half the recommended value at 298 K. The work of De Bruyn et al.[3] covered a wide range of pH and NaCl and $(NH_4)_2SO_4$ concentrations. At 298 K, they obtained $K_s = 0.314\ M^{-1}$ for $(NH_4)_2SO_4$ and $K_s = 0.143\ M^{-1}$ for NaCl. From the latter, we calculate $h_G = 0.003\ M^{-1}$; the values for $(NH_4)_2SO_4$ from this work have tended to be high.

C_2H_5SH The recommendation is based on the data of Przyjazny et al.[4] The results of Vitenberg[6] are slightly lower than the extrapolated value at 293 K.

CH_3SCH_3 The recommendation is based on the values of Dacey et al.[2] The single temperature point of Wong and Wang[8] and the higher temperature results of Przyjazny et al.[4] are in good agreement. The results of De Bruyn et al.[3] are about 30% lower. A more recent value of 0.47 M atm^{-1} at 298 K, in good agreement with the value recommended here, was obtained by a dynamic gas stripping approach coupled to a mass spectrometer.[5] The studies of Dacey et al.[2] and Wong and Wang[8] were also carried out with seawater. The work of De Bruyn et al.[3] covered also a wide range of NaCl and $(NH_4)_2SO_4$ concentration and of pH. Salt effect parameters based on the values of Dacey et al.[2] for Sargasso sea water from 0 to 29 C. The values for K_H obtained by Wong and Wang[8] for sea water from 18 to 44 C are in good agreement. Dacey et al.[2] also measured K_H at 18 C for NaCl solutions up to 32%. For the 10–32% data, a value of $K_s = 0.117$ M^{-1} can be derived, in good agreement with the predicted value of 0.113 M^{-1}. The 278 K value of $K_s = 0.180\ M^{-1}$ obtained by De Bruyn et al.[3] is somewhat larger. Note also the De Bruyn, et al.[3] obtained $K_s = 0.332\ M^{-1}$ for $(NH_4)_2SO_4$, whereas these values would predict 0.223.

$CH_3SC_2H_5$, $C_2H_5SC_2H_5$, $CH_2CHCH_2SCH_3$, higher alkyl sulfides

Obtained by a dynamic gas stripping approach coupled to a mass spectrometer.[5] An uncertainty of ±0.03 M atm^{-1} was estimated for $CH_3SC_2H_5$, of ±0.01 M atm^{-1} for $C_2H_5SC_2H_5$, and ±0.02 M atm^{-1} for $CH_2CHCH_2SCH_3$.

$CH_3S(O)CH_3$

The recommendation is from Watts and Brimblecombe[7] cited by Allen et al.[1]

CH_3NCS, methyl isothiocyanate

Measured by stripping technique in pure water.[9] Measurements in NaCl and buffer solutions tended to be lower (0.1 M NaCl, 9 M atm^{-1}; 0.2 M, 7 M atm^{-1}).

CH_3SSCH_3 and $C_2H_5SSC_2H_5$

Obtained by a dynamic gas stripping approach coupled to a mass spectrometer.[5] An uncertainty of ±0.04 M atm^{-1} was estimated for CH_3SSCH_3 and ±0.03 M atm^{-1} for $C_2H_5SSC_2H_5$.

Cr^{3+}	0.0648		SO_3^{2-}	0.127
Fe^{3+}	0.1161		SO_4^{2-}	0.1117
La^{3+}	0.2297		$S_2O_3^{2-}$	0.1149
Ce^{3+}	0.2406		PO_4^{3-}	0.2119
Th^{4+}	0.2709		$Fe(CN)_6^{4-}$	0.3574

The values in this table can be used to estimate the solubility of a gas in various mixed electrolyte solutions, even if these data have not been obtained experimentally for all of the ions. For example, the solubility of ozone in a solution of 0.8 M HCl and 1.2 M Na_2SO_4 at 273 K would be estimated as follows:

First, $H^o = 0.024$ M atm^{-1} at 273 K, from the Henry's Law Table; from the same Table, the gas-specific parameters for ozone are $h_{G,o} = 0.00396$ M^{-1} and $h_T = 1.79 \times 10^{-3}$ M^{-1} K^{-1}, thus:

$$k_G = 0.00396 + 1.79 \times 10^{-3} \times (273 - 298) = -0.0408 \text{ M}^{-1}$$

The specific ion parameters from Table 5-4 are corrected by this value to calculate the change in the logarithm of the Henry's law constant

$\log (H^o/H^{273}) = 2 \times 1.2 \text{ M} \times (0.1143 - 0.0408) \text{ M}^{-1} + 1.2 \text{ M} \times (0.1117 - 0.0408) \text{ M}^{-1} +$

$0.8 \text{ M} \times (0 - 0.0408) \text{ M}^{-1} + 0.8 \text{ M} \times (0.0318 - 0.0408) \text{ M}^{-1} = 0.181$

Thus, $(H^o/H^{273}) = 1.517$

$H = 0.024 \text{ M atm}^{-1}/1.517 = 0.016 \text{ M atm}^{-1}$ for O_3 in this salt solution at 273 K.

5.7 Table 5-6. Henry's Law Constants for Acids

	T(K)	Wt.% H_2SO_4	H or H* (M/atm)	Notes
O_3 in $H_2SO_4\bullet nH_2O(l)$	293	1–70	$\ln(H_o/H) = (4.08 \pm 0.2) \times 10^{-3} \times wt$ $H_o = 0.012$ M atm^{-1} wt is the H_2SO_4 wt%	1
NO_2 in $H_2SO\bullet nH_2O(l)$	203–343	39–68	See Note	2
HONO in $H_2SO_4\bullet nH_2O(l)$	248–298	>60	$\ln H^* = a_1 + a_2\,wt + a_3\,wt^2 + (b_1 + b_2\,wt)/T$ $a_1 = 26.1 \pm 9.4$, $a_2 = -1.095 \pm 0.21$, $a_3 = 0.00732 \pm 0.00121$ $b_1 = -5792 \pm 1610$, $b_2 = 181.3 \pm 24$	3

$CH_3C(O)O_2NO_2$ in $H_2O(l)$, $H_2SO_4\bullet nH_2O(l)$	199–295	0–75	$\ln H^* = 1.07 - mH_2SO_4 \times (0.69 - 152/T) - 5810 \times (1/T_o - 1/T)$, mH_2SO_4 = molality of the H_2SO_4 solution $T_o = 298.15$ K	11
CF_2O in $H_2SO_4\bullet nH_2O(l)$	215–230	60	<5	12
CF_3OH in $H_2SO_4\bullet nH_2O(l)$	250	40 50	>240 210	13
HOCl in $H_2SO_4\bullet nH_2O(l)$	200–300	46–80	$H_{HOCl} = 1.91\times10^{-6} \times \exp(5862.4/T) \times \exp(-S_{HOCl}\,M_{H2SO4})$ M atm^{-1} where: $S_{HOCl} = 0.0776 + 59.18/T$ M^{-1}, M_{H2SO4} = H_2SO_4 molar conc.	14
$ClONO_2$ in $H_2SO_4\bullet nH_2O(l)$	200–265	40–75	$H_{ClONO2} = 1.6 \times10^{-6} \times \exp(4710/T) \times \exp(-S_{HOCl}M_{H2SO4})$ M atm^{-1} where: $S_{ClONO2} = 0.306 + 24.0/T$ M^{-1}, M_{H2SO4} = H_2SO_4 molar conc.	15
HBr in $H_2SO_4\bullet nH_2O\bullet H_2O(l)$ and $H_2SO_4\bullet nHNO_3\bullet mH_2O(l)$	200–240	40–72	$\ln H^* = a_1 + (b_1 + b_2\,wt)/T$ $a_1 = -11.695 \pm 0.537$, $b_1 = 11{,}101 \pm 163$, $b_2 = -90.7 \pm 1.2$	16
HOBr in $H_2SO_4\bullet nH_2O(l)$	201–252	45–252	See Note	17
SO_2 in $H_2O(l)$, $H_2SO_4\bullet nH_2O(l)$	193–242	0–97	$\ln H^* = a_1 + a_2\,wt + a_3\,wt^2 + (b_1 + b_2\,wt + b_3\,wt^2)/T$, where: wt is the H_2SO_4 wt%, $a_1 = -10.778 \pm 2.07$, $a_2 = -0.11541 \pm 0.0827$, $a_3 = 0.0012506 \pm 0.000811$ $b_1 = 3310 \pm 578$, $b_2 = 30.581 \pm 22.2$, $b_3 = -0.35469 \pm 0.209$	18

5.7.1 Notes for Table 5-6

1. **O_3 in H_2SO_4•nH_2O(l).** Bubble train uptake measurements where performed by Rattigan et al.[1] at 293 K for 1–70 wt% H_2SO_4. Recommended expression is a Sechenov coefficient formulation where $H_o = 0.012$ M atm^{-1} is the 293 K value of H for pure water from Wilhelm et al.[2] In the measurement, account was taken of the loss of O_3 due to reaction with H^+.

2. **NO_2 in H_2SO_4•nH_2O(l).** Langenberg et al.[1] present novel capillary gas chromatography measurements for 39, 59, and 68 wt% H_2SO_4 over the temperature range of 203 to 243 K. However, NO_2 solubility must be derived from chromatographic waveforms, which are contorted by much higher N_2O_4 solubility. The resulting values for H_{NO2} are in the 1 to 10^2 range, but show inconsistent trends with temperature and concentration, indicating possibly large systematic error.

3. **HONO in H_2SO_4•nH_2O(l).** Becker et al.[1] measured HONO partial pressure, P_{HONO}, over bulk solutions in a temperature range of 248–298 K and a H_2SO_4 concentration range of 0–67 wt%. Longfellow et al.[2] measured P_{HONO} in a wetted wall flow reactor over a temperature range of 218–295 K and an acid concentration range of 60–83 wt%. Agreement between these two data sets is excellent. H* decreases from 0 wt% to 53 wt% due to physical solubility, then increases above 53 wt% due to protonation and/or association with H_2SO_4 to make nitrosyl sulfuric acid. Becker et al. parameterized their data as a function of sulfuric acid wt% and temperature. However, the Becker et al. parameterization is not able to fit the combined sets of Becker et al.[1] and Longfellow et al.[2] data, particularly at the lower temperatures and higher wt% most relevant to the stratosphere. Therefore, the recommended functional form was used to fit the data for >60 wt%. This function fits both sets of data very well. It is important to note that this function is only valid for H_2SO_4 concentrations near 60 wt% and above. The parameterization in Becker et al.[1] should be used to calculate H for H_2SO_4 concentrations <60 wt%. (Note that the units for H are mol/kg-bar in Becker et al.[1] The density parameterization of Myhre et al.[3] was used to convert to M/atm units.)

4. **HNO_3 and HCl in H_2SO_4•nH_2O(l) and H_2SO_4•nHNO_3•mH_2O(l).** Effective Henry's law coefficients, H^*, for HNO_3, and HCl in binary H_2SO_4/H_2O and ternary $H_2SO_4/HNO_3/H_2O$ solutions over the temperature range 195 to 300 K are required to model the composition and heterogeneous chemistry of stratospheric and upper tropospheric aerosols. Solubility data can be obtained from analysis of heterogeneous uptake experiments with the liquid phase diffusion coefficient estimated from acid solution viscosity (Williams and Long[15]). Solubilities can also be obtained from equilibrium or from vapor pressure data.

   Experimental solubility data for HNO_3 is provided by Van Doren et al.,[12] Reihs et al.,[9] and Zhang et al.[16] Data for HCl solubility is provided by Watson et al.,[13] Hanson and Ravishankara,[5,6] Zhang et al.,[16] Williams and Golden,[14] Abbatt,[1] Elrod et al.,[4] and Robinson et al.[10]

These studies all show that trace species solubility in H_2SO_4/H_2O and $H_2SO_4/HNO_3/H_2O$ solutions is a strong function of water activity, which, in turn, depends on both temperature and acid concentrations. Prediction of HNO_3 and HCl H^* values for atmospheric compositions requires a sophisticated model. Comprehensive thermodynamic models of acid solutions for a range of atmospheric conditions have been published by Carslaw et al.,[2] Tabazadeh et al.,[11] and Luo et al.[7] and reviewed by Carslaw et al.[3] These models do an excellent job of reproducing the available experimental data, even for ternary $H_2SO_4/HNO_3/H_2O$ solutions (Elrod et al.[4]). These models and the Carslaw et al.[3] review should be consulted for plots/predictions of H^* for HNO_3 and HCl in strong acid solutions over the atmospheric temperature range. The most widely used model of Carslaw et al.[2] was revised in Massucci et al.[8]

5. **HO_2NO_2 in H_2SO_4•nH_2O(l).** Zhang et al.[3] performed wetted wall flow reactor studies using CIMS to detect HO_2NO_2 uptake over a temperature range of 201–230 K and an acid concentration range of 52.9–74 wt% H_2SO_4. $HD_l^{1/2}$ values where determined for 52.9, 58.3/59.1, 66.4 and 73.8/74 wt%, with 5 to 15 data points per temperature or temperature pair. All uptake appeared to be reversible with the variation in H strongly

temperature dependent, but only moderately dependent on H_2SO_4 wt%. D_l values were calculated from a cubic cell model to derive H. Uncertainties in measured H values were estimated by authors to be 25% for H <1 × 10^6 M atm^{-1} and 50% for H >1 × 10^6 M atm^{-1}. These data were parameterized by Leu and Zhang [2] in the Sechenov coefficient form adopted by Huthwelker et al.[1] for HOCl, and their formulation is recommended.

6. CH_2O in H_2SO_4•$mHNO_3$•nH_2O(l). The recommended Henry's Law relationship is:

$$H^* = H(1 + K_2 a_{H_2O} + K_3 a_{H^+})$$

where: H = 3.4 × 10^{-5} exp –[(–0.0456 + 55.5/T) (0.46 $m_{H_2SO_4}$ + 0.13 m_{HNO_3})] M atm^{-1}, T is the temperature in K, and $m_{H_2SO_4}$ and m_{HNO_3} are the respective acid molalities; K_2 = exp (4020/T–5.83) M^{-1}, K_3 = 0.56 exp [8.84–(T–260/T)] M^{-1}, and a_{H_2O} and a_{H+} are the water and H^+ activities which are obtained from a thermodynamic model of the solution, e.g. Carslaw et al.[1] Valid for 10–85 wt% H_2SO_4, 8–40 wt% HNO_3, T = 240–300 K.

Knudsen cell studies by Tolbert et al.[4] and Iraci and Tolbert[2] and droplet train/flow reactor studies by Jayne et al.[3] all yield data showing that CH_2O is strongly absorbed by sulfuric acid solutions, and Jayne et al. also provide data for ternary acid solutions. The Jayne et al.[3] study included H_2SO_4 concentrations from 10 to 85 wt% and HNO_3 concentration between 8 and 40 wt% with temperature variations from 241 to 300 K. These data were parameterized with three terms, representing physical CH_2O solubility, reversible hydrolysis to $CH_2(OH)_2$, important in more dilute solutions, and reversible formation of CH_3O^+, dominant at high acidities. The Jayne et al.[3] parameterization is recommended above. The H* data from Iraci and Tolbert[2] cover 49 to 95 wt% H_2SO_4 and a temperature range of 197 to 214.5 K and are in fair agreement with extrapolation of H* expression from Jayne et al.[3] for concentrations below ~75 wt%. However, the Iraci and Tolbert data are taken on such thin acid films that initial uptake slopes are difficult to determine accurately and the data scatter is large. While the Iraci and Tolbert data do indicate significantly larger H* values for H_2SO_4 concentrations above 75 wt%, the data do not compel a reformulation of the Jayne et al. parameterization.

7. CH_3OH in H_2SO_4•nH_2O(l). H* data from Kane and Leu,[3] taken over 40–85 wt% H_2SO_4 and from 210–235 K, indicate soluble uptake below 65 wt% and predominately reactive uptake to form methanesulfonic acid and dimethysulfate above 65 wt%. Uptake decreased slightly with temperature below 65 wt% and increases slightly with temperature above. Data yield $H^*k^{1/2}$ at high acid concentrations. Weakly temperature dependent γs of ~0.15 were measured for 65, 75, and 80 wt%. However, Knudsen cell studies by Iraci et al.[1] at 45, 61 and 72 wt% over a 197–223 K temperature range show only well behaved reversible uptake. They argue that low vapor pressures explain the lack of CH_3OH recovery for the short observation times used by Kane and Leu. They also cite three older literature studies on the reaction of methanol and ethanol at room temperature in sulfuric acid which report reaction rate constants much lower than those deduced by Kane and Leu.[1] Iraci et al. present the following parameterization of their data plus data for water:

$$\log H^* = A + 1000B/T$$

where $A = 7.00 + \log M_{H2O}$, $B = 0.000619\ m^2 + 0.00544\ m + 2.267$, M_{H2O} is the molarity of water in the solution (mol L^{-1}) and m is the molality of the H_2SO_4 (moles H_2SO_4 per kg H_2O).

Note that this parameterization is based only on the Iraci et al. data. A reanalysis of the Kane and Leu[3] results to provide additional data in the 40–72 wt% range, and H^* values for higher wt% should be undertaken to validate and extend the Iraci et al. data.

Iraci et al.[2] used infrared spectroscopy to monitor the production of gas phase methyl nitrate, CH_3ONO_2, from the bulk reaction of ternary sulfuric acid/nitric acid/water solutions with 0.00005–0.005 M CH_3OH in 50.5 to 63.6 wt% H_2SO_4 with 0.03–0.21 M HNO_3 between 278.2 and 328.6 K. This reaction may complicate determinations of Henry's law solubility of methanol in ternary acid solutions when sulfuric acid concentrations are high enough (probably >70 wt%) to produce high levels of NO_2^+, the assumed nitrating agent.

8. **CH_3CH_2OH in H_2SO_4•nH_2O (l).** Michelsen et al.[1] reported Knudsen cell ethanol uptake experiments for 36–76 wt% H_2SO_4 over a 209–237 K temperature range as well as equilibrium ethanol vapor pressure measurements for 0.5 M ethanol in 59.1 wt% acid between 214.3 and 230.8 K and 0.1 M ethanol in 38.5 wt% acid between 214.0 and 223.9 K. Henry's law solubility parameters from the two methods agreed well. Solubility increased dramatically with increasing acid wt% and decreasing temperature. Michelsen et al. present the following parameterization of their data:

$$\log H^* = A + 1000B/T$$

where $A = \Delta S^o/2.303R + \log M_{H2O}$, $B = 5.319\ (\chi_{acid})^2 + 0.812\ (\chi_{acid}) + 2.647$, and ΔS^o is –174 J mol^{-1} K^{-1}, M_{H2O} is the molarity of water in the solution calculated at 220K (mol L^{-1}) and χ_{acid} is the mole fraction of sulfuric acid in the solution. Representative values of these parameters are presented in Table 2 of Michelsen et al.[1] Williams et al.[3] performed Knudsen cell H* measurements on the effect of 0.1M acetone on the uptake of ethanol by 38.4 wt% H_2SO_4 at 219.1 K yielding $H^* = (2.2 \pm 0.1) \times 10^5$ M atm^{-1} in good agreement with values without added acetone reported by Michelsen et al.[1] and Timonen and Leu;[2] indicating no effect of added acetone.

Timonen and Leu[2] calculated H* values from their uptake coefficients on 41.1 wt% H_2SO_4 that are in moderate agreement with the Michelsen et al. parameterization.

9. **CH_3CHO in H_2SO_4•nH_2O(l).** Michelsen et al.[1] reported Knudsen cell acetaldehyde uptake experiments for 39–76 wt% H_2SO_4 over a 211–241 K temperature range. Tabulated H* values for 37 experiments covering four acid concentrations ranged from 2×10^2 to 1.5×10^5 M atm^{-1}; with highest values at highest acid concentration and lowest temperatures. Data for the highest acid concentrations (~76 wt% H_2SO_4) generally

indicated simple solubility behavior, while some measurements at lower acid concentrations (39–66 wt%) showed indications of reactive uptake.

Williams et al.[2] performed Knudsen cell H* measurements on the effect of 0.1M ethanol or acetone on the uptake of acetaldehyde, reproducing a few temperatures and acid concentrations used for the data reported in Michelsen et al.[1] The solubility of acetaldehyde in acid with 0.1 M ethanol or 0.1 M acetone was nearly an order of magnitude higher than the corresponding organic free measurements. Two measurements at 216.1 and 226.8 K with 0.0016 M formaldehyde added to 38.5 wt% H_2SO_4 showed no H* enhancement over organic free measurements but time resolved uptake measurements showed evidence for enhanced reactive uptake.

10. **$CH_3C(O)CH_3$ in H_2SO_4•$nH_2O(l)$.** Duncan et al.[2,3] used IR spectra of thin sulfuric acid films to establish that acetone is absorbed as the protonated species. Above 70 wt% protonated acetone undergoes a self-condensation/dehydration reaction to form protonated mesityl oxide, which, in turn, reacts with an additional protonated acetone to form trimethyl benzene. Duncan et al.[3] measured reversible uptake and derived Henry's law constants for 70 wt% H_2SO_4 at 180, 187 and 195 K and a value at 201 K for 76 wt%. Kane et al.[6] measured uptake in a wetted wall flow reactor and derived H* parameters for 40, 50, 65, and 75 wt% over a much wider temperature range than Duncan et al.[3] Their data diverge above 80 wt% which they attribute to reactive uptake as suggested by Duncan et al.[2,3] Klassen et al.[7] provide Knudsen cell uptake derived data for 48.7 to 78.3 H_2SO_4 wt% between 210 and 240 K that are generally consistent with that of Kane et al.[6] Imamura and Akiyoshi[5] report wetted wall flow reactor H* measurements at 230 K for 50 and 60 wt%, 250 K for 60, 69 and 76 wt%, and 270 K for 76 and 79 wt%; their data diverges a factor of 2 to 4 from that of Kane et al.[6] and Klassen et al.[7]

Equally weighted data sets from Kane et al.[6] and Klassen et al.[7] were combined and fit to generate the recommended parameterization. Two points for the solubility of acetone in water at 298 K and 273 K (Benkelberg et al.[1]) were included to improve the extrapolation to low wt% solutions. The data points from Imamura and Akiyoshi[5] were not included because they were inconsistent with the other data and have a very different temperature dependence. The few data points from Duncan et al.[2,3] are also inconsistent with the other data and were not included in the parameterization. Using a rotating wetted-wall flow reactor Esteve and Nozière[4] measured H* coefficients at 298 ± 3K for 89.4, 85, 80.8 73.9 and 70 wt% H_2SO_4, reporting values of 840, 650, 500, and 320 M atm^{-1}, respectively. These data are not included in the recommended parameterization since the temperature/wt% ranges they cover are unlikely to occur in the atmosphere.

Williams et al.[8] performed Knudsen cell H* measurements on the effect of 0.1 M ethanol on the uptake of acetone by 38.4 to 75.0 wt% H_2SO_4 at temperatures between 217.6 and 238.5 K, corresponding to data points previously reported by Kane et al. and Klassen et al. Their data indicated that the added ethanol had "no significant effect" on the solubility of acetone for comparable ethanol free measurements.

11. $CH_3C(O)O_2NO_2$ in H_2O and $H_2SO_4 \bullet nH_2O(l)$. Zhang and Leu[5] performed wetted wall flow reactor studies using CIMS to detect $CH_3C(O)O_2NO_2$ uptake over a temperature range of 199 to 226 K. Uptake studies were performed at 46, 54, 59, and 72 wt% H_2SO_4 to yield $H^*D_l^{1/2}$ values. D_l values were calculated from a cubic cell model to derive H*. Leu and Zhang[4] fit their data from Zhang and Leu,[5] including water data from Kames and Schurath[2] and Kames et al.,[3] using the Sechenov coefficient form adopted by Huthwelker for HOCl.[1] This formulation is recommended for both water and sulfuric acid solutions.

12. CF_2O in $H_2SO_4 \bullet nH_2O(l)$. Hanson and Ravishankara[1] calculate an upper limit for H of CF_2O based on assumed solubility limit resulting in lack of measurable uptake into 60 wt% H_2SO_4.

14. HOCl in $H_2SO_4 \bullet nH_2O(l)$. Recommendation is from the model of Shi et al.[5] which is based on wetted wall flow tube data from Hanson and Ravishankara[3] and Hanson and Lovejoy,[2] and uptake by stirred and static solutions by Donaldson et al.[1] This model incorporates newer, higher temperature data and replaces earlier recommended formulation by Huthwelker et al.[4]

15. $ClONO_2$ in H_2SO_4•nH_2O(l). Recommendation is from the model of Shi et al.[2] who used a measurement of the hydrolysis reaction's reacto-diffusive length by Hanson and Lovejoy[1] on 60 wt% H_2SO_4 at 250 K to derive the hydrolysis rate constant, k_{hyd}, and constrain H_{ClONO2} at 250 K. Shi et al. fit the $Hk^{1/2}$ dependence of the $ClONO_2$ uptake coefficients for a variety of $ClONO_2$ hydrolysis and $ClONO_2$ + HCl data to derive a parameterization for H as a function of wt% and T.

16. HBr in H_2SO_4•$mHNO_3$•nH_2O(l). Experimental data for HBr solubility is provided by Williams et al.,[7] Abbatt,[1] Abbatt and Nowak,[2] Kleffman et al.,[4] and Behr et al.[3] Data from time-dependent uptake measurements and from vapor pressure measurements are in good agreement after correcting for the fact that for some of the vapor pressure measurements the HBr concentration in solution was high enough to increase the acidity and thereby decrease the HBr solubility. By comparing pairs of data points with different HBr concentrations (from the same experiment), an average correction factor was obtained. The correction factor was used to correct the vapor pressure data of Williams et al.,[7] Abbatt and Nowak,[2] and Kleffmann et al. to zero effective HBr concentration. (This is different than the approach taken in Kleffmann et al. of using a "corrected" H_2SO_4 wt%. However, the resulting parameterization is very similar to the one in Kleffmann et al.[4]) The time-dependent uptake data of Williams et al.[7] and Abbatt,[1] and the molecular beam uptake data of Behr et al.[3] did not require correction. All of the experimental data have been fit to obtain the recommended parameterization as a function of H_2SO_4 wt% and temperature.

Agreement between this parameterization and the updated activity coefficient model of Massucci et al.[6] (and http://www.hpc1.uea.ac.uk/~e770/aim.html) is good for >60 wt%, but not very good at lower H_2SO_4 wt%, particularly at low temperatures. Therefore, this parameterization is recommended for calculating HBr Henry's law solubilities.

The only data for HBr solubilities in ternary solutions is from Kleffmann et al.[4] The data do not agree well with the updated activity coefficient in Massucci et al.[4] or with the older activity coefficient model in Luo et al.[5] Until further information becomes available, the recommendation is to use the parameterization for ternary solutions given in Kleffmann et al.[4]

(6) Massucci, M.; Clegg, S. L.; Brimblecombe, P. Equilibrium partial pressures, thermodynamic properties of aqueous and solid phases, and Cl_2 production from aqueous HCl and HNO_3 and their mixtures. *J. Phys. Chem. A* **1999**, *103*, 4209-4226, doi:10.1021/jp9847179.
(7) Williams, L. R.; Golden, D. M.; Huestis, D. L. Solubility of HBr in sulfuric acid at stratospheric temperatures. *J. Geophys. Res.* **1995**, *100*, 7329-7335, doi:10.1029/95JD00218.

17. **HOBr in H_2SO_4•nH_2O(l).** HOBr solubility measurements have been reported from coated wall flow reactor uptake studies by Waschewsky and Abbatt[3] and Hanson[1] and from Knudsen cell uptake studies from Iraci et al.[2] Although they were performed in different temperature ranges, extrapolations of Hanson's higher temperature data to the temperature range investigated by Waschewsky and Abbatt predicted much higher HOBr solubility than they measured. Iraci et al. subsequently measured HOBr uptake over both of the temperature ranges covered in the prior experiments. Their data agreed well with data from Waschewsky and Abbatt[3] at lower temperatures (213–238 K) but fall far below Hanson's higher (250–270 K) temperature measurements. The Iraci et al. measurements were performed at ~45, 55, 61 and 70 wt% H_2SO_4 and investigated over the temperature range from 201 to 252 K. Their results, like the earlier studies, indicate that the dependence of H* on acid concentration is relatively weak. For H_2SO_4 acid wt% from 55 to 75, H* is well described by: $\log H^* = (2349 \pm 280)/T - (5.27 \pm 1.24)$. Their ~45 wt% data are fit by: $\log H^* = (3665 \pm 270)/T - (10.63 \pm 1.23)$.

18. **SO_2 in H_2SO_4•nH_2O(l).** Room temperature vapor pressure measurements reviewed by Hayduk et al.[1] and bubble train reactor uptake measurements by Rattigan et al.[4] for 0–70 wt% H_2SO_4 agree very well. Langenberg et al.[2] used a novel capillary gas chromatography technique to deduce H* values for 41–83 wt% H_2SO_4 over a temperature range of 193–242 K. The recommended parameterization is a fair fit to the Rattigan et al. and Langenberg et al. data sets and allows reasonable extrapolation over the full range of atmospheric temperatures. Note that the Langenberg et al.[2] data is in mol/kg-bar units and was converted to mole/l units using the density parameterization of Myhre et al.[3]

1,1,1-$C_2H_3Cl_3$	275−298	0.043	−17.27	4210	III	11
C_2HCl_3	275−318	0.087	−16.58	4215	II	11

Substance	Temperature Range, K	*H*(298 K) (M atm^{-1})	A	B (K)	Uncertainty Range	Note
C_2Cl_4	275−318	0.047	−17.635	4350	II	11
C_2H_5I	274−303	0.14	−18.06	4800	IV	12

Uncertainty Classes:

I—Better than 10%
II—10% to 50%
III—50% to 100%
IV—Factor of 2 to factor of 10
V—Factor of 10 to factor of 100
VI—Greater than a factor of 100

5.8.1 Notes for Table 5-7

Note 1: *Inorganic Gases*

Back to Table

N_2O. Measurements at 36.13‰ NaCl using a microgasometric technique.[5] Data taken from the IUPAC evaluation.[7]

CO. The two published reports on the solubility of CO into salt water were evaluated by Wiesenburg,[6] who concluded that the data of Douglas[1] were significantly more reliable than those of Schmidt.[3] Those data were fit to a function of temperature and salinity. The present recommendation takes this function, calculates the values for 35‰ salinity, and fits those results to a two-parameter equation. A three parameter fit over the temperature range 274–303 K yields $\mathrm{Ln}\,H = -179.224 + 8620/T + 25.13\mathrm{Ln}(T)$.

CO_2. Published data on the solubility of CO_2 into salt water were evaluated by Weiss,[4] who also carried out some confirmatory measurements. The extensive results of Murray and Riley[2] were accepted and fit as a function of temperature and salinity. The present recommendation for seawater takes the calculated values for 35‰ salinity and the newer values for 35.33‰ and fits them to a two-parameter equation over the indicated temperature range. A three parameter fit over the temperature range 272–313 K yields $\mathrm{Ln}\,H = -157.779 + 8810/T + 21.88\mathrm{Ln}(T)$.

CHF_2Cl. Gas solubilities measured at 278, 308, and338 K and at NaCl concentrations from 0 to 0.0564 mole/mole (0 to 174‰) with a gas absorption unit.[4] Calculated values for 35‰ NaCl taken at each temperature and fitted to a two-parameter equation. These values were double-weighted and fit together with the values measured[2] in seawater by a purge-and-trap technique.

$CFCl_3$. A linear fit to the results of Hunter-Smith, et al.[1] and Ooki and Yokouchi[2] in seawater. The results are in good agreement at low temperatures (<293 K) but diverge at room temperature and above.

CF_2Cl_2, CF_3Cl.
Ostwald coefficients determined in filtered seawater with a salinity of 35‰.[3] Results fit to a linear equation.

Note 5: *Chloromethanes*

Back to Table

CH_3Cl. From a measurement of the concentration of the substance in a column of seawater at 30.4 or 34.34‰ salinity as a stream of nitrogen is bubbled through.[5,6] Similar results were reported by Elliott and Rowland at 0 and 22°C.[3]

CH_2Cl_2. From a measurement of the concentration of the substance in a column of seawater at 34.34‰ salinity as a stream of nitrogen is bubbled through[5] combined with values determined in seawater of salinities of 33.1‰ to 36.1‰ by using a purge-and-trap method and an equilibrator.[7]

$CHCl_3$. Taken from a linear fit to the results of Moore, et al.,[5,6] Hunter-Smith et al.,[4] and Dewulf, et al.[2] The latter were from a study as a function of salinity and the calculated value at 35‰ was used. These data were double-weighted in the fit. A measurement at 25°C with a purge-and-trap/GC method gave a result in close agreement.[8]

CCl_4. A linear fit to the results of Hunter-Smith, et al.,[4] Bullister and Wisegarver,[1] and Dewulf, et al.[2] The latter were from a study as a function of salinity and the calculated value at 35‰ was used. These data were double-weighted in the fit. The Bullister and Wisgarver[1] data were from a study of the solubility as a function of temperature and salinity. Calculated values for 35‰ from a complex expression were used.

Note 6: *Bromomethanes*

Back to Table

CH_3Br. Solubility determined with a gas-liquid membrane equilibrator with a 35‰ NaCl solution.[1] An approximately 5% correction was applied for non-ideality and to express the result in terms of fugacities. Very similar values were measured for filtered seawater. The results of Elliott and Rowland at 0 and 22°C are very close to these.[2]

CH_2Br_2. From a measurement of the concentration of the substance in a column of seawater at 34.34‰ salinity as a stream of nitrogen is bubbled through[3] combined with values determined in seawater of salinities of 33.1‰ to 36.1‰ by using a purge-and-trap method and an equilibrator.[5]

$CHBr_3$. A linear fit to the results from a purge-and-trap method,[5] calculated from the expression presented, and with a stripping technique with mass spectrometric detection.[4] Another measurement at 25°C with a purge-and-trap/GC method gave a result about 50% higher.[6]

Note 11: *Chloroethanes* Back to Table

1,1-$C_2H_4Cl_2$.

Derived from an equilibrium partitioning study as a function of salinity and temperature.[1] The derived value at 35‰ at each temperature was used.

1,2-$C_2H_4Cl_2$.

Derived from an equilibrium partitioning study as a function of salinity and temperature.[1] The derived value at 35‰ at each temperature was used. The data at 2°C were rejected due to a high reported standard deviation and a poor fit to the other results.

1,1,1-$C_2H_3Cl_3$.

The results from a multiple equilibration technique,[2] were combined with the derived values at 35‰ at each temperature from an equilibrium partitioning study as a function of salinity and temperature.[1] The highest temperature point from this latter study was not included in the fit.

C_2HCl_3, C_2Cl_4.

A fit to results from measurements of the concentration of the substance in a column of seawater at 34.34‰ salinity as a stream of nitrogen is bubbled through,[3] from an equilibrium partitioning study as a function of salinity and temperature,[1] and from a gc/headspace method with seawater of 35‰ salinity.[4] The derived value at 35‰ at each temperature from Dewulf et al.[1] was used and double-weighted.

[a] Uncertainty classes and uncertainties (1σ) in k (σ_k) and n (σ_n):

I: λ = 0.3–1.0 μm: k is an upper limit; σ_n is ±0.01
II: λ = 0.532 μm: σ_n(532 nm) is ±0.004
III: λ = 1.07–2.78 μm: σ_k is ±10%; σ_n is ±0.02; From Toon et al.[18]
IV: λ = 2.94–3.88 μm: σ_k is ±10%; σ_n is ±2%
V: λ = 4.01–6.69 μm: σ_k is factor of 3, k is likely a lower limit; σ_n is ±3%
VI: λ = 6.74–7.22 μm: σ_k is ±10%; σ_n is ±5%; Estimated from measurement spread
VII: λ = 7.27–8.58 μm: σ_k is factor of 15, k is likely a lower limit; σ_n is ±5%
VIII: λ = 8.64–9.79 μm: σ_k is ±10%; σ_n is ±5%
IX: λ = 9.85–15.12 μm: σ_k is factor of 30, k is likely a lower limit; σ_n is ±5%
X: λ = 15.23–16.89 μm: σ_k is ±10%; σ_n is ±7%
XI: λ = 16.9–40 μm: σ_k is factor of 5; σ_n is ±15%; Measurements strongly impacted by unmeasured mode at >40 μm

[b] Values reported as zero by Earle et al.,[9] see Note 4

Uncertainty estimates for complex refractive indices of ammonium sulfate by wavelength range

Wavelength Range (μm)	k	n	Comments
0.3–1.0	Upper limit	±0.01	Estimated uncertainty in n at 532 nm is ±0.004
1.07–2.78	±10%	±0.02	From Toon et al.[18]
2.94–3.88	±10%	±2%	
4.01–6.69	Factor of 3; likely lower limit	±3%	Estimated from measurement spread

6.74–7.22	±10%	±5%	
7.27–8.58	Factor of 15; likely lower limit	±10%	
8.64–9.79	±10%	±5%	
9.85–15.12	Factor of 30; likely lower limit	±5%	
15.23–16.89	±10%	±7%	
>16.89–40	Factor of 5	±15%	Measurements strongly impacted by unmeasured mode at >40 μm

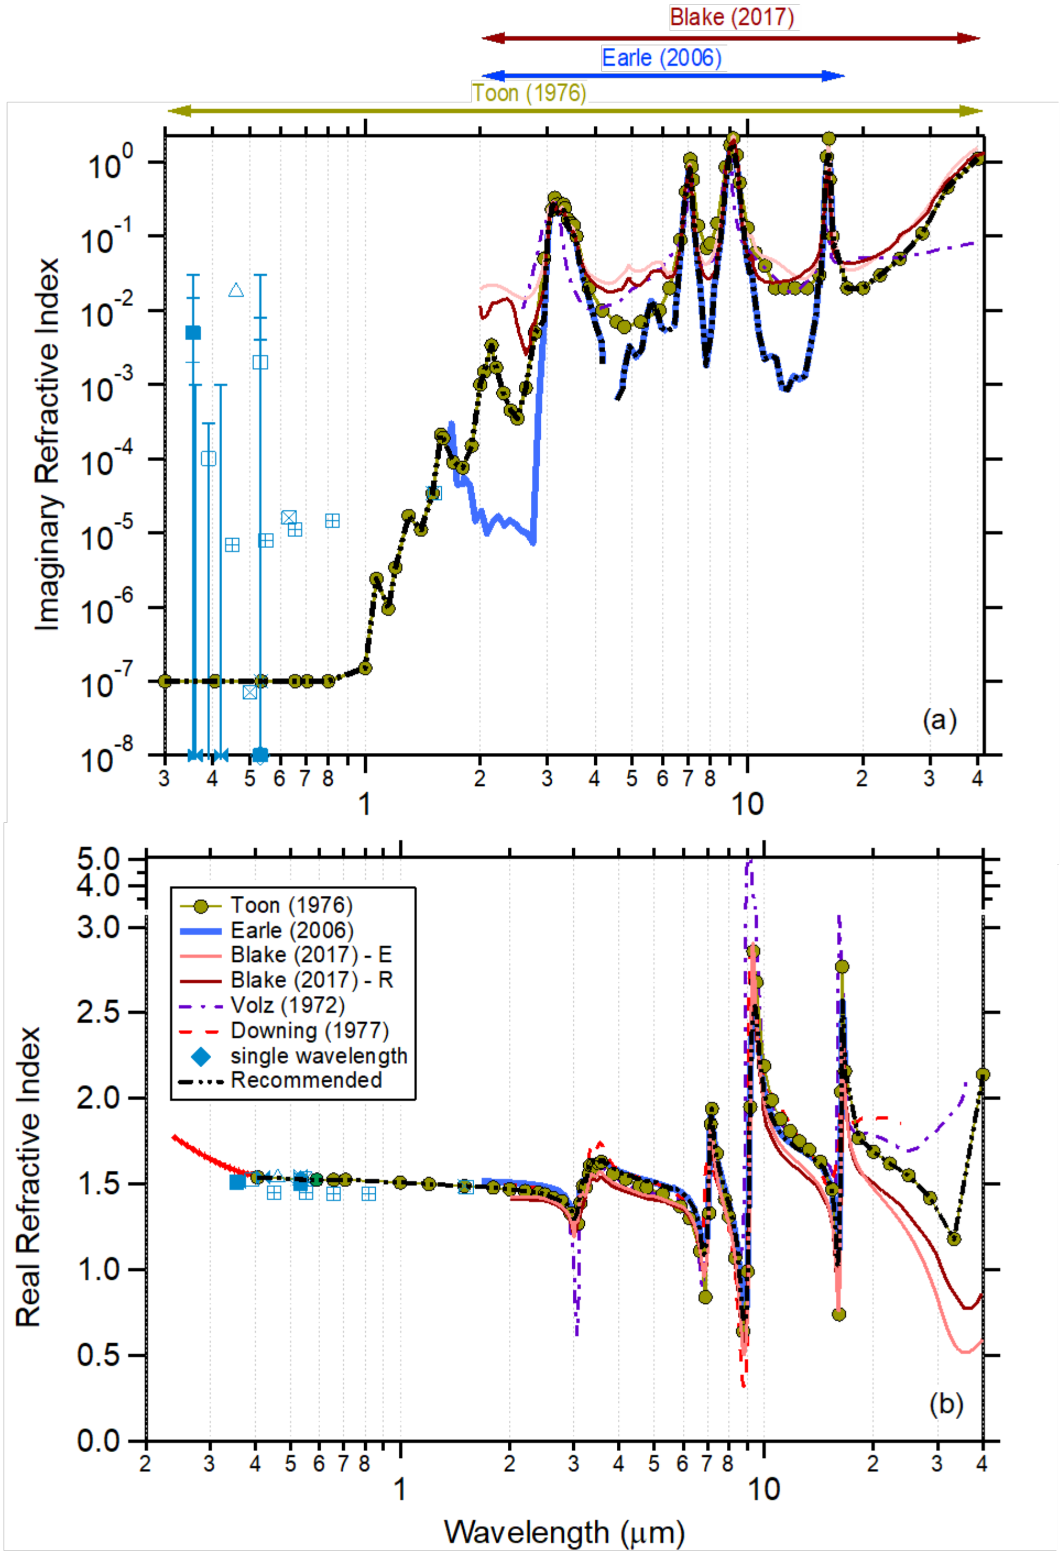

Figure 5-8-1: Wavelength dependent (a) imaginary and (b) real refractive indices for ammonium sulfate. For the single wavelength measurements, if a value of zero was reported for the imaginary RI it is shown as 10^{-8}. For (b), note the break and change in scale at $n = 3$. Recommended values are reported in Table 5-8-1 and discussed in Notes 3 and 4.

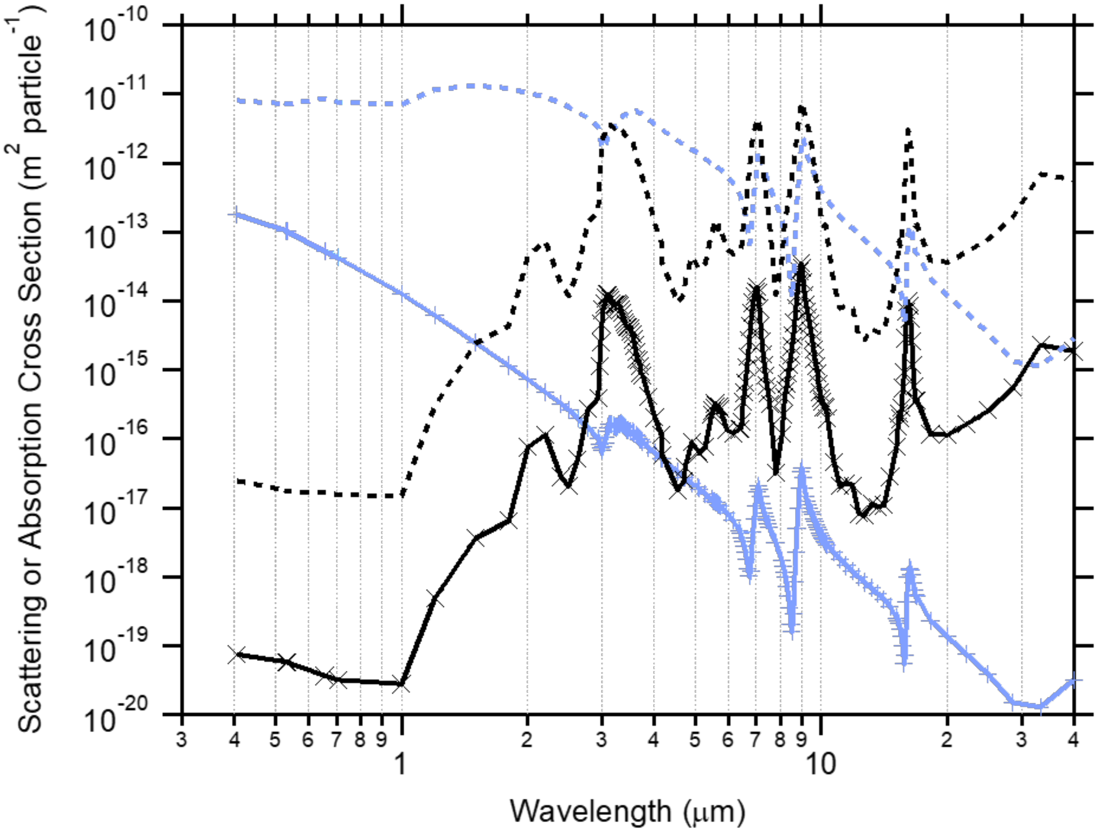

Figure 5-8-2: Wavelength dependent scattering (blue) and absorption (black) cross sections calculated from spherical particle Mie theory using the recommended complex refractive index (CRI) values assuming either 300 nm (solid lines, with symbols) or 2 μm (dashed lines) diameter particles. See Note 5.

5.10 Table 5-8-2. Summary of studies having measured the complex refractive index of ammonium sulfate across the infrared range

Study	Wavelength Range (μm)	Method
Chermack[5]	1.2–2.5	Transmission and Reflection
	2.5–40	Reflection at 25° and 75°
Volz[20]	2.5–40	Transmission and Reflectivity Using KBr method
Toon et al.[18]	0.2–2.5	Transmission
	2.5–40	Reflectivity with dispersion analysis
Downing et al.[8]	2.8–25	Spectral reflectance of aqueous solutions
Earle et al.[9]	1.67–17	Aerosol Extinction
Blake et al.[3]	2–40	Reflectivity or Ellipsometry

(see Note 1)

[a] Acronym definitions: P-CRDS = pulsed cavity ringdown spectroscopy; CW-CRDS = continuous wave cavity ringdown spectroscopy; BBCEAS = broadband cavity enhanced absorption spectroscopy; IBBCEAS = integrated broadband cavity enhanced absorption spectroscopy

(see Note 2)

5.11.1 Notes for Optical Properties Tables

Note 1: *Summary of Broadband Visible-IR Measurements:* Studies reporting the infrared wavelength-dependent CRI of ammonium sulfate are summarized in Table 5-8-2. Many of the studies determine *n* and *k* from measurement of transmission through a sample of the substance and/or reflectivity measurements. Volz[20] measured IR transmittance using the KBr disk technique to determine *k* and near-normal reflectance of disks made by compressing a power of $(NH_4)_2SO_4$ to determine *n*. Toon et al.[18] made transmission and reflectivity (at 11° from normal) measurements on slowly grown pure crystals of $(NH_4)_2SO_4$ to determine *n* and *k* over different wavelength ranges based on dispersion analysis. Their measurements were made along each of the three crystallographic axes, with minor differences between them. Chermack[5] reported *n* and *k* values based on transmissivity and reflectivity measurements; for the range 2.5–40 µm, the reflectivity was measured at 25° and 75°, rather than at near-normal, and Toon et al.[18] argues that the Chermack[5] values contain some unreported errors. We thus exclude the Chermack[5] values. Downing et al.[8] measured spectral reflectance from aqueous solutions of $(NH_4)_2SO_4$, and derived *n* and *k* values from a Kramers-Kronig phase-shift analysis. They determined *k* for the $(NH_4)_2SO_4$ solute specifically by subtracting the absorption of pure water, and then extrapolated these to match the number densities of the ions in crystalline $(NH_4)_2SO_4$. They report *n* values only for a 3.4 M aqueous solution, not for ammonium sulfate specifically. Given the assumptions involved in the Downing et al.[8] analysis, their reported *n* and *k* values should be considered only for general comparison with direct measurements of crystalline $(NH_4)_2SO_4$ and not used in a quantitative manner. More recently, Blake et al.[3] made independent measurements of *n* and *k* using single-angle reflectance and ellipsometry with pellets pressed from ammonium sulfate powder. The *n* and *k* were determined from the reflectance measurements using the Kramers-Kronig relationship and from the ellipsometry measurements using an oscillator model. Earle et al.[9] used a different approach, making measurements of the light extinction by suspended polydisperse aerosol particles. They derived *n* and *k* values using a combination of Mie theory and the Kramers-Kronig relationship, and anchoring their values to a value of *n* = 1.528 in the visible wavelength range. See Table 5-8-1.

Note 2: *Summary of Narrowband or Single-Wavelength Measurements in the near UV to near IR range:* There have been numerous individual measurements of *n* and *k* for $(NH_4)_2SO_4$ at discrete wavelengths or over narrow wavelength ranges in the near UV, visible and near-IR, which are summarized in Table 5-8-3. Most of these measurements have been made using cavity ringdown spectroscopy (CRDS), with a few using broadband cavity enhanced absorption spectroscopy (BBCEAS), with all of these occurring since 2007. With these studies, the *n* and *k* are determined from minimization of the difference between the observed extinction coefficients and that calculated from Mie theory. There is a group of measurements from the early 1980's that are all derived from the First International Workshop on light absorption by aerosol particles (Clarke and Waggoner;[6] Egan;[10] Patterson and Marshall[16]). Not all of the studies clearly indicate the uncertainties in the derived values. See Table 5-8-1.

Note 3: *Assessment of Near-UV and Visible Studies:* The spectral dependence of *n* and *k* is featureless across the near UV and visible spectrum, up to 1 µm. Based on the discrete-wavelength and narrowband measurements, we conclude that *n*(532 nm) = 1.524 ± 0.004, where the uncertainty is the standard error of the mean across the measurements reported at 532 nm and 550 nm. (These wavelengths have been combined given the negligible wavelength dependence of n in this range.) The n values reported by Egan[10] are excluded as they are clearly outliers. There is little evidence to indicate that the n values change appreciably from n(532 nm) as the wavelength decreases.

All of the CRDS and BBCEAS studies indicate that the k for ammonium sulfate is zero to within the uncertainty of the measurements from 355-532 nm; these methods are not suitable for determining k values smaller than about 0.001. The other measurements in this wavelength range, and up to 820 nm, indicate an upper-limit of $k = 10^{-5}$. However, the measurements of Toon et al.[18] and Chermack[5] clearly indicate that k increases rapidly starting at 1 µm, and both Toon et al.[18] and Mellon et al.[15] report that $k = 3.4 \times 10^{-5}$ around 1500 nm. As such, the upper-limit of $k = 10^{-7}$ for λ <1 µm from Toon et al.[18] is recommended. From the standpoint of calculation of aerosol optical properties, the calculated extinction, scattering and absorption are insensitive to differences in k for all $k < 10^{-4}$. See Table 5-8-1 and Figure 5-8-1.

Note 4: *Assessment of Infrared Studies:* At wavelengths greater than 1 µm, absorption by ammonium sulfate increases appreciably. A series of resonances occur at 3 µm, 7 µm, 9 µm, and 16 µm. Only Toon et al.[18] reports wavelength-dependent n and k between 1 and 1.7 µm, and those values are recommended. Between 1.7 µm and 9 µm, there is good agreement between all of the studies on crystalline or powder samples in terms of n, although differences are larger at the resonances where n changes rapidly with λ. In these resonance regions, the n from Volz[20] differs most notably from the other studies. The estimated uncertainty outside of the resonance regions, characterized as σ_n/n, is 0.03 between 1.7 µm and 9 µm. Between 9 and 17 µm the two measurements from Blake et al.[3] differ from the other studies, with overall lower n values. The estimated uncertainty in this range increases to σ_n/n, = 0.05. At λ >20 µm, the n values differ substantially between studies. The difference increases with λ to the longest wavelengths considered (λ = 40 µm). Most likely, these differences result largely from the existence of a strong absorption band at 50 µm, which contributes substantial uncertainty to the n values at λ >20 µm from limitations of either the Kramers-Kronig or dispersion analysis. Differences in n between the three crystallographic axes may also contribute to the greater differences between studies above λ = 20 µm. The estimated uncertainty at λ = 20 µm is 0.08, which increases monotonically to 0.6 at 40 µm.

There are substantial differences in the k values among studies across the IR. The k values vary over many orders of magnitude. The differences among studies is best characterized by the logarithmic difference. The logarithmic differences are generally largest when the k values are smallest. In the low k regions (k <~0.02), the aerosol extinction measurements (Earle et al.[9]) consistently yield the lowest k values, while the transmission/reflection measurements and ellipsometry measurements that used pressed pellets Blake et al.[3] tend to yield the largest k values. That the pellet-based measurements yield the largest k values is consistent with unaccounted for scattering. Differences between studies in the high k regions (k >~0.02) are reasonably small, and the normalized error (σ_k/k) generally decreases with increasing k.

In all analyses, the values of n and k are not independent, but linked through various mathematical relationships that depend on the interpretation method used. In general, in wavelength regions where only reflectivity is measured (common for λ >3 µm) the uncertainties in n and k are anti-correlated; when k is small the uncertainty in n is smaller and when k is large the uncertainty in n is larger, and vice versa. The direct transmission measurements of Toon et al.[18] up to 2.5 µm are likely the most robust, as they are least dependent on interpretation; we recommend the Toon et al.[18] values be used up to 2.78 µm as this limits the occurrence of obvious discontinuities in the observations. In the major resonance regions (k >0.1) we recommend that Earle et al.[9] values are adopted, as these are available at the highest resolution and there are only minor differences between studies. The measurements are available at much higher resolution (2 cm^{-1}) than is necessary for robust aerosol optical property calculations. For simplicity we recommend binning these into smaller wavelength bands, with $\Delta\log(\lambda) = 0.001$ providing sufficient resolution. Between the resonance at 3 and 7 µm we recommend the Earle et al.[9] values be adopted; there is a clear feature at 5.5 µm in the IR spectrum measured by Earle et al.[9] and, separately by Garland et al.[13] , that is not evident in the Toon et al.[18] measurements. This feature is also somewhat apparent in the Blake et al.[3] measurements, but their estimate of k is likely an overestimate in this low k region. In the other between-resonance regions, we also recommend the Earle et al.[9] values be adopted for consistency. However, the Earle et al.[9] k values should not be used at the reported resolution in these low k regions, as the individual values are subject to substantial uncertainties from instrument noise. We recommend that the reported n and k values are averaged into $\Delta\log(\lambda) = 0.015$ bins for regions where k <0.01. Above 17 µm we recommend the Toon et al.[18] measurements are adopted as they were made on ammonium sulfate crystals, as opposed to pressed pellets. Values of both n and k above 17 µm have large uncertainties. See Table 5-8-1 and Figure 5-8-1.

Note 5: The wavelength-dependent scattering and absorption cross sections were calculated using spherical particle Mie theory. Values were calculated for each of the wavelengths reported in Table 5-8-1 using the reported recommended *n* and *k*. Calculations were performed assuming that the particle diameters were either 300 nm or 2 μm to illustrate how the calculated cross-sections depend on particle size. See Figure 5-8-2.

SECTION 6. HOMOGENEOUS AQUEOUS-PHASE CHEMISTRY
Table of Contents

6.1 Introduction

These evaluations initially focused only on homogeneous gas-phase chemistry likely to be important in the stratosphere. The scope of the effort has evolved over the years to include heterogeneous processes, including reactions on surfaces and uptake of molecules into aerosols and liquid droplets. The scope also includes chemistry in the troposphere which may have an impact on the stratosphere by, for example, removing halogen-containing molecules which may diffuse to the stratosphere and contribute to chemical processes there. This obviously includes homogeneous gas-phase chemistry. In addition, however, some of the chemistry may take place on or in atmospheric particles, aerosols, or droplets. These processes are often referred to as heterogeneous, and this characterization is certainly the case for those involving gas-surface interactions. Chemical transformations which take place within the atmospheric aqueous phase, however, are more properly considered homogeneous aqueous-phase reactions. This includes reactions taking place in clouds, fogs, aqueous aerosols, and raindrops.

For many atmospheric species, the aqueous environment is quite different than the gas phase. In water, molecules can hydrate, protonate, deprotonate, or dissociate. In addition to participating in similar reactions as in the gas phase, such as abstraction or addition, species may also react by electron transfer. Sometimes, reactions that appear to be simple reactions between neutrals can actually involve concerted protonation or deprotonation, or even electron transfer. An important example is proton transfer-assisted electron transfer, which appears to be a simple hydrogen abstraction, but the features of which can only be explained by assuming a proton transfer mediated by the solvent coupled to an electron transfer.[15,17] Other examples of liquid water having a strong impact on the course of a reaction can be found in the reactions of NH_2 with O_2 and SH with O_2. These reactions are vanishingly slow in the gas phase, but proceed rapidly in the aqueous phase, probably due to the ability of water to interact with the hydrogen atoms.[4,17]

Many of the important reactions in the atmospheric aqueous phase involve charged species. Thus, their reactivity depends on the activity of the solution, which is essentially its deviation from ideality. It is similar to an "effective concentration". This difference is expressed as the activity coefficient. The activity coefficient of an ion can be estimated for dilute solutions by use of the extended Debye-Hückel equation:[10]

$$log\,\gamma_{\pm} = \frac{-Az_a z_b I}{1 + Ba\sqrt{I}}$$

where A and B are collections of fundamental constants which depend on temperature and the solution dielectric constant, a is the mean ionic radius, I is the ionic strength of the solution, and z_a and z_b are the charges on the two reactants.[14] If the ionic strength is in mol $L^{-1}$and the mean effective diameter of the ions, a, is in nm, $A = 1.82455 \times 10^6/(DT)^{3/2}$ and $B = 502.904/(DT)^{1/2}$ for any solvent, where D is the dielectric constant. We have recalculated these values of A and B at various temperatures using a more recent recommendation for the dielectric constant of water[18] and present these in the Table below.

Temperature (ºC)	A	B (nm)$^{-1}$
0	0.49020	3.24507
5	0.49385	3.25312
10	0.49774	3.26164
15	0.50186	3.27061
20	0.50621	3.28003
25	0.51079	3.28989
30	0.51560	3.30018
35	0.52064	3.31089

For a = 0.3 nm, the product Ba is very close to unity.

By inserting the activity into the transition-state expression for the rate constant, we obtain[3]

$$log\,k = log\,k_0 + \frac{2Az_az_bI}{1 + Ba\sqrt{I}}$$

At very low ionic strength, this becomes

$$log\,k = log\,k_0 + 2Az_az_bI$$

Rate constants for reactions in aqueous solutions are often pH dependent, sometimes strongly. This is typically a consequence of a pH dependence of the reduction potential of one or both of the reactants. A dramatic example is the HO_2/O_2^- radical. HO_2 behaves as an oxidant, with a standard potential for the half-reaction $HO_2 + e^- + H^+ \rightarrow H_2O_2$ of $E^\circ = +1.46 \pm 0.01$ V.[1] O_2^-, on the other hand, behaves as a reductant, with $O_2(aq) + e^- \rightarrow O_2^-$ having $E^\circ = -0.18 \pm 0.02$ V. A pH dependence can also result from the protonation of the product. An important example is OH, for which $OH + e^- \rightarrow OH^-$ has $E^\circ = +1.902 \pm 0.017$ V and $OH + e^- + H^+ \rightarrow H_2O$ has $E^\circ = +2.730 \pm 0.017$ V.[1]

The standard potentials of non-radical species have been measured extensively over the years. These results were reviewed by a team under the auspices of IUPAC in 1985.[2] More recently, in another IUPAC-sponsored effort, recommended values for the standard potentials for inorganic free radicals were reported, with extensive background information as supplementary material.[1] Also, in 1989 Wardman published an extensive review of organic free radical standard potentials, including a thorough discussion of the methodology used in obtaining these data and on the practical application of this information.[21] This latter review is recommended as a very useful tutorial on the use of standard potentials.

This section of the report focuses on reactions that lead to the activation of halides in atmospheric droplets. That is, reactions that transform halides, X^-, into a volatile halogen molecule, X_2. These reactions are listed in the Tables along with a rate constant or rate expression. Unless otherwise indicated in the Table or the note, the rate constants are at 25 ºC, or room temperature, and have units of L mol^{-1} s^{-1}. The reactions are grouped according to some defining characteristic.

The first grouping is reactions leading to and consuming the hydroxyl radical, the major atmospheric oxidant, but not including its reactions with halogen species. The next grouping is reactions of oxygen species with halogen species, including reactions of OH with halides. Particularly important here in addition to OH are reaction of O_3, H_2O_2, and HO_2. Subsequent groupings involve further reactions of halogen species, including interconversion reactions, reactions of other oxidants that might be formed in atmospheric droplets with halides, reactions of reductants with oxidized halogen species, and reactions that can generate volatile halogens.

At present, this section covers only a small fraction of the chemistry of the atmospheric aqueous phase: those reactions directly involved in the activation of halides. There is, for example, a rich chemistry involving organic compounds which is just beginning to be understood (see: Herkes, et al., McNeill, Ervens, and Shen, et al.)[5,11,16,19] Nor does this section cover photolysis,[8,9] which also can lead directly to reactive halogen species.[12] It is important to point out that some of the chemistry discussed here is also mentioned in other reviews, often as a part of larger picture of halogens and their role in atmospheric chemistry.[7,13,20] This includes tying together the chemistry of the gas phase with the homogeneous aqueous phase, and even with the surface of the drops. In an earlier discussion of halogen chemistry, Finlayson-Pitts presents evidence for halogen activation involving the atmospheric aqueous phase and its importance in atmospheric gas-phase chemistry.[6]

Kinetics of Reactions Leading to the Activation of Halogens in the Aqueous Phase

6.2 Reactions Leading to and Consuming OH

Reaction			k (L mol^{-1} s^{-1}) *	Note
$O_3 + OH^-$	→	$HO_2 + O_2^-$	52 ± 20	A1
$O_3 + H_2O$	→	chain initiation	See Note	A2
$O_3 + HO_2^-$	→ →	$OH + O_2^- + O_2$ $OH^- + 2O_2$	$(2.8 \pm 0.5) \times 10^6$	A3
$O_3 + H_2O_2$	→	products	<0.06	A3
$O_3 + O_2^-$	→	$O_3^- + O_2$	$(1.6 \pm 0.2) \times 10^9$	A4
$H_2O + O(^1D)$	→ →	H_2O_2 $2OH$	0.9 (yield) 0.1	A5
O_3^-	→	$O_2 + O^-$	9×10^{10} exp(-5170/T) s^{-1}	A6
$O_3^- + H^+$	→	$O_2 + OH$	$(9 \pm 1) \times 10^{10}$	A7
$O_3^- + OH$	→	$O_3 + OH^-$	2.6×10^9	A8
$(+OH^-)$	→	$2O_2^- + (H_2O)$	5.9×10^9	A8
$O_3 + OH$	→	$HO_2 + O_2$	$(1 \pm 0.2) \times 10^8$	A9
$OH + CO_3^{2-}$	→	$OH^- + CO_3^-$	6.68×10^{12} exp(−2840/T)	A10
$OH + HCO_3^-$	→	$H_2O + CO_3^-$	6.21×10^{10} exp(−2550/T)	A10
$CO_3^- + O_3$	→	products	$<1 \times 10^5$	A11
$CO_3^- + O_2^-$	→	$O_2 + CO_3^{2-}$	$(5 \pm 2) \times 10^8$	A12
$CO_3^- + O_3^-$	→	$O_3 + CO_3^{2-}$	$(5.5 \pm 0.5) \times 10^7$	A13
$OH + O_2$	→	HO_3	$<10^4$	A14
$OH + H_2O_2$	→	$H_2O + HO_2$	8.47×10^9 exp(−1680/T)	A15
$OH + HO_2^-$	→	$H_2O + O_2^-$	7.5×10^9	A15
$OH + HO_2$	→	$H_2O + O_2$	1×10^{10}	A16
$OH + O_2^-$	→	$HO^- + O_2$	1.4×10^{13} exp(−2120/T)	A17
$HO_2 + HO_2$	→	$H_2O_2 + O_2$	3.98×10^9 exp(−2480/T)	A18
$HO_2 + O_2^-$ $(+H_2O)$	→	$H_2O_2 + O_2$ $(+OH^-)$	9.7×10^7	A19
$O_2^- + O_2^-$ $(+2H_2O)$	→	$H_2O_2 + O_2$ $(+2OH^-)$	Negligible, See Note	A19
$O_2^- + H_2O_2$	→	$O_2 + OH + OH^-$	0.13	A20
$HO_2 + H_2O_2$	→	$O_2 + OH + H_2O$	0.5	A20
$OH + HSO_4^-$	→	$H_2O + SO_4^-$	4.7×10^5	A21
$OH + H_2SO_4$	→	$H_2O + H^+ + SO_4^-$	1.4×10^7	A21
$OH + NO_2^-$	→	$OH^- + NO_2$	$(1 \pm 0.5) \times 10^{10}$	A22
$OH + HONO$	→	$H_2O + NO_2$	3×10^9	A23
$OH + HNO_3$	→	$H_2O + NO_3$	$(8.6 \pm 1.3) \times 10^7$	A24
$NO_3 + OH^-$	→	$NO_3^- + OH$	8.2×10^7	A25
$H + N_2O$	→	$N_2 + OH$	$(9 \pm 2) \times 10^4$	A26
$H + H_2O$	→	$H_2 + OH$	7×10^{-5}	A27
$H + O_2$	→	HO_2	1.3×10^{10}	A28
$H + H_2O_2$	→	$H_2O + OH$	3.4×10^7	A29
$OH + OH$	→	H_2O_2	5.5×10^9	A30
$SO_4^- + OH^-$	→	$SO_4^{2-} + OH$	5.6×10^7	A31

* Unless units noted otherwise

6.2.1 Notes: Reactions Leading to and Consuming OH

A1. **O_3 + $OH^–$.** There have been three pathways proposed for the reaction of $OH^–$ with O_3:

(a) $\rightarrow HO_2^– + O_2$
(b) $\rightarrow HO_2 + O_2^–$
(c) $\rightarrow OH + O_3^–$

Reaction (a) generates no free radicals in the initial step, whereas reaction (b) generates two $HO_2/O_2^–$ radicals and reaction (c) produces (after protonation and decomposition of $O_3^–$) two OH radicals. Under typical experimental conditions, secondary chain reactions make the exact identity of the initial step seem not too important. But from the perspective of chemistry induced by ozone in an atmospheric droplet, these differences are likely to be critical. Reaction (c) has been discounted based on apparent OH yields of 0.55±0.08[44] or 0.78[21]. An induction period in the formation of $O_3^–$ was interpreted as indicating reaction (b) was not as important as reaction (a)[47]. But Merényi et al.,[28] have argued, based on thermokinetic and quantum chemical calculations, that the reaction between $OH^–$ and O_3 leads to the formation of an adduct, $HO_4^–$ ($\Delta G = 3.5$ kJ mol^{-1}), which decays rapidly ($k \sim 10^7$ s^{-1}). Although the direct decay route to $HO_2^–$ and O_2 is exoergonic ($\Delta G = -73.3$ kJ mol^{-1}), it is spin forbidden; the spin-allowed route to $HO_2^–$ and $O_2(^1\Delta_g)$ is endergonic ($\Delta G = 23.2$ kJ mol^{-1}), whereas the route to HO_2 and $O_2^–$ is spin allowed and less endergonic ($\Delta G = 14.8$ kJ mol^{-1}).

The rate constant for this reaction has been measured at 20 ± 1 ºC in alkali (pH>11) solutions containing carbonate by monitoring ozone decay (38 ± 14 L mol^{-1} s^{-1}, assuming a stoichiometry of 3) or carbonate radical formation (57.5 ± 10 L mol^{-1} s^{-1} assuming a stoichiometry of 2).[21] An upper limit to the rate constant of 80 ± 10 L mol^{-1} s^{-1} from the formation of ozonide was also reported. The authors recommend the average of the first two results of 48 ± 12 L mol^{-1} s^{-1}.

A second study at 20 ± 1 ºC over the pH range 8-10 was carried out using either carbonate or methyl mercury as radical scavengers at 20 ºC.[44] Again taking a stoichiometry of 3, this study resulted in a rate constant of 70 ± 7 L mol^{-1} s^{-1}.

In a stopped-flow study at 20 ºC in slightly basic ([OH] = 0.0117 M) and basic ([OH] = 0.126 M) solutions containing carbonate at 20 ºC, rate constants of 37 and 43 L mol^{-1} s^{-1}, respectively, were reported.[47]

An extensive study of ozone decomposition at 25 ºC by following O_3 (260 nm), $O_3^–$ (430 nm), and $CO_3^–$ (600 nm), followed by a simultaneous fit of 60 kinetic traces, led to a value of 170 ± 2 L mol^{-1} s^{-1}.[18] Six additional critical rate constants were also fitted, which may make this less reliable than the stated error limits would suggest.

Several other studies of ozone decomposition without the use of radical scavengers have also been carried out (see Sotelo[43] and references contained within). Due to the high reactivity of radicals toward ozone, it does not seem possible to extract useful rate constants from these studies. Therefore, the value reported in the Table is an average of the values from the three studies which employed scavengers.

An investigation of the decomposition of O_3 in phosphate-buffer solutions at pH 4.5, 6.1, and 9 resulted in an apparent value of the mean value over the temperature range 20 to 30 °C for the rate constant for $OH^– + O_3$ of 71.4 L mol^{-1} s^{-1}, in good agreement with the chosen value.[19] The simplified model used, however, did not include the fast reaction $O_3 + O_2^– \rightarrow O_3^– + O_2$. This may be compensated for somewhat by the fact that the subsequent reactions, $O_3^– + H^+ \rightarrow OH + O_2$ and $OH + O_3 \rightarrow HO_2 + O_2$ are very fast. Back to Table

A2. **O_3 + H_2O.** Several studies have been carried out on the decomposition of ozone in water at low pH values. The chain nature of the reaction makes the extraction of absolute rate constants problematic; the temperature dependent studies all result in quite high activation energies, 40–110 kJ mol^{-1} (Sotelo, et al.[43] and references contained therein). Indeed, not only is the magnitude of the measured decomposition rate constants highly scattered, so is the order of the reaction.[22] A careful study of the thermal decomposition found a retarding effect of O_2 on the rate, along with an increase in isotopic scrambling in $^{18,18}O_2$ with temperature(0–46 ºC).[36] In this study, an activation energy of 79.5 ± 8.0 kJ mol^{-1} was reported. These authors used this information to suggest that the decomposition in pure water arose from the thermal decomposition of ozone, followed by reaction with water

$O_3 \rightarrow O + O_2$

$O + H_2O \rightarrow 2OH$

A similar activation energy of 82.5 ± 8.0 kJ mol^{-1} was found in an acetate solution.[37]

A more recent investigation of the decomposition of O_3, based on solubility measurements, in the presence of added H_2SO_4 suggested a significantly enhanced rate below pH 2.[13] The possibility of trace amounts of metal ions, however, makes this result uncertain.

It is very unlikely that these reactions would be important in atmospheric chemistry. Back to Table

A3. **$O_3 + H_2O_2$.** The reaction of hydrogen peroxide with ozone has generally been accepted to be an electron transfer from the HO_2^- anion.[44]

$$O_3 + HO_2^- \rightarrow OH + O_2^- + O_2 \qquad \text{(or } O_3^- + HO_2\text{)}$$

More recently, however, this conclusion has been called into question in a study of the deuterium-isotope effect on the reaction.[25] The large effect was interpreted as due to a hydride-transfer reaction:

$$O_3 + HO_2^- \rightarrow HO_3^- + O_2$$

A subsequent study, however, involving the use of radical scavengers, found very little kinetic isotope effect.[42] These authors suggested that the earlier work was compromised by the presence of trace impurities in the D_2O.

Merényi, et al.[28] have argued, based on thermokinetic and quantum chemical calculations, that the reaction between HO_2^- and O_3 leads to the formation of an adduct, HO_5^- ($\Delta G° = -39.8$ kJ mol^{-1}), which decays to HO_2 and O_3^- ($\Delta G° = 13.2$ kJ mol^{-1}) and to $2O_2 + OH^-$. The latter decay pathway accounts for the peroxone process, which is based upon this chemistry, being only ~50% efficient. This reduced yield of OH has been confirmed by Fischbacher, et al.,[20] who found an average yield of slightly over 0.5 by following trace reactants in the presence of excess *t*-butanol. This approach was confirmed by generating OH by γ-radiolysis under the same conditions.

The kinetics of the reaction of ozone with hydrogen peroxide were measured over the pH range 5 to 6 at 20ºC in the presence of methyl mercury as a free radical scavenger.[44] The rate was found to increase by one order a magnitude per pH unit, supporting the contention that only the anion reacts. The reported rate constant, $(2.8 \pm 0.5) \times 10^6$ L mol^{-1} s^{-1}, for the reaction of O_3 with HO_2^- includes a stoichiometric factor of 2. Another stopped-flow measurement, without radical scavenger but fitting only the initial rate, led to 2.2×10^6 L mol^{-1} s^{-1}.[47] A kinetic spectrophotometric measurement with a *t*-butanol scavenger, also at 20 °C, led to a slightly higher value of $(4.8 \pm 1) \times 10^6$ L mol^{-1} s^{-1}.[42] A simultaneous fit to a complex system involving ten rate constants (See Note A1) led to $k = (3.1 \pm 0.1) \times 10^6$ L mol^{-1} s^{-1}, in remarkable agreement.[18]

The rate constant for the reaction of ozone with hydrogen peroxide has also been studied by the reactive-absorption method.[4] At 20°C, this approach led to rate constants of 2.40 or 1.91×10^6 L mol^{-1} s^{-1}, depending on the value chosen for the Henry's Law constant; at 35°C, these values were 5.68 and 7.31×10^6 L mol^{-1} s^{-1}. These suggest an activation energy for the reaction of between 45 and 69 kJ mol^{-1}.

The rate of loss of ozone at pH 2 in the presence of H_2O_2 was determined in acetic acid solutions. At 31 ºC, a rate constant of 0.065 L mol^{-1} s^{-1} was determined.[37] But measurements over the temperature range 18−46 ºC suggested an activation energy, 73.5 ± 8.0 kJ mol^{-1}, only slightly lower than in the absence of peroxide, so it is probably best to consider this an upper limit. Indeed, results from this group suggest considerable complications associated with the formation and loss of H_2O_2 in ozone decomposition at low pH.[38] A measurement, also following ozone loss, at 20 ºC led to a reported rate constant of (0.023 ± 0.002) L mol^{-1} s^{-1}.[33] The pH in this study was not completely clear, but seemed to be about 6.2.

An investigation of the decomposition of O_3 in phosphate-buffer solutions at pH 4.5, 6.1, and 9 resulted in an calculated value of the value over at pH 7 for the rate constant for $HO_2^-/H_2O_2 + O_3$ of 251 L mol^{-1} s^{-1}.[19] This leads to approximately 1 x 10^6 L mol^{-1} s^{-1} for the anion. The simplified model used, however, did not include the fast reaction $O_3 + O_2^- \rightarrow O_3^- + O_2$. This may be compensated for somewhat by the fact that the subsequent reactions, $O_3^- + H^+ \rightarrow OH + O_2$ and $OH + O_3 \rightarrow HO_2 + O_2$ are very fast. Back to Table

A4. **$O_3 + O_2^-$.** Two independent pulse radiolysis measurements, both following the build-up of O_3^- at 430 nm, give 1.5 and 1.6 × 10^9 L mol^{-1} s^{-1}.[6,7,41] A simultaneous fit involving ten rate constants (see Note A1) led to $k = (7 \pm 0.6) \times 10^7$ L mol^{-1} s^{-1}, in very poor agreement.[18] A calculation at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy for this reaction of $\Delta G° = -176$ kJ mol^{-1}.[30] There was no evidence for the formation of an adduct as a minimum on the potential energy surface. Back to Table

A5. **$H_2O + O(^1D)$.** Quantum yields were derived from a study of the photolysis of solutions containing ~3 × 10^{-4} mol L^{-1} O_3 in the presence of varying amounts of *t*-butanol over a wavelength range of 245–300 nm. The direct product of photolysis at these wavelengths is $O(^1D)$. The quantum yield for ozone loss was $\Phi(-O_3)$ ~0.5, based on a measurement of 0.64 coupled with corrections for loss to organic radicals.[34] See also work on the photochemical oxidation of chloride by ozone.[26] Back to Table

A6. **$O_3^- \rightarrow$.** Obtained from a pulse radiolysis study over 298–343 K.[15] ($E_a = 43.0$ kJ mol^{-1}) Derived from decay kinetics of O_3^- as a function of O_2, methanol, and 2-propanol in 1 molar KOH. At 298 K, $k = 2.6 \times 10^3$ s^{-1}, in agreement with earlier pulse radiolysis and flash photolysis studies, which ranged from 3.3–6.2 × 10^3 s^{-1}.[35] HO_3 is a very strong acid, with $pK_a = -2.1$.[29] Back to Table

A7. **$O_3^- + H^+$.** From a pulse radiolysis study following the temporal behavior of the absorption at 260 and 430 nm at pH 10–13.[39] The use of this rate constant leads to a "satisfactory" fit. Another report from the same laboratory gave $k = 5.2 \times 10^{10}$ L mol^{-1} s^{-1} at pH 5.[6,7] Back to Table

A8. **O_3^-+ OH.** From a high-pressure pulse radiolysis study (40 atm. N_2O) following the decay of O_3^- at 430 nm and formation of O_2^- at 260 nm and ~20 °C.[39] Total rate constant is 8.5 × 10^9 L mol^{-1} s^{-1}. Back to Table

A9. **O_3 + OH.** From a pulse radiolysis study using product formation kinetics at pH 9-10, following O_3^- from the subsequent reaction of O_2^- with O_3, along with decay kinetics at pH 1 following O_3 at 280-310 nm. This value is supported by a relative rate measurement at pH 10.3 against OH + CO_3^{2-}.[40] A calculation at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy for this reaction of $\Delta G° = -229$ kJ mol^{-1}.[30]There was no evidence for the formation of an adduct on the potential energy surface. Back to Table

A10. **OH + CO_3^{2-}/HCO_3^-.** From a pulse radiolysis study using product formation kinetics over a range of carbonate concentrations and four different hydroxide ion concentrations between 20 and 200 °C.[9] (Ea = 23.6 kJ mol^{-1} for carbonate and 21.2 kJ mol^{-1} for bicarbonate.) Other reported values range from 3.2 × 10^8 to 4.2 × 10^8 L mol^{-1} s^{-1} at ~298 K, in good agreement.[35] Back to Table

A11. **$CO_3^- + O_3$.** Obtained by following decay kinetics of CO_3^- after pulse radiolysis in a 0.1 mol L^{-1} bicarbonate solution containing 90 µmol L^{-1} ozone.[41] Back to Table

A12. **$CO_3^- + O_2^-$.** A pulse radiolysis study,[16] following the decay of CO_3^- at 600 nm gave 6.5 × 10^8 L mol^{-1} s^{-1} and a flash photolysis study[3]monitoring both the decay of CO_3^- and of O_2^- at 260 nm gave 4.0 × 10^8 L mol^{-1} s^{-1}. A simultaneous fit involving ten rate constants (see reaction 1) led to $k = (6.8 \pm 0.4) \times 10^9$ L mol^{-1} s^{-1}, in poor agreement.[18] Back to Table

A13. **$CO_3^- + O_3^-$.** Derived from an investigation of the effect of carbonate on ozone decomposition at pH 10.7–12.8. The ozone concentration was about 10^{-4} mol L^{-1} and 1 × 10^{-5} to 4 × 10^{-3} mol L^{-1} carbonate at an ionic strength of 0.5 mol L^{-1}. The temporal dependence of the absorption at 260, 430, and 600 nm was monitored and fit to a complex mechanism.[31] Back to Table

A14. **OH + O_2.** A Gibbs energy change of +47 kJ mol^{-1} was calculated for this reaction at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver.[29] That, together with kinetic and acidity information on OH and HO_3, leads to this upper limit. HO_3 is a very strong acid, with $pK_a = -2.1$.[29] Back to Table

A15. $OH + H_2O_2/HO_2^-$. From a pulse radiolysis study following product formation at 250–270 nm (O_2^-) over 287–433 K at pH 7.8.[12] ($E_a = 14.0$ kJ mol^{-1}.) Several other studies at room temperature agree with the 298 K value (2.7×10^7 L mol^{-1} s^{-1}). Yu recommends $(3.2 \pm 1.5) \times 10^7$.[49] From the pH dependence over the range 6.8–13.8, the rate constant for the reaction with HO_2^- was derived. Other published values are in basic agreement.[35] Back to Table

A16. $OH + HO_2$. From a pulse radiolysis study in 0.01 M $HClO_4$. The rate constant is about twice as high at 200 °C.[14] Back to Table

A17. $OH + O_2^-$. From a pulse radiolysis study of solutions containing 0.3 MPa O_2 and 0–10 MPa H_2 over 293–558 K.[11] ($E_a = 17.6$ kJ mol^{-1}.) Back to Table

A18. $HO_2 + HO_2$. From a pulse radiolysis study of solutions containing 0.2 MPa O_2 and 10 MPa H_2 over 293–373 K.[10] ($E_a = 20.6$ kJ mol^{-1}.) A recommended value at 298 K of 8.3×10^5 L mol^{-1} s^{-1} in good agreement.[5] Back to Table

A19. $O_2^- + HO_2/O_2^-$. Recommended value from the evaluation of Bielski, et al. based on the pH dependence of the measured decay rate.[5] Back to Table

A20. $H_2O_2 + HO_2/O_2^-$. Based on the observed O_2 yield in the gamma radiolysis of H_2O_2 solutions over the pH ranges 7–9.9 and 0.5–3.5.[48] Other studies report both higher and lower rate constants.[35] Back to Table

A21. $OH + HSO_4^-/H_2SO_4$. From the pulse radiolysis of concentrated sulfuric acid solutions, 0.4 to 7.5 mol L^{-1}, following the build-up of the product SO_4^- at 450 nm.[23] Back to Table

A22. $OH + NO_2^-$. There have been several pulse radiolysis and flash photolysis determinations of this reaction, with results ranging from 0.6 to 1.4×10^{10}. The listed value represents this range. Due to the very weak optical absorption by NO_2, the studies were usually competition kinetics or, in one case, the analysis of a complex system involving the formation of peroxynitrate.[35] Back to Table

A23. OH + HONO. The rate constant for this reaction is assumed to be equal to that for the gas-phase reaction. Note that this is the case for the gas and aqueous phase reactions of OH with $HONO_2$. Back to Table

A24. $OH + HNO_3$. From a pulse radiolysis study of the behavior of the optical absorbance due to NO_3 as the concentration of HNO_3 was varied at a total ionic strength of 1 mol L^{-1} and pH values from 0 to 1. The reverse rate constant of $(3 \pm 1) \times 10^2$ L mol^{-1} s^{-1} was also derived.[32] These values lead to a reduction potential for the NO_3 radical of 2.58 V, significantly higher than the recommended value of 2.466 ± 0.019 V.[1] Back to Table

A25. $NO_3 + OH^-$. From a study of the flash photolysis of persulfate solutions containing 0.1 mol L^{-1} nitrate and 1.9–10 μmol L^{-1} OH^-.[17] Decay of the NO_3 absorption at 633 nm was followed. Back to Table

A26. $H + N_2O$. Derived from a pulse-radiolysis study on N_2O-saturated, 0.1 mol L^{-1} HCl solutions at room temperature.[24] The decay of the Cl_2^- absorbance at 340 nm was monitored and fit to a multi-step mechanism. Back to Table

A27. $H + H_2O$. The Gibbs energy change for this reaction was derived from thermodynamic arguments utilizing a non-symmetric standard state convention. The resulting equilibrium constant was then combined with experimental values of the reverse reaction.[46] See also the original paper by these authors[45] and the comment on that article by Bartels.[2] Back to Table

A28. $H + O_2$. The value given is an average of a large number of experimental determinations.[27] Back to Table

A29. **$H + H_2O_2$.** Recommendation based on averaging selected values.[27] Note that the reaction probably involves H-atom addition followed by dissociation of the adduct. A rate constant of 1.4×10^9 L mol^{-1} s^{-1} was recommended for $H + HO_2^-$. Back to Table

A30. **OH + OH.** Recommended value from an extensive review of the literature.[8]. Back to Table

A31. **$SO_4^- + OH^-$.** The value listed is the average of five investigations reporting results for this reaction. The range is $(1.4–8.3) \times 10^7$ L mol^{-1} s^{-1}.[35] Back to Table

* Unless units noted otherwise

6.3.1 Notes: Reactions of Oxygen Species with Halogen Species

B1. **$O_3 + Cl^-$.** The reaction between ozone and chloride was investigated using a bubble-column reactor over the temperature range 7 to 60 °C and with HCl concentrations ranging from 0.01 to 1 mol L^{-1}, typically at a total ionic strength of 1 mol L^{-1}.[48] The reaction was followed by monitoring the concentration of Cl_2 at the reactor outlet and the O_3 concentration in the reaction solution. The observed rate showed a significant dependence on proton concentration, leading to the proposed mechanism and the rate and equilibrium constants. Values were reported at 7, 24, 41.5, and 60 °C, but for the second and third steps, these rates were only upper and lower limits, respectively. The fits to these values were not presented in this paper, but are taken from a subsequent paper from the same group.[43] The results are in good agreement with an earlier report from the same group,[52] an upper limit of 0.018 L mol^{-1} s^{-1} for the uncatalyzed reaction,[35] and measurements made at 0 and 9.5 °C over a somewhat lower range of acid concentrations.[72]

The authors reported a small positive effect of ionic strength when going from 0.5 to 3 mol L^{-1} using $NaClO_4$ or KNO_3, but a slight negative effect when using NaCl. A positive ionic strength effect may, at these high salt concentrations, simply reflect an impurity effect. There is also some evidence for a slow reaction between ozone and nitrate.[61]

Since the earliest work, this reaction has been assumed to involve oxygen-atom transfer to generate hypochlorite or chlorite, $HClO/ClO^-$ and molecular oxygen, as shown in the Table. An alternate mechanism, however, has been proposed in which an electron transfer takes place:[63]

$$O_3 + Cl^- \rightarrow O_3^- + Cl$$

followed by

$$Cl + O_3 \rightarrow ClO + O_2$$

$$ClO + O_3 \rightarrow Cl + 2O_2$$

This mechanism was proposed to account for the lack of spectral evidence for the formation of ClO^- and some spectral indication of H_2O_2. Further, the authors argued that a gravimetric analysis of the products was not consistent with a mass increase that should be associated with the formation of chlorine oxides, such as sodium chlorite. The possibility that the reaction might proceed by electron transfer is quite important since the reaction would generate two free radicals, OH (from the decomposition of O_3^-) and Cl. The arguments presented in this paper are not particularly compelling, however, and have been thoroughly critiqued by Levanov et al.[42] The earlier observation that chlorine gas is generated in the reaction,[48] means that the residue of the reaction would not be expected to weigh much more that the starting materials. It is also not surprising that no absorption due to ClO^- is observed, since the rate constant for the reaction of this species with ozone is much faster than the reaction of chloride with ozone, so its steady-state concentration would be low. The expected final product, ClO_3^-, has an absorption maximum at 197 nm and is unlikely to be observed in the presence of the other reactants. Beyond this, Levanov, et al. have analyzed this reaction thermodynamically and concluded that the electron-transfer mechanism would be highly endothermic, in agreement with the well-known gas-phase electron affinities of O_3 and Cl. In a companion paper, Levanov et al.[43] have summarized and expanded on the arguments in favor of an oxygen-atom transfer mechanism, concluding that the reaction likely goes through an adduct to circumvent spin restrictions. In an investigation of the stoichiometry of the reaction, Levanov et al.[45] found that, in a 1 mol L^{-1} Cl^- solution at low pH, the consumption of one ozone molecule results in the formation of one chlorine molecule. This is consistent with the atom-transfer mechanism, since the product hypochlorous acid is driven to chlorine under those conditions.

In alkali solutions, the main product of the reaction is chlorite, $OClO^-$, formed from the subsequent reaction of ClO^- with O_3.[44] The effective rate constant for the production of chlorite is 7.7×10^{-4} L mol^{-1} s^{-1} (pH 8.4–9.6 at 20 °C).

The reaction of O_3 with Cl^- in acid solutions of increasing concentrations has been investigated and shown to lead to increasing evolution of Cl_2.[46,47] In the same study, a significant effect of added metal ion catalysts was observed.

Note that ClO_4^- is produced in very small yields from the overall reaction system.[38,62] The is probably due to subsequent reactions of oxyradicals with ozone and other secondary reactions. Back to Table

B2. **O_3 + Cl.** No rate constant has been reported for this reaction, but a calculation at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy change of $\Delta G° = -204$ kJ mol^{-1}.[59] There was no evidence for the formation of an adduct as a minimum on the potential energy surface. Back to Table

B3. **O_3 + Cl_2^-.** Rate constant obtained from decay kinetics at 340 nm in solutions containing NaCl, $HClO_4$ and ozone following pulse radiolysis.[6] The products were not determined, but were assumed to be ClO + O_2 + Cl^-. A calculation at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy change of $\Delta G° = -133$ kJ mol^{-1}.[59] There was no evidence for the formation of an adduct as a minimum on the potential energy surface. Back to Table

B4. **O_3 + Br^-.** Kinetics obtained from a stopped-flow spectrophotometric study following both the rate of loss of O_3 and the rate of formation of Br_3^- over T = 1−25 °C.[50] (E_a = 33.7 kJ mol^{-1} presented in paper.) The rate constant was found to be pH dependent and was resolved through a mechanism involving the formation of an intermediate $BrOOO^-$ and its subsequent reaction with either H^+ or H_2O to give O_2 and HOBr. Quoted value in Table is for the H^+-independent path at $\mu = 1.0$ mol L^{-1}. The H^+-dependent pathway gives $k = 3.27 \times 10^{11}$ exp(-45.6 kJ/RT) L mol^{-1} s^{-1}. Arrhenius parameters were calculated by the reviewer and agree with the activation enthalpies presented in the paper. In earlier work, activation energies of 37 kJ mol^{-1} and 24 kJ mol^{-1} were reported by Haag and Hoigné (1−30 °C) and by Haruta and Takeyama (5 −30 °C), respectively.[29,32] The energetics of the reaction have been calculated at the B3LYP/6-311+G(d) level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, supporting adduct formation and subsequent decay into BrO^- and $O_2(^1\Delta_g)$.[58] The formation of $BrOOO^-$ at a water surface was confirmed in an X-ray photoeclectron experiment.[3] Computational studies also showed that the singlet pre-complex is stabilized by water.[3] Back to Table

B5. **O_3 + I^-.** A pulsed-accelerated-flow spectrophotometric study at $\mu = 0.1$ M and 25 ± 0.1 °C following the loss of O_3 at 260 nm was used to obtain the kinetics of this reaction. Adduct formation prior to O-atom transfer is proposed,[50] which is supported by a computational study which revealed three conformers of $IOOO^-$.[26] An investigation of the uptake kinetics of O_3 into aqueous solutions of I^- led to estimated rate constants in the range 3.2×10^8 to 2.4×10^9 L mol^{-1} s^{-1} between 275 and 293 K.[54] High concentrations (0.5 to 3 mol L^{-1}) were employed, so activities were used in calculating the rate constants. A fit to the data gave $k = 1.4 \times 10^{22}$ exp(-73.08 kJ/RT) L mol^{-1} s^{-1}. Back to Table

B6. **O_3 + ClO^-.** The decay of O_3 was followed at 258 nm over the temperature range 11–34 C.[30] ($E_a = 57 \pm 6$ kJ mol^{-1} presented in paper.) Product measurements were carried out by ion chromatography, iodometric titration, and uv absorption. The overall rate constant corresponds to two basic reactions:

$$ClO^- + O_3 \rightarrow 2O_2 + Cl^- \qquad k = 1.1 \times 10^2 \text{ L mol}^{-1}\text{ s}^{-1} \text{ (25 °C)}$$

$$ClO^- + O_3 \rightarrow O_2 + OClO^- \qquad k = 3.0 \times 10^1 \text{ L mol}^{-1}\text{ s}^{-1} \text{ (25 °C)}$$

followed by

$$OClO^- + O_3 \rightarrow ClO_3^- + O_2.$$

The reaction of O_3 with HOCl was too slow to measure. Back to Table

B7. **O_3 + BrO^-.** The decay of O_3 was followed at 258 nm over the temperature range 10–30 °C.[29] ($E_a = 60 \pm 10$ kJ mol^{-1} presented in paper.) Product analysis was carried by a bromide-selective electrode, iodometric titration, UV absorption, and by GC analysis after solvent extraction. This overall rate constant corresponds to two basic reactions:

$$BrO^- + O_3 \rightarrow 2O_2 + Br^- \qquad k = 3.3 \times 10^2 \text{ L mol}^{-1}\text{ s}^{-1} \text{ (20 °C)}$$

$$BrO^- + O_3 \rightarrow O_2 + OBrO^- \qquad k = 1.0 \times 10^2 \text{ L mol}^{-1}\text{ s}^{-1} \text{ (20 °C)}$$

followed by

$$BrO_2^- + O_3 \rightarrow \quad BrO_3^- + O_2 \qquad k > 10^5$$

The reaction of O_3 with HOBr was too slow to measure. The energetics of the reaction, including possible adduct formation, have been calculated at the B3LYP/6-311+G(d) level of theory, but suffered from spin contamination.[58] Back to Table

B8. **O_3 + IO^-/HOI.** The kinetics of oxidation of HOI/IO^- was determined over pH 6.0–9.7 by measuring O_3 depletion in a flow apparatus at 25 ± 2 ºC.[5] Back to Table

B9. **O_3 + ClO.** There have been no reported experimental measurements on this reaction in the aqueous phase. A calculation at the B3LYP/LACV3P** level of theory, with solvent interactions calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy change of $\Delta G° = -119$ kJ mol^{-1} for the path leading to OClO and $\Delta G° = -229$ kJ mol^{-1} for the path to ClOO.[59] The species that was observed as a minimum on the potential energy surface had a Cl-OO bond length of 1.888 Å, indicating that ClOO is probably a van der Waals complex with $\Delta G° = +5$ kJ mol^{-1} for dissociation. Back to Table

B10. **O_3 + BrO.** There have been no reported experimental measurements on this reaction in the aqueous phase. A calculation at the B3LYP/LACV3P** level of theory, with interactions between water and the molecules were calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy change of $\Delta G° = -47$ kJ mol^{-1} for the path leading to OBrO and $\Delta G° = -268$ kJ mol^{-1} for the path to BrOO.[59] There was no evidence for the formation of an adduct as a minimum on the potential energy surface. Back to Table

B11. **BrOO →.** There have been no reported experimental measurements on this reaction in the aqueous phase. A calculation at the B3LYP/LACV3P** level of theory, with interactions between water and the molecules were calculated using Jaguar's Poisson-Boltzmann solver, led to a free energy change of $\Delta G° = -11$ kJ mol^{-1}.[59] Back to Table

B12. **O_3 + $OClO^-$/$OBrO^-$.** Kinetics of the reaction were determined by stopped-flow kinetic spectrophotometry, following the loss of O_3 at 260 nm at a pH 6 and an ionic strength of 1 mol L^{-1}.[60] The reported Eyring parameters are $\Delta H^‡ = 29 \pm 2$ kJ mol^{-1} and $\Delta S^‡ = -14.6 \pm 0.7$ J $mol^{-1}K^{-1}$ for chlorite and $\Delta H^‡ = 54.9 \pm 0.8$ kJ mol^{-1} and $\Delta S^‡ = 34 \pm 3$ J $mol^{-1}K^{-1}$ for bromite. The reported rate constants at 298 K for chlorite is $(8.2 \pm 4) \times 10^8$ L mol^{-1} s^{-1} and for bromite, $(8.9 \pm 3) \times 10^4$ L mol^{-1} s^{-1}. The rate constant at room temperature is about twice that reported by Kläning et al.[39] In the chlorite reaction, as the ratio of $[ClO_2^-]/[O_3]$ is increased to greater than 200, the stoichiometry of ClO_2 production becomes 2, supporting a mechanism in which the product O_3^- yields OH, which in turn reacts with ClO_2^- by electron transfer. On the other hand, in the bromite reaction, the products are found to be O_2 and BrO_3^-. Although this could suggest an atom-transfer reaction, the observation of BrO_2 as an intermediate supports an electron-transfer mechanism. Bromate, then, is formed in the disproportionation of BrO_2 which, unlike the comparable ClO_2 reaction, is fast. The electron-transfer mechanism has been supported in a study of the ozonation of bromide in the presence of methanol or *t*–butanol.[25] Back to Table

B13. **O_3 + OClO.** There have been several stopped-flow determinations of this reaction, all in close agreement.[64] The path leading to ClO_3 and O_2 has a calculated free energy of $\Delta G° = +6$ kJ mol^{-1} while that leading to ClO + $2O_2$ has $\Delta G° = -311$ kJ mol^{-1} at the B3LYP/LACV3P** level of theory, with interactions between water and the molecules calculated using Jaguar's Poisson-Boltzmann solver.[59] The generation of ClO_3 in the reaction of O_3 with OClO has been suggested as a possible step in the formation of ClO_4^-.[62] The fact that perchlorate production is a minor process in the oxidation of OClO, however, suggests this is not a very fast reaction. Back to Table

B14. **O_3 + OBrO.** No rate constants have been reported for this reaction. The path leading to BrO_3 and O_2 has a calculated free energy of $\Delta G° = +81$ kJ mol^{-1} while that leading to BrO + $2O_2$ has $\Delta G° = -380$ kJ mol^{-1}.[59] Unlike OClO, OBrO is unstable in water, lessening the chance of other secondary reactions. Back to Table

B15. **$O_3 + ClO_3^-$.** In a study of the production of perchlorate from the oxidation of chloride, a solution of chlorate was exposed to ozone for seven days. No reaction was observed.[62] Back to Table

B16. **$OH + Cl^-$.** Derived from a pulse radiolysis determination of the rise in Cl_2^- absorption with pH, with a steady-state analysis.[37] An equilibrium constant of 0.7 ± 0.13 M^{-1} was derived, leading to the rate constant for the reverse reaction. Other direct and indirect measurements are discussed in the review of Yu,[73] who recommends $k_f = (4.2 \pm 0.2) \times 10^9$ L mol^{-1} s^{-1} and $k_r = 6.1 \pm 0.8$ s^{-1} and by Ershov,[24], who also provides a thorough discussion of the effect of ionic strength on the overall system. The binding in the $ClOH^-$ complex has been investigated by *ab initio* quantum mechanical/molecular mechanics calculations for the aqueous phase at the CCSD(T) level. The calculations indicate a hemibonded ($HO{-}Cl^-$) structure,[68] contrary to earlier calculations at lower levels of theory[17] and contrary to gas-phase observations,[18] which indicated a hydrogen-bonded structure. This difference is due to the greater solvation stabilization of the hemibonded complex. The energy difference appears small, so that the hydrogen-bonded structure might still be important at the interface, as indicated by earlier studies.[40] Back to Table

B17. **$ClOH^- + H^+$ and $Cl + H_2O$.** Recommendation of Yu based on an analysis of the reported studies.[73] Back to Table

B18. **$ClOH^- + Cl^-$.** Obtained from a pulse radiolysis study of a concentrated chloride solution following product Cl_2^- formation at 340 nm.[28] The rate constant was derived through a complex analysis. Back to Table

B19. **$OH + Br^-$.** Rate constant obtained from a pulse-radiolysis study of N_2O and Ar saturated solutions containing 0.9 to 900 mmol L^{-1} NaBr by Yamashita, et al.[71] The results were improved by using a spur-diffusion model for very short times after the pulse. The kinetic model was optimized and the experimental observations were reproduced with the addition of one reaction to the set commonly employed: the self-reaction of $BrOH^-$ to produce Br_2, with a rate constant of 3.8×10^9 L $mol^{-1}s^{-1}$. For most of these individual reactions, similar results were reported earlier by Zehavi and Rabani,[74] the largest difference being for $OH + Br^-$, $k = 1.06 \times 10^{10}$ L $mol^{-1}s^{-1}$. A value for $BrOH^- + H^+$ was not reported by Yamashita, et al. and the listed value is from Zehavi and Rabani. The spectrum of the intermediate $BrOH^-$ has been characterized using picosecond pulse radiolysis, augmented by quantum chemical calculations that suggest the importance of different water-$BrOH^-$ complexes.[41] Back to Table

B20. **$OH + I^-$.** Absolute value at 297 K derived from the growth in optical absorbance at 380 nm following pulse radiolysis.[57] Temperature dependence obtained from rate constants measured relative to $OH + HCO_2^-$ by pulse radiolysis.[21] ($E_a = 12$ kJ mol^{-1} presented in paper.) Back to Table

B21. **$IOH^- \rightarrow$.** Taken from an optical study with modeling of reaction system at 22 ± 2 ºC following pulse radiolysis of an alkaline solution.[57] $k = (1.2 \pm 1.0) \times 10^8$ s^{-1} was reported in an older pulse radiolysis measurement of the formation of I_2^-.[22] Back to Table

B22. **$OH^- + Cl_2$.** Derived from measurements of the uptake of Cl_2 gas into water in a bubble-train flow reactor.[27] Measurements were made from 275 to 303 K and pH 6 to 10.4. Rate constants of 1.3 ± 0.5 (275 K), 6 ± 2 (293K) and 8 ± 3 (303 K) × 10^8 L mol^{-1} s^{-1} were reported. Back to Table

B23. **OH + HOCl.** OH generated by pulse radiolysis with the rate constant measured in competition with HSO_4^- (1.4×10^8) and HNO_3 (1.1×10^8).[75] A later study by continuous photolysis (primarily 254 nm) of HOCl and competition with OH + nitrobenzene, resulted in $k = 8.5 \times 10^4$ L mol^{-1} s^{-1}.[70] In this latter study, there appeared to be no allowance for any complication from ClO + nitrobenzene, which would tend to lower the apparent rate constant. A density-functional calculation on this reaction at the B3LYP/6-31(2df,p) level of theory, including the implicit polarizable continuum model SMD, has been reported.[55] Values of $\Delta G^{react} = -87.0$ kJ mol^{-1} and $\Delta G^{act} = 49.4$ kJ mol^{-1} were obtained. This high activation energy leads Minakata, et al. to argue in favor of this lower rate constant. But this argument only holds for a simple hydrogen-abstraction reaction. This is more likely to be a proton-transfer assisted electron-transfer reaction. This would make the reaction more similar to the Cl-atom reaction with HOCl, which is even faster and that is generally agreed to be an electron transfer reaction. Back to Table

B24. OH + ClO^-. Pulse radiolysis at pH 10.3, measured relative to the reaction of OH with CO_3^{2-}.[75] An earlier pulse radiolysis study at pH 11, also relative to CO_3^{2-}, resulted in a rate constant of 8.8×10^9 L mol^{-1} s^{-1} and a rate constant for oxidation by O^- of 2.3×10^8 L mol^{-1} s^{-1}.[13] Back to Table

B25. OH + HOBr. Kinetics derived from a flash photolysis study of HOBr solutions.[39] Back to Table

B26. OH + BrO^-. Rate constant obtained through a pulse radiolysis study of HOBr solutions containing carbonate at pH 11–13,[10] relative to OH + CO_3^{2-} (3.9×10^8 L mol^{-1} s^{-1}).[11] Also assuming pKa(OH) = 11.9. The rate constant for O^- + BrO^- was determined to be also 4.2×10^9 L mol^{-1} s^{-1}. Back to Table

B27. OH + HOI. Pulse radiolysis of HOI solution containing a borax buffer, with product formation kinetics at 350–550 nm, pH 9.[9] Back to Table

B28. OH + OClO. The average of two reported values, both by pulse radiolysis following the absorption of ClO_2, 4.0×10^9 L mol^{-1} s^{-1} [39] and 3.5×10^9 L mol^{-1} s^{-1}.[75] The reaction is probably electron transfer, with subsequent hydration of the ClO_2^+ product to yield ClO_3^-. Back to Table

B29. OH + $OClO^-$ (+ H^+). An average of three reported values, 6.1×10^9 L mol^{-1} s^{-1} by pulse radiolysis and competition with carbonate;[13] 7.0×10^9 L mol^{-1} s^{-1} following the production of ClO_2 after pulse radiolysis;[23] and 7.9×10^9 L mol^{-1} s^{-1} following ClO_2 after the flash photolysis of H_2O_2.[75] Back to Table

B30. O^- + IO^-. Rate constant obtained by formation kinetics of IO at 490 nm after pulse radiolysis of HOI solution containing 0.4 mol L^{-1} OH^-.[12] Back to Table

B31. O_2^- + Cl^-. Decay kinetics at 240 nm following the pulse radiolysis of a O_2-saturated formate solution.[51] Back to Table

B32. O_2^- + HOCl. Derived from the effect of pH on the decay kinetics at 240 nm in an O_2-saturated formate solution, using pulse radiolysis. K(HOCl) taken as 3.8×10^8 mol L^{-1}.[51] The formation of free OH radicals was confirmed by the hydroxylation of benzoate.[14] The reaction of HO_2 with HOCl is likely to be considerably slower, since it is a much weaker reductant than O_2^-.[2] Back to Table

B33. O_2^- + HOBr/OBr^-. Derived from a pH dependence study of the pulse radiolysis of bromine solutions containing formate.[66] The reaction of HO_2 with HOBr is likely to be considerably slower, since it is a much weaker reductant than O_2^-. Back to Table

B34. O_2^- + HOI/OI^-. Derived from a pH dependence study of the pulse radiolysis of iodine solutions containing formate.[66] The reaction of HO_2 with HOI is likely to be considerably slower, since it is a much weaker reductant than O_2^-. Back to Table

B35. HO_2 + Cl_2. Obtained from a pulse radiolysis study, following the decay of HO_2 and the formation of Cl_2^- at pH 2.[7] The rate constant for Cl_3^- was taken to be the same. Back to Table

B36. O_2^-/HO_2 + Br_2. Kinetics obtained by following the decay of HO_2 and the formation of Br_2^- as a function of pH and Br^- concentration, after pulse radiolysis.[66] Back to Table

B37. HO_2 + I^-. Limiting value from a pulse radiolysis study cited in a paper primarily about sonolysis. No reaction observed.[31] Back to Table

B38. O_2^-/HO_2 + I_2. Pulse radiolysis of an oxygen-saturated solution containing at least 10^{-4} mol L^{-1} iodide at 25 ºC.[66] The pH dependence and dependence on total iodine determined, allowing the determination of rate constants for individual species. For the HO_2 + I_2^- reaction, the equilibrium constant for was also obtained, K_{eq} = 30 mol L^{-1}. Kinetics were also measured at 3, 45, and 60 °C, leading to activation energies of 3.3 ± 0.4 kcal mol^{-1} for O_2^- + I_2 and 4.9 ± 0.4 kcal mol^{-1} for O_2^- + I_3^-. Back to Table

B39. **$H_2O_2 + X^-$.** Rates determined by following the evolution of oxygen from reaction mixtures containing hydrogen peroxide and the halide at temperatures from 0 to 50 °C (40 °C with added acid). Third-order rate constants listed for $[H^+]$-dependent pathway.[56] Activation energies of 23.6 ± 0.57 and 20.74 kcal mol^{-1} were reported for the Cl^- reactions; 21.1 ± 0.45 and 16.7 ± 0.18 kcal mol^{-1} for the Br^- reactions. Back to Table

B40. **$H_2O_2 + I^-$.** Reaction followed by monitoring the formation of triiodide by thiosulfate titration in solutions containing hydrogen peroxide and iodide at temperatures from 0 to 40 °C. Third-order rate also constants listed for a $[H^+]$-dependent pathway.[49] Activation energies of 13.4 ± 0.15 and 10.45 ± 0.12 kcal mol^{-1} were reported for the I^- reactions. Back to Table

B41. **$HO_2^- + HOCl$.** Reaction monitored at 25 ºC by spectrophotometry and O_2-evolution over the pH range 5–13, building on earlier work by Connick.[16] Measured rate constants reach a peak at about pH 9.5. Arguments based on the nucleophilic character of HO_2^- used to justify the preferred mechanism. The alternate mechanism, $H_2O_2 + OCl^- \rightarrow H_2O + Cl^- + O_2$ would have a derived rate constant of 3.4 x 10^3.[33] Studies from 8–25 ºC indicate weak temperature dependence with scattered results ($\Delta H^\# \sim 3$ kcal mol^{-1}). Chemical trapping by 2,5-dimethylfuran indicated an essentially 100% yield of singlet oxygen. See also discussion by Hurst.[36] Maetzke and Jensen and Storch, et al. have investigated the generation of singlet oxygen in the reaction with quantum chemical calculations, finding three possible pathways for the reaction[53] and predict close to a 100% yield.[67]

Castagna, et al.[15] observed OH from the reaction by using spin traps and electron-spin resonance spectroscopy. They ascribed this to the mechanism:

$$ClO^- + H_2O_2 \rightarrow ClO + OH + OH^-$$

This paper did not cite the earlier work by Held et al.,[33] or the various papers indicating singlet oxygen production. Also, no particular care to prevent exogenous transition-metal ions was indicated. This is particularly troublesome since both reagents, HOCl and H_2O_2, participate in Fenton chemistry, leading to OH production. Some arguments were presented based on reduction potentials, but used a very low value of the ClO/ClO- potential (0.64V) vs. the recommended value (1.39 ± 0.03 V).[2] DFT calculations also indicated that the direct reaction was about 10 kcal/mol endothermic. Much stronger evidence is needed to conclude that ClO and OH are generated directly in this reaction. Back to Table

B42. **$HO_2^- + HOBr$.** Measurements were performed using a stopped-flow spectrometer at 265 and 340 nm over the pH range 6–12 at 25 °C. Arguments based on the nucleophilic character of HO_2^- were employed to justify the preferred mechanism. The alternate mechanism, $H_2O_2 + OBr^- \rightarrow H_2O + Br^- + O_2$ would have a derived rate constant of $(1.2 \pm 0.2) \times 10^6$.[69] Back to Table

B43. **$H_2O_2 + IO^-$.** Based on a re-analysis of several studies of the reduction of I_2 by H_2O_2 by Schmitz.[65] Contradictions among the results were resolved by assuming the equilibria for HOI in the presence of I^-

$$HOI \leftrightarrow IO^- + H^+$$
$$HOI + I^- \leftrightarrow I_2OH^-$$

Both reactions are thought to proceed through an IOOH intermediate, which is assumed to react rapidly with OH^-. There are significant differences between this mechanism and that proposed earlier by Ball and Hnatiw.[4] Back to Table

B44. **O_2 + I.** In a study involving the flash photolysis aryl iodides to generate I atoms, no effect of O_2 was observed on the subsequent reaction of I with I^-.[1] Back to Table

B45. **HO_2^-/H_2O_2 + OClO.** Rate constant obtained from a stopped-flow study over the pH range 5 to 11 and 22–24 ºC, correcting for the stoichiometry of 2.[34] Back to Table

B46. **OH + I_2.** Pulse radiolysis of acidic iodine solutions, following the decrease in iodine absorption at 460 nm and modeling a complex mechanism, led to the rate constant.[20] A product formation study, monitoring the I atom at 280 nm, found $k = 1.1 \times 10^{10}$.[66] Back to Table

B47. **$O_2(^1\Delta_g)$ + Cl^-.** Rate from a flash-photolysis study in the presence of a photosensitizer. No information to indicate that this is a chemical reaction as opposed to physical quenching.[19,64] Back to Table

B48. **$O_2(^1\Delta_g)$ + I^-.** Rate obtained by following the $O_2(^1\Delta_g) \rightarrow O_2(^3\Sigma)$ emission at 1.3 µm. Evidence for the oxidation of I^- instead of quenching was obtained by observing I_3^- formation. The mechanism was postulated to involve the formation of HOOI/IO_2^- followed by subsequent reaction with I^- to give I_3^- and H_2O_2.[8] Earlier studies, primarily by chemical analysis of sensitized systems, support these conclusions.[64] Back to Table

6.4 Formation and Dissociation of Dihalo Radicals

Reaction	k (L mol^{-1} s^{-1}) *	Note
$Cl + Cl^- \rightarrow Cl_2^-$	$(7.8 \pm 0.8) \times 10^9$	C1
$Cl_2^- \rightarrow Cl + Cl^-$	$(5.7 \pm 0.4) \times 10^4\ s^{-1}$	C1
$Br + Br^- \rightarrow Br_2^-$	$(5.11 \pm 0.98) \times 10^{12} \exp(-1812 \pm 60/T)$	C2
$Br_2^- \rightarrow Br + Br^-$	$(2.54 \pm 2.03) \times 10^{10} \exp(-4068 \pm 255/T)\ s^{-1}$	C2
$I + I^- \rightarrow I_2^-$	$(2.4 \pm 0.1) \times 10^{13} \exp(-2324 \pm 77/T)$	C3
$I_2^- \rightarrow I + I^-$	$(2.6 \pm 0.4) \times 10^{12} \exp(-5157 \pm 198/T)\ s^{-1}$	C3
$Br + Cl^- \rightarrow ClBr^-$	1.0×10^{10}	C4
$ClBr^- \rightarrow Br + Cl^-$	$8.5 \times 10^7\ s^{-1}$	C4
$Cl_2^- + Br^- \rightarrow ClBr^- + Cl^-$	4×10^9	C4
$ClBr^- + Cl^- \rightarrow Cl_2^- + Br^-$	1.1×10^2	C4
$ClBr^- + Br^- \rightarrow Br_2^- + Cl^-$	8.0×10^9	C4
$Br_2^- + Cl^- \rightarrow ClBr^- + Br^-$	4.3×10^6	C4
$I + Br^- \rightarrow BrI^-$	1.0×10^{10}	C5
$BrI^- \rightarrow I + Br^-$	$5.7 \times 10^8\ s^{-1}$	C5
$Br_2^- + I^- \rightarrow BrI^- + Br^-$	4.3×10^9	C5
$BrI^- + Br^- \rightarrow Br_2^- + I^-$	$<1 \times 10^5$	C5
$BrI^- + I^- \rightarrow I_2^- + Br^-$	5.8×10^9	C5
$I_2^- + Br^- \rightarrow BrI^- + I^-$	4.3×10^6	C5
$Cl_2^- + I^- \rightarrow 2\ Cl^- + I$	4.5×10^9	C6
$ICl + Br^- \rightarrow IBr + Cl^-$	See Note	C7
$ICl + I^- \rightarrow I_2 + Cl^-$	$(1.1 \pm 0.1) \times 10^9$	C8
$HOI + Cl^- + H^+ \rightarrow ICl + H_2O$	fast	C9
$HOI + Br^- + H^+ \rightarrow IBr + H_2O$	fast	C10
$HOI + I^- (+ H^+) \rightarrow I_2 + H_2O$	$(0.3\text{–}3) \times 10^9$	C11

* Unless units noted otherwise

6.4.1 Notes: Formation of Dihalo Radicals

C1. **$Cl + Cl^- \leftrightarrow Cl_2^-$.** Selected values from review of the extensive literature on these reactions and the equilibrium constant.[10] Back to Table

C2. **$Br + Br^- \leftrightarrow Br_2^-$.** Bromine atoms produced by flash photolysis of 1,2-dibromoethane in solutions containing Br^-, monitoring Br_2^- at 365 nm by optical absorption, over the temperature range 10.5−50 ºC.[6] Room temperature value for forward reaction in agreement with the several earlier flash photolysis and pulse radiolysis studies.[9] Back to Table

C3. **$I + I^- \leftrightarrow I_2^-$.** Flash photolysis of iodide solutions following the temporal behavior of the absorption due to I_2^- over the temperature range 286-320 K. Forward reaction shows some ionic strength dependence; somewhat greater was observed for the reverse reaction.[7] Back to Table

C4. **$Br + Cl^- \leftrightarrow ClBr^-$.** Rate constant derived in a pulse radiolysis investigation of the oxidation of Br^- by Cl_2^-.[5] The kinetics was determined by following the absorbance at 700 nm, where Br_2^- and $BrCl^-$ absorb, but not Cl_2^-, and then modeling a complex mechanism. Back to Table

C5. **$I + Br^- \leftrightarrow BrI_2^-$.** Pulse radiolysis of a 0.1 mol L^{-1} NaBr solution (pH 3.3) containing 5×10^{-5} mol L^{-1} NaI and modeling a complex mechanism led to the rate constant. Data obtained by absorption spectroscopy at 725, 340, and 400 nm.[4] Back to Table

C6. **Cl_2 + I^-.** Pulse radiolysis of a 1 mol L^{-1} NaCl solution pH 3.3) containing 5 × 10^{-5} mol L^{-1} NaI. Rate constant derived from a fit to a complex model.[3] Back to Table

C7. **ICl + Br^-.** The uptake of ICl into droplets containing Br^- showed a rapid production of ICl suggesting a fast reaction.[1] No rate constant was derived, however. Back to Table

C8. **ICl + I^-.** Rate constants were measured at an ionic strength of 1.0 mol L^{-1} by investigating the reaction of ICl_2^- with I^- using a pulsed-accelerated flow system at 25 °C, monitoring at 350 nm.[8] Back to Table

C9. **HOI + Cl^- + H^+.** A study of the uptake of HOI on solutions containing Cl^- suggested that this reaction is fast.[1] No rate constant was derived, however. Back to Table

C10. **HOI + Br^- + H^+.** By analogy with the reaction of HOI with Cl^- and with I^-, this reaction is expected to be fast. Back to Table

C11. **HOI + I^- (+ H^+).** Results from a pulse radiolysis study of N_2O- saturated solutions of iodide at pH 9.5–11.1 were combined with earlier studies of the γ-radiolysis of unbuffered solutions, to derive this rate constant.[2] Back to Table

6.5.1 Notes: Formation and Loss of Halogen Molecules and Dihalo Radicals

D1. **$Cl_2^- + Cl_2^-$.** The value given is an unweighted average taken from an extensive literature review.[16]

D2. **$Br_2^- + Br_2^-$.** In a pulse radiolysis study of decay kinetics at 360 nm at an ionic strength of 0.01 mol L^{-1} and pH 2–7 and taking ε = 9,900 L mol^{-1} cm^{-1}, rate constants of 2.2 and 2.5 × 10^9 L mol^{-1} s^{-1} were measured at ionic strengths of 0.1 and 1.0 mol L^{-1}.[2] These values are in agreement with a number of other reports.[11]

D3. **$I_2^- + I_2^-$.** Pulse radiolysis study of decay kinetics at 725 nm at an ionic strength of 0.1 mol L^{-1}, T = 15−90 °C, and pH 7 and taking ε = 2,650 L mol^{-1} cm^{-1}.[4] E_a = 15 kj mol^{-1}. Room temperature value slightly below some earlier reports, but in agreement with more recent measurements.[11]

D4. **$Cl + Cl_2^-$.** Selected value, which is an unweighted average of two reports, from review of the literature.[16]

D5. **$Br + Br_2^-$.** An assumed value that was used in modeling hydrogen abstraction reactions of bromine atoms generated from the one-electron reduction of 1,2-dibromoethane.[8] This reaction would be followed by the rapid reaction $Br^- + Br_2 \rightarrow Br_3^-$.

D6. **$I + I_2^-$.** Value is an unweighted average of results from Elliot[3] and Ishigure, et al. (See Note on $O_2^-/HO_2 + I_2^-$)[6], both of which were obtained in pulse radiolysis studies.

D7. **$OH^- + Cl_2^-$.** Rate constant taken from a study involving the pulse radiolysis of concentrated chloride solutions, following the decay of Cl_2^- at 340 nm.[5]

D8. **$HO_2 + Cl_2^-$.** An unweighted average of three values taken from a review of the literature.[16] The possibility that the reaction might yield Cl_2 and H_2O_2 was considered in a pulse radiolysis study of the HO_2/Cl_2 reaction. It was concluded that this path was not important and an upper limit of 5×10^7 L mol^{-1} s^{-1} was suggested.[1]

D9. **$O_2^- + Cl_2^-$.** From an analysis of the decay kinetics of Cl_2^- in an O_2-saturated solution compared with a deaerated solution.[18] By comparison with the other dihalide radicals, this rate constant seems too low.

D10. **$O_2^-/HO_2 + Br_2^-$.** Results from the flash photolysis of bromide solutions following conductivity changes. Computer simulation utilized to extract rate constants and branching ratios.[15] Earlier studies assumed only Br^- was formed. A more recent study with continuous illumination at 313 nm and following Br_2(g) production, led to the conclusion that the rate constants for Br_2 and Br^- production in the $HO_2 + Br_2^-$ reaction were equal at 4.4×10^9 L mol^{-1} s^{-1}.[7]

D11. **$O_2^-/HO_2 + I_2^-$.** Data obtained in an investigation on the radiolysis of aqueous iodine solutions.[6] The main study utilized continuous radiation and a flow system to investigate the mechanism of the overall reaction. Pulse radiolysis was then utilized to obtain kinetic data. Results were presented, but there was no detailed analysis. An earlier study, fitting to a complex mechanism and assuming a concentration of $\sim 7 \times 10^{-8}$ mol L^{-1} for the radicals, resulted in k ~ 1×10^{10} L mol^{-1} s^{-1} for the HO_2 reaction.[12]

D12. **$H_2O_2 + Cl$.** Rate constant obtained from a study of the photolysis of H_2O_2 in acid solutions.[17] Derived value depends on $K_{eq}(Cl + Cl^- \leftrightarrow Cl_2^-) = 1.4 \times 10^5$ L mol^{-1}.

D13. **$H_2O_2 + Cl_2^-$.** Preferred value from a review of the literature. [16] The large spread in the reported values is reflected in the error limit.

D14. **$ClO^- + Cl_2^-$.** Rate constant extrapolated to zero ionic strength. From the pulse radiolysis of a 5 mol^{-1} L^{-1} LiCl solution containing HClO.[19]

D15. **$OClO^- + Cl_2^-$.** Average of two rate constants extrapolated to zero ionic strength at ~20 ºC. One from the pulse radiolysis of a 5 mol^{-1} L^{-1} LiCl solution containing $HClO^-$; the other from the flash photolysis of a persulfate solution at an ionic strength of 0.25 mol^{-1} L^{-1}.[19]

D16. **$OClO^- + Br_2^-$.** Radicals generated by the pulse radiolysis of an 0.1 mol L^{-1} solution of NaBr, saturated with N_2O, at pH 6.8, over the temperature range 5-79 ºC and rate constants derived by following the decay of the optical absorption at 360 nm.[13] $E_a = 20 \pm 2.7$kJ mol^{-1}. At 298 K, the rate constant is 1.9×10^7 L mol^{-1} s^{-1}, which is significantly greater than the value obtained from fitting a multi-step mechanism to observations on the chlorite - bromine system, $k = (4.0 \pm 0.1) \times 10^6$ L mol^{-1} s^{-1}.[14]

D17. **$OClO^- + Cl_2$.** The formation of ClO_2 was followed in the reaction of Cl_2 with ClO_2^- at 359 nm with stopped-flow spectrophotometry over the pH range 3.6 to 6.0, at 25 ºC and at an ionic strength of 1 mol L^{-1}.[10] The possibility of an electron-transfer reaction leading to the direct formation of ClO_2 was ruled out by the lack of suppression by added ClO_2. The results indicated that the rate constant for the reaction of ClOClO with ClO_2^- must be >>6 x 10^5 L mol^{-1} s^{-1}.

D18. **$OClO^- + Br_2$.** Rate constant obtained by fitting observations at 25 ºC on the chlorite-bromine system to a multi-step model.[14] The rate constant for the reverse reaction was reported to be $k = 1.1 \times 10^9$ L mol^{-1} s^{-1}. See also Note on $ClO_2^- + Br_2^-$.

D19. **$HCO_3^-/CO_3^{2-} + Cl$.** Rate constants were determined relative to the reaction of chlorine atoms with tetrachlorethene during its 254 nm photolysis in the presence of added carbonate/bicarbonate.[9]

6.6.1 Notes: Halogen Interconversion Reactions

E1. **OCl/ClO^- + Br^-.** The reaction was studied by the stopped-flow method and appears to take place by two mechanisms, both a general-acid catalyzed reaction:

$$HA + HOCl + Br^- \rightarrow A^- + H_2O + BrCl$$

and a direct reaction

$$HOCl + Br^- \rightarrow OH^- + BrCl$$

followed, in both cases, by the rapid hydrolysis reaction

$$BrCl + H_2O \rightarrow HOBr + H^+ + Cl^-$$

Kumar and Margerum[27] measured the rate constant for direct reaction in acid by stopped-flow kinetic spectrophotometry to be $k = 1.55 \times 10^3$ L mol^{-1} s^{-1}. The acid-catalyzed reaction has a rate constant of $(1.32 \pm 0.03) \times 10^6$ L^2 mol^{-2} s^{-1} for HA = H^+ and $(6.11 \pm 0.34) \times 10^4$ L^2 mol^{-2} s^{-1} and $(2.09 \pm 0.01) \times 10^4$ L^2 mol^{-2} s^{-1} for chloroacetic acid and acetic acid, respectively. No values were reported for the inorganic acids of importance in atmospheric aerosols. All rate constants are at 25 °C.

Farkas, et al.[15] carried out rate measurements over the pH range 10–14 by using batch reactors and titrating aliquots. The rate constant was proportional to [H^+], indicating HOCl is the only oxidant. At 25 °C, a value of 2.95×10^3 L mol^{-1} s^{-1}was determined, in good agreement with the value of Kumar, et al. From measurement at 15 to 40 °C, a temperature dependence of ~2300 K was estimated.

Bousher, et al.[9] determined rate constants both with and without the addition of alkali and alkaline-metal ions. Measurements over the pH range 8.1–11.4 confirmed that HOCl was the reactive species. There was a small dependence on ionic strength above $\mu = 0.3$ mol L^{-1}, which was suggested to be due to the formation of NaOCl ion-pairs. Rate constants measured over the temperature range 3.3–37.0 °C led to the rate expression $k = 1.57 \times 10^6 \exp(-1.62 \times 10^3/T)$ L mol^{-1} s^{-1} ($k_{298} = 6.8 \times 10^3$ L mol^{-1} s^{-1}). Third-order rate constants were derived to express the effect of alkali and alkaline-metal ions: Na^+, 11.6; K^+, 2.9; Mg^{2+}, 4.2×10^3; Ca^{2+}, 1.7×10^4, all in units of L^2 mol^{-2} s^{-1}. Transition-metal ions were found to have no effect on the reaction, other than to be oxidized themselves. Back to Table

E2. **ClO^- + I^-.** This value was estimated by Gerritsen and Margerum [18] from a study of the oxidation of iodide by hypochlorite reported earlier from the same laboratory.[26] Back to Table

E3. **HOCl + I^-.** In the reaction of HOCl with I^-, there is kinetic evidence from the pulsed-accelerated flow method for the formation of an intermediate addition product.[32]

$$HOCl + I^- \leftrightarrow HOClI^-$$

This is followed by the dissociation of this complex, either directly or acid-assisted

$$HOClI^- \rightarrow OH^- + ICl$$
$$HOClI^- + H^+ \rightarrow H_2O + ICl$$
$$HOClI^- + HA \rightarrow A^- + H_2O + ICl$$

At 298 K and I = 0.1 mol L^{-1}, the equilibrium constant for the formation of the intermediate is K = (2.2 ± 0.5)

$\times 10^2$ L mol^{-1}. The forward and reverse rate constants are $(4.3 \pm 0.3) \times 10^8$ L mol^{-1} s^{-1} and $(1.9 \pm 0.7) \times 10^6$ s^{-1}, respectively. Rate constants for the direct dissociation of the complex is $(9 \pm 3) \times 10^5$ s^{-1}; for the proton-assisted dissociation $k = (2.3 \pm 0.5) \times 10^9$ L mol^{-1} s^{-1}; and for the dissociation assisted by $H_2PO_4^-$, $k = (1.7 \pm 0.6) \times 10^8$ L mol^{-1} s^{-1}.

It is expected that any similar complexes for the other halides are too short lived to be important.

The rate constant for the overall reaction

$$HOCl + I^- + H^+ \rightarrow H_2O + ICl$$

can be calculated to be 3.5×10^{11} L^2 mol^{-1} s^{-1}.

For the overall reaction assisted by phosphorous acid

$$HOCl + I^- + H_2PO_4^- \rightarrow H_2O + ICl + HPO_4^{2-}$$

$k = 2.6 \times 10^{10}$ L^2 mol^{-1} s^{-1}.

An earlier study using a rapid-flow technique at 17.3, 25, and 34.3 °C at [NaOH] = 0.3 mol L^{-1} and an ionic strength of 1.0 mol L^{-1} resulted in a rate expression of $k = 1.6 \times 10^9 \exp(-0.9\ \text{kcal}/RT)$ L mol^{-1} s^{-1} ($1.6 \times 10^9 \exp(-450/T)$).[30] An earlier study demonstrated that the reaction showed an inverse dependence on [OH$^-$] and derived a rate constant at 25 °C of 61 s^{-1}.[11] Back to Table

E4. **BrO$^-$/HOBr + I$^-$.** The reaction was studied by the accelerated-pulsed flow method at 25 °C and an ionic strength of 0.5 mol L^{-1} by following the loss of BrO$^-$ at 329 nm. [OH$^-$] was varied from 0.10 to 0.50 mol L^{-1}, leading to the individual rate constants.[42] (As part of this study, the pK_a value for HOBr was determined under these conditions to be 8.8 ± 0.1.) The formation of an intermediate HOBrI$^-$ was suggested, but its lifetime was too short for observation. Back to Table

E5 **IO$^-$ + I$^-$.** The rate constant was derived during a study of the I_2/I^- system under strongly basic conditions (25 ºC,1 mol L^{-1}, and pH 10.5 and 12). UV/VIS and Raman spectroscopy were used to monitor IO$^-$, I_2OH^-, and IO_2^-.[46] Back to Table

E6. **HOCl + HOCl.** The decomposition of HOCl/ClO$^-$ has been studied extensively over the past century. In general, the final products have been reported to be chlorate, ClO_3^-, and chloride, with a ratio of HOCl to ClO_3^- of 2.91 ± 0.09.[1] The overall rate is proportional to [OCl$^-$] and to [HOCl]^2, with a maximum at pH 6.9. The observation of both HOCl and Cl_2O in the vapor above HOCl solutions, with the latter predominating at high concentrations,[35] along with the kinetic observations, has led to the accepted mechanism for the system:[1]

$$2\,HOCl \leftrightarrow Cl_2O{\cdot}H_2O \quad (1)$$

$$OCl^- + Cl_2O{\cdot}H_2O \rightarrow HCl_2O_2^- + HOCl \quad (2)$$

$$HCl_2O_2^- \rightarrow HClO_2 + Cl^- \quad (3)$$

$$ClO_2^- + Cl_2O{\cdot}H_2O \rightarrow HCl_2O_3^- + HOCl \quad (4)$$

$$HCl_2O_3^- \rightarrow HClO_3 + Cl^- \quad (5)$$

The equilibrium constant for reaction (1) is uncertain, but has been estimated to be 1.15×10^{-2} at 298 K.[5] A value of 1.5×10^{-2} has also been theoretically calculated (see Note on HOCl + HOBr).[37] A rate constant of $k_1 = 0.12$ L mol^{-1} s^{-1} for the reaction was determined by monitoring the oxidation of $Ni^{II}(CN)_4^{2-}$ by the Cl_2O generated in HOCl solutions at pH 5–6 and $\mu = 0.1$ mol L^{-1}.[5] An acetic acid catalyzed pathway with a rate constant of 280 L^2 mol^{-2} s^{-1} was also reported. A rate constant at $\mu = 0.6$ mol L^{-1} of 0.124 L mol^{-1} s^{-1} for the direct reaction and 3.1 L^2 mol^{-2} s^{-1} for the general acid catalyzed reaction were reported from a study of the chlorination of anisole.[40] The acid-catalyzed pathway is expected to be negligible above pH 4.

At higher pH values (>9), the decomposition reaction is very slow and seems to involve only a second-order interaction of OCl$^-$

$$2\,OCl^- \rightarrow OClO^- + Cl^- \quad (6)$$

$$OCl^- + OClO^- \rightarrow ClO_3^- + Cl^- \quad (7)$$

where reaction (6) is rate limiting.[2] The rate constant was determined by following the decomposition of 2.15 mol L^{-1} ClO^- at $[OH^-]$ = 0.10 mol L^{-1}.[2] A fit of kinetic data taken as a function of temperature (25–50 °C) and ionic strength, μ = (2.5–5.7 mol L^{-1}) led to the complex rate constant expression: $\log k = 0.149\mu + \log[2.083 \times 10^{10}\,T \exp(-1.018 \times 10^5/RT) \exp(-56.5/R)]$. The enthalpies and entropies of activation range from $\Delta H^{\neq}$ = 101.0 kJ mol^{-1} and $\Delta S^{\neq}$ = –56.2 J mol^{-1}K^{-1} at u = 1 mol L^{-1} to $\Delta H^{\neq}$ = 97.1 kJ mol^{-1} $\Delta S^{\neq}$ = –54.8 J mol^{-1} K^{-1} at μ = 6 mol L^{-1}. The rate constant for reaction (7) was from the formation and decay of ClO_2^-.

There is also a less important pathway leading to O_2:[29,36]

$$HOCl + HOCl \rightarrow O_2 + 2Cl^- + 2H^+$$

Subsequent work demonstrated that some significant fraction of the oxygen was formed in the excited state, $O_2(^1\Delta_g)$.[24] Mechanistic details for the generation of singlet oxygen in this system have been investigated theoretically.[22] Back to Table

E7. **$BrCl + ClO^-/BrO^-$ and subsequent reactions.** Rate constants for individual steps were obtained in a study of the effect of the bromide ion on solutions of HOCl, by following the evolution of the system spectrophotometrically.[31] This set of reactions, along with others previously reported, was proposed to explain the observations. Back to Table

E8. **HOCl + HOBr.** In a spectrophotometric study of the effect of the bromide ion on solutions of HOCl, no direct reaction of HOCl with HOBr was observed.[31]

$$K(HOCl + HOBr) = 0.35$$

Sivey, et al.[37] have carried out quantum chemical calculations on the reaction

$$HOCl + HOBr \rightarrow BrOCl + H_2O$$

Geometric parameters were optimized at the CCSD(T) level of theory using the acg-cc-pVTZ basis set. Energies were computed extrapolating to infinite basis set and corrected for higher order excitations. Additional correction for core/valence correlation and scalar relativistic effects were applied. These gas-phase Gibbs energies were then transferred to the aqueous phase by using a variant of the cluster continuum approach. They obtained a value of Keq = 0.35, with a suggested uncertainty of a factor of two. Taking the same approach, $K_{eq}(HOCl + HOCl)$ = 0.015 was also calculated. Back to Table

E9. **$K_{eq}(HOBr + HOBr)$ = 6.31** Beckwith and Margerum measured the rate of hydrobromous acid decomposition at 25 °C from pH 0.2 to 10.2 spectrophotometrically at 260 nm (310 nm for pH <2).[6] They combined their measurements with literature results, primarily at higher pH, to derive the listed values. A value of K_{eq} = 6.3 for $2HOBr \rightarrow Br_2O + H_2O$ has also been theoretically calculated (see Note on HOCl + HOBr).[37] Back to Table

E10. **$HOCl/ClO^-$ + HOI.** The kinetics of the reaction of $HOCl/ClO^-$ with HOI + IO^- was investigated over pH 5.3–8.9 by following the formation of IO_3^-. The rate constant for the HOCl reaction decreased to 5.6 ± 1.0 at 10 ºC. The reaction involved both second-order and a third order paths (second-order in HOCl). The derived third-order rate constant was $k^{3d} = (8.3 \pm 0.8) \times 10^4$ M^{-2}s^{-1}.[7] For the ClO^-, the rate constant decreased to 33 ± 4 at 10 ºC. Back to Table

E11. **$HOI + HOI/IO^-$.** The overall disproportionation of HOI involves the self-reaction of HOI to generate IO_2^- in the rate-limiting step, followed by the rapid reaction of IO_2^- with HOI to yield IO_3^- and I^-. The reaction was followed over the pH range 7.6─11.1 by Bichsel and von Gunten[8] at 25 ºC in a batch reactor containing borate or carbonate buffer solutions. Aliquots were withdrawn and an excess of KI added to convert the HOI to I_3^-, which was then measured spectrophotometrically. The measured rates were found to be proportional to $[HOI]^2$, $[HOI][OI^-]$, and $[base][HOI]^2$, where "base" is the basic form of the buffer. The rate constants obtained for HCO_3^-, CO_3^{2-}, and $B(OH)_4^-$ were 50 ± 20, 5000 ± 500, and 1700 ± 600 L^2 mol^{-2} s^{-1}, respectively.

As part of this study, the acid dissociation constant of HOI was determined to be $pK_a = 10.4 \pm 0.1$ at 25 °C and μ = 0.05 mol L^{-1}.

In an earlier study by Urbansky, et al.,[43] an upper limit of 2 L mol^{-1} s^{-1} for the uncatalyzed reaction at 25 ºC was determined. Both catalysis and inhibition by acetate were observed.

In an earlier work, a rate constant for the reaction at 25 ºC of $k = 25 \pm 5$ L mol^{-1} s^{-1} was reported for a system in which a significant concentration of sulfate/bisulfate was present.[17]

In a study of the I_2/I^- system under strongly basic conditions (25 ºC, 1 mol L^{-1}, and pH 10.5 and 12), using both uv/vis and Raman spectroscopy,[46] a rate constant for HOI + IO^- was reported to be $k = 40 \pm 5$ L mol^{-1} s^{-1}. Back to Table

E12. **$IO^- + IO^-$.** In a study of the I_2/I^- system under strongly basic conditions (25 ºC, 1 mol L^{-1}, and pH 10.5 and 12), using both uv/vis and Raman spectroscopy,[46] this upper limit was reported for the $IO^- + IO^-$ reaction. Back to Table

E13. **IO^-/HOI + IO_2^-.** The rate constant for the reaction of $IO^- + IO_2^-$ was reported under strongly basic conditions.[46] From a study over the pH range 7.6–11.1, the reaction HOI + IO_2^- was simply reported as "fast".[8] Back to Table

E14. **$Cl_2 + I^-$.** Pulse radiolysis of a 1 mol L^{-1} NaCl solution pH 3.3) containing 5×10^{-5} mol L^{-1} NaI. The absorption increase at 725 nm was followed and fit to a complex model.[13] Back to Table

E15. Reactions of Cl and Br with HOCl and HOBr and subsequent reactions. Rate constants derived from a laser-flash photolysis study at 248 nm and 308 nm of hypochlorous and hypobromous acid.[25] The X_2O_2 products of the XO self-reactions are expected to convert to XO^- and XO_2^-, primarily through hydrolysis. Back to Table

E16. **IO + IO.** Pulse radiolysis of an N_2O-saturated borate-buffer solution (pH 9) containing HOI.[10] Similar values found using flash photolysis at pH 12.8 (2.1×10^9,[39]) and pulse radiolysis at pH 13.6 (2.0×10^9 [4]) Back to Table

E17. **$BrO_2 + OClO^-$.** Pulse radiolysis at pH 9.2, following both the decay of BrO_2 at 475 nm and the formation of ClO_2^- at 360 nm.[21] In a study of the bromite ion catalysis of ClO_2 disproportionation, the rate constant for the reverse reaction was determined to be 36 L mol^{-1} s^{-1}.[45] Back to Table

E18. **HOCl + ClO_2^-.** The reaction was studied by kinetic spectrophotometry.[23] The mechanism is complex and the formation of $HOClOClO^-$ is reversible. This intermediate also reacts with a general base to form the ClO dimer:

$$HOClOClO^- + HA \rightarrow ClOClO + A^- + H_2O$$

For the phosphate monoanion, $H_2PO_4^-$, the ratio of the rate constants is $k^{\mathrm{H2PO4}}\ H_2PO_4^-/k^{-1} = 8.5 \pm 0.9$ M^{-1}. For acetic acid, the ratio is 20 M^{-1}. From the study in acetic acid, the value for $k^{\mathrm{H+}}/k^{-1}$ was calculated to be $(1.6 \pm 0.5) \times 10^4$ M^{-1}.

The ClO dimer reacts with $OClO^-$, OH^-, or a general base catalyst, A^-, all in rapid reactions. The first yields two molecules of ClO_2; the other two generate ClO_3^-.

The work of Jai, et al.[23] built upon and expanded the earlier work of Taube and Dodgen,[41] Peintler, et al.,[34] and Gordon and Tachiyashiki.[19]

In a kinetic spectrophotometric experiment, Yin and Ni determined that the generation or addition of chloride positively influenced the generation of OClO.[47] The mechanism for this effect is not clear. Back to Table

E19 **HOCl + $OBrO^-$.** The reaction was studied by kinetic spectrophotometry.[33] The mechanism is complex and the products of the over-all reaction are given. The loss of BrO_2^- and formation of ClO_2 were both monitored, and ion chromatography was used to determine the end products. The rate-determining steps are:

(1) $HOCl + OBrO^- \leftrightarrow HOClOBrO^-$ $\qquad k_1 = 1.6 \times 10^2$ L mol^{-1} s^{-1}

(2) $HOClOBrO^- + H^+ \rightarrow {}^-OClOBrOH + H^+$ $k_2/k_{-1} = 2.8 \times 10^5\ M^{-1}$

These are followed by:

(3) ${}^-OClOBrOH \rightarrow ClO_2^- + HOBr$ k_3 = fast
(4) ${}^-OClOBrOH + H^+ \rightarrow ClOBrO + H_2O$ k_4 = fast

The ClO_3^- and BrO_3^- are formed thru subsequent reactions of HOCl with the ClOBrO intermediate. Cl_2O, formed in the self-reaction on HOCl, $2HOCl \leftrightarrow Cl_2O + H_2O$, $K = 0.0115\ M^{-1}$, also reacts with BrO_2^-

(5) $Cl_2O + OBrO^- \leftrightarrow HOClOBrO^-$ $k_5 = 1.8 \times 10^5\ L\ mol^{-1}\ s^{-1}$ Back to Table

E20. $ClO^- + OClO$. From a spectrophotometric study of the effect of hypochlorite on the decomposition of chlorine dioxide.[44] The suppression of the reaction by the addition of ClO_2^- led to the conclusion that the reaction is electron transfer, unlike the addition reaction proposed in an earlier study.[12] Activation parameters were determined from measurements over 5−25 °C to be $\Delta H^{\neq} = 61 \pm 3\ kJ\ mol^{-1}$ and $\Delta S^{\neq} = -43 \pm 2\ J\ mol^{-1}\ K^{-1}$. Back to Table

E21. $ClO + OClO^-$. Pulse radiolysis of a N_2O-saturated solution of 0.01 mol L^{-1} sodium hypochlorite containing $3. \times 10^{-5}$ to 2.5×10^{-4} mol L^{-1} added sodium chlorite at pH 10.[3] Wang and Margerum estimated $k = 7 \times 10^9\ L\ mol^{-1}\ s^{-1}$.[44] Back to Table

E22. $HOBr + OClO^-$. A study of the formation of ClO_2 and ClO_3^- from the action of HOBr with ClO_2^- that the intermediate $HOBrOClO^-$ (or $HOBrClO_2^-$) is formed in a reversable reaction with the listed rate constant.[16] This intermediate then either reacts with a general acid to yield BrOClO or reverts to the original reactants. The ratios of the acid-assisted rate constant to the decomposition rate constant were: $(3.1 \pm 0.5) \times 10^5$ (H_3O^+); 8.3 ± 0.6 ($H_2PO_4^-$); 0.064 ± 0.004 (HCO_3^-); and $\sim 3.5 \times 10^{-6}$ (H_2O), all in units of $L\ mol^{-1}$. The intermediate BrOClO then reacts rapidly with either ClO_2^- to generate 2 molecules of ClO_2, or with OH^- to generate ClO_3^-. Back to Table

E23. $BrO/BrO^- + ClO_2/ClO_2^-$. From a spectrophotometric study of the effect of hypohalites on the decomposition of chlorine dioxide.[44] The suppression of the reaction by the addition of ClO_2^- led to the conclusion that the reaction is electron transfer. The equilibrium constant for the reaction was estimated from the reduction potentials, leading to the calculated value for the reverse reaction. The rate constant for the addition of BrO to ClO_2 was evaluated from the effect of excess ClO_2^- on the reaction, which leads to a second-order dependence. For the reaction of BrO^- with ClO_2, activation parameters of $\Delta H^{\neq} = 55 \pm 1\ kJ\ mol^{-1}$ and $\Delta S^{\neq} = -49 \pm 2\ J\ mol^{-1}\ K^{-1}$ for T = 5–25 °C were determined. Back to Table

E24. $ClO_2 + Cl^-$. In a careful study of this reaction, either as expressed as a bimolecular reaction or as a termolecular reaction, $2ClO_2 + Cl^-$, it was concluded that what little reaction observed was probably due to photolysis by the light source used to monitor the reaction.[38] Back to Table

E25. $ClO_2 + Br^-$. The absorbance of ClO_2 at 358 nm was monitored and no reaction observed.[20] Back to Table

E26. $ClO_2 + I^-$. The reaction was monitored in a stopped-flow study over the temperature range 3 to 46 °C by following the generation of I_3^- in the 350–470 nm range.[14] The 298 K value, $(1.87 \pm 1.02) \times 10^3\ L\ mol^{-1}\ s^{-1}$ is slightly higher than the earlier value of $(1.4 \pm 0.2) \times 10^3\ L\ mol^{-1}\ s^{-1}$,[20] but less than the value of $6 \times 10^3\ L\ mol^{-1}\ s^{-1}$ derived from fitting a complex mechanism for the complete chlorine dioxide/chlorite - iodide system.[28] A reaction component second-order in I^- was also observed, with $k = 9.4 \times 10^{10} \exp(-4710/T)\ M^{-2}s^{-1}$ ($(1.25 \pm 0.2) \times 10^4\ M^{-2}s^{-1}$ at 298 K). Back to Table

6.7 Other Reactions of Possible Importance

Reaction			k (L mol^{-1} s^{-1})	Note
OH + NO	→	HONO	1.0×10^{10}	F1
OH + NO_2	→	$HONO_2$	4.5×10^{9}	F2
HO_2/O_2^- + NO	→	HOONO/$^-$OONO	$>7.5 \times 10^{9}$	F3
$HO_2 + NO_2$	→	HO_2NO_2	1.8×10^{9}	F4
$CO_3^- + H_2O_2$	→	$HCO_3^- + HO_2$	8×10^{5}	F5
$SO_4^- + CO_3^{2-}$	→	$SO_4^{2-} + CO_3^-$	$2 \times 10^{11} \exp(-6410/T)$	F6

6.7.1 Notes: Other Reactions of Possible Importance

F1. **OH + NO.** Rate constant determined in a complex reaction system by the pulse radiolysis of NO solutions at pH 7, monitoring NO_2^- at 220 nm.[6]

F2. **OH + NO_2.** Rate constant determined by monitoring the formation of $OONO^-$ at 300 nm in N_2O-saturated solutions containing $(0.05\text{-}1.0) \times 10^{-3}$ mol L^{-1} $NaNO_2$.[4]

F3. **O_2^-/HO_2 + NO.** A limiting rate constant obtained from the flash photolysis investigation of $OONO^-$ solutions at 37 ºC and pH >12.[2] It was obtained by extrapolating values obtained from the equilibrium constant and the measured dissociation rate constant, to $[OONO^-] \rightarrow 0$. This rate constant is essentially at the diffusion rate and shows a small negative temperature dependence. This value agrees with $k = 6.7 \times 10^9$ L mol^{-1} s^{-1} at room temperature obtained from the flash photolysis of nitrate ion in the presence of formate.[3] In this study, no dependence of the rate constant on pH was found.

Computer fit to yield of ONO_2^- at 300 nm 8 ms after the pulse in N_2O-saturated solution containing $(0.05\text{-}1.0) \times 10^{-3}$ mol L^{-1} $NaNO_2$; pK_a (HO_2NO) = 6.5.

F4. **$HO_2 + NO_2$.** Product buildup kinetics after the pulse radiolysis of a 1 mmol L^{-1} nitrate solution at 10 atm O_2.[4]

F5. **$CO_3^- + H_2O_2$.** Pulse radiolysis of aqueous carbonate solutions at pH 8-9 following the decay of the absorption at 600 nm.[1] A rate constant of 5.6×10^7 L mol^{-1} s^{-1} for the reaction of CO_3^- with HO_2^- was also obtained.

F6. **$SO_4^- + CO_3^{2-}$.** Laser-flash photolysis of a persulfate solution containing various amounts of carbonate over the temperature range 11-58 ºC.[5] $E_a = -26.8 \pm 0.5$ kJ mol^{-1}.

6.8.1 Notes: Reactions of other Oxidants with Halides

G1. **$NO_3 + Cl^-$.** Derived from a study at room temperature, 20 ± 2 ºC, of the pulse radiolysis of deoxygenated solutions containing nitric acid and sodium chloride, monitoring NO_3 at 641 nm and Cl_2^- at 340 nm. The equilibrium constant, $K = 3.5 \pm 0.5$, and the forward rate constant were derived from modeling a complex mechanism.[12] The rate constant for the reverse reaction, $(1.02 \pm 0.04) \times 10^8$, was taken from a study in which chlorine atoms were generated through the flash photolysis of chloroacetone.[2] In this latter work, there was some apparent dependence of the forward rate constant on ionic strength, with an almost identical rate constant when extrapolated to zero ionic strength, to that listed here. A measurement using flash photolysis of cerium nitrate in nitric acid resulted in $k = 9.1 \times 10^6$ L mol^{-1} s^{-1}, considerably lower than other reported measurements.[16] This is similar to values reported earlier from persulfate flash photolysis, when extrapolated to zero ionic strength.[3]

G2. **$NO_3 + Br^-$.** Pulse radiolysis in a 5 mol L^{-1} $NaNO_3$ solution monitoring the decay of NO_3 at 640 nm.[11]

G3. **$NO_3 + I^-$.** Derived from studies of the uptake of NO_3 into KI solutions at 273 ± 1 K.[15]

G4. **$NO_3 + HClO$.** Pulse radiolysis of a 0.015 mol^{-1} L^{-1} HNO_3 solution, following the decay of NO_3 at 635 nm.[16]

G5. **$NO_3 + ClO^-$.** Pulse radiolysis of a 5 mol^{-1} L^{-1} $NaNO_3$ solution, following the decay of NO_3 at 635 nm.[16]

G6. **$NO_2 + I^-$.** Pulse radiolysis study. Actual data unpublished, but cited.[4] Rate constant for the reverse reaction was measured to be $k = 8.8 \times 10^8$ in an investigation of the laser-flash photolysis of triiodide solutions.[1]

G7. **$HOONO_2 + X^-$.** Decay of peroxynitric acid at 298.2 K was followed by spectroidometry, in which a small aliquot of the dilute reaction mixture was added to a solution containing a great excess of KI and the I_3^- generated monitored at 352 nm.[14] Back to Table

G8. **$CO_3^- + 2Br^-$.** Derived from a pulse radiolysis study of the equilibrium reaction at an ionic strength of 3 mol L^{-1}.[7] The rate constant for the reverse reaction is $(1.05 \pm 0.1) \times 10^5$ L $mol^{-1}s^{-1}$. Back to Table

G9. **$CO_3^- + I^-$.** Pulse radiolysis of a carbonate solution at pH 11.4 over the temperature range 4 to 79 °C. The negative temperature dependence of Ea = 11.4kJ kJ mol^{-1} suggests that this reaction involves the formation of an intermediate adduct.[8] Back to Table

G10. **$CO_3^- + ClO^-$.** From a pulse radiolysis study of the approach to equilibrium, monitoring CO_3^- at 600 nm.[7] The rate constant for the reverse reaction is $(6 \pm 2) \times 10^2$ L $mol^{-1}s^{-1}$. Back to Table

G11. **$SO_4^- + Cl^-$.** Rate constants measured by laser-flash photolysis over the temperature range 11 to 35 °C and corrected to zero ionic strength gave a constant value within experimental error.[6] The absorption due to SO_4^- was followed at 500 nm to avoid interference from absorption due to Cl_2^-. The rate constant for the reverse reaction was determined by modeling the system to be 2.5×10^8 L $mol^{-1}s^{-1}$.[7] Back to Table

G12. **$SO_4^- + Br^-$.** Rate constant measured through the pulse radiolysis of a $S_2O_8^{2-}$ solution containing 0.5 mol L^{-1} *tert*-BuOH.[13] Back to Table

G13. **$SO_4^- + I^-$.** A rate constant for this reaction of $(1.8 \pm 0.1) \times 10^8$ L $mol^{-1}s^{-1}$ was calculated from fitting a complex mechanism for the photoinitiated autoxidation of S(IV) in the presence of iodide ion.[9] Based on the values for the reactions of SO_4^- with Cl^- and Br^-, this value seems much too low. Back to Table

G14. **$SO_4^- + HOCl$.** Pulse radiolysis of a 1 mol^{-1} L^{-1} H_2SO_4 solution containing HOCl, following the decay of SO_4^-.[16] Back to Table

G15. **$SO_4^- + ClO^-$.** Pulse radiolysis of a 2 mol^{-1} L^{-1} Li_2SO_4 solution containing ClO^-, following the decay of SO_4^-.[16] A rate constant of 1.3 x 10^9 L mol^{-1} s^{-1} at zero ionic strength was calculated. Back to Table

G16. **$HSO_5^-/SO_5^{2-} + X^-$.** Rate constants determined by kinetic spectrophotometry, both regular and stopped-flow.[10] At a halide excess, for Cl^-, Cl_2 is the dominate product; for I^-, it is I_3^-, but for Br^-, the final product depends upon pH. Kinetics were measured over the pH range 0 to 10, with the results independent of pH in the acid region, but dropping rapidly from pH 7 to 10, reflecting the deprotonation of HSO_5^-. For the reactions of HSO_5^- with the halides, measurements over the temperature range of ~10–30 ºC resulted in $\Delta H^\# = 58.9 \pm 0.5$ k J mol^{-1} and $\Delta S^\# = -100 \pm 2$ J K^{-1} mol^{-1} for Cl^-; $\Delta H^\# = 44.8 \pm 1.6$ k J mol^{-1} and $\Delta S^\# = -97 \pm 5$ J K^{-1} mol^{-1} for Br^-; $\Delta H^\# = 27.7 \pm 0.7$ k J mol^{-1} and $\Delta S^\# = -91 \pm 2$ J K^{-1} mol^{-1} for I^-. These rate constants are in good agreement with those reported earlier by Fortnum, et al.[5] Back to Table

NH_3 + HOCl	→	$NH_2Cl + H_2O$	$5.40 \times 10^9 \exp(-2237/T)$	H11
NH_3 + HOBr	→	$NH_2Br + H_2O$	5.5×10^7	H12
$NH_3 + BrO^-$ (+ H^+)	→	$NH_2Br + H_2O$	8.8×10^4	H12

6.9.1 Notes: Reactions of Reductants with Halides

H1. **HOCl + NO.** This reaction was investigated by Ghibaudi, et al. by bubbling a gas stream containing NO through solutions of HOCl. A rapid uptake was observed, along with the evolution of NO_2.[7] The uptake lessened at higher pH, leading to the conclusion that ClO^- is 30 times less reactive toward NO than HOCl. Based upon their observations, the authors suggested that the reaction involved a OH transfer, followed by a short chain:

$$NO + HOCl \leftrightarrow HONO + Cl$$

$$Cl + HOCl \rightarrow HCl + ClO$$

$$ClO + NO \rightarrow Cl + NO_2$$

The initial reaction is endothermic, necessitating the subsequent chain.

Subsequent studies have demonstrated that Cl^+ transfer is the predominant mode of HOCl oxidations[10] and, thus, the following reaction scheme seems more likely:

$$NO + HOCl \leftrightarrow NOCl^+ + OH^-$$

$$NOCl^+ + H_2O \rightarrow NOClOH + H^+$$

$$NOClOH \rightarrow NO_2 + HCl$$

Regardless of the mechanism, the observation that NO_2 bubbles out of the solution as NO is bubbled in suggests that any reaction of HOCl with NO_2 must be slow.

H2. **HOCl + NO_2^-.** Although there have been a number of measurements, discussed below, we report here only an equilibrium constant along with rate constants for the two subsequent reactions, all in a NaCl solution at $\mu = 0.01$M.

There have been a large number of studies of the reaction of hypochlorous acid with nitrous acid. There is essential agreement on the overall behavior of the reaction system, but some differences in the details of how the data are interpreted. The earliest studies identified nitrate and chloride as products, leading to the suggestion that this was an O-atom transfer reaction from the hypochlorite ion.[1,15] Pendelbury and Smith[17] suggested the reaction instead involved the reversible formation of nitryl chloride, NO_2Cl, with subsequent reactions leading to the final products. This was supported in kinetic studies at 25 ºC by Cachaza, et al.[3] and Johnson and Margerum.[10] Other studies of the reaction have further supported this basic mechanism. For example, it has been observed that when hypochlorous acid reacts with nitrite, a reactive species capable of nitrating and chlorinating organic compounds is generated.[5,11] Further, a transient species with the spectral characteristics of nitryl chloride, NO_2Cl, has been observed directly in the reaction.[5] One of the proposed mechanistic steps, the reaction of nitryl chloride with nitrite, has been confirmed by observing the release of NO_2 into the gas phase in a wetted-wall flow tube.[6] The uptake is suppressed by Cl^-, suggesting that the hydrolysis reaction is reversible (probably in an initial step involving the formation of NO_2^+) and that the reaction of nitryl chloride with chloride is slow.

The generally-agreed upon mechanism for the reaction is:

(1) $ClO^- + H^+ \leftrightarrow HOCl$

(2) $HOCl + NO_2^- \leftrightarrow NO_2Cl + OH^-$

(3) $NO_2Cl + NO_2^- \rightarrow N_2O_4 + Cl^-$

(4) $N_2O_4 + OH^- \rightarrow NO_2^- + NO_3^- + H^+$

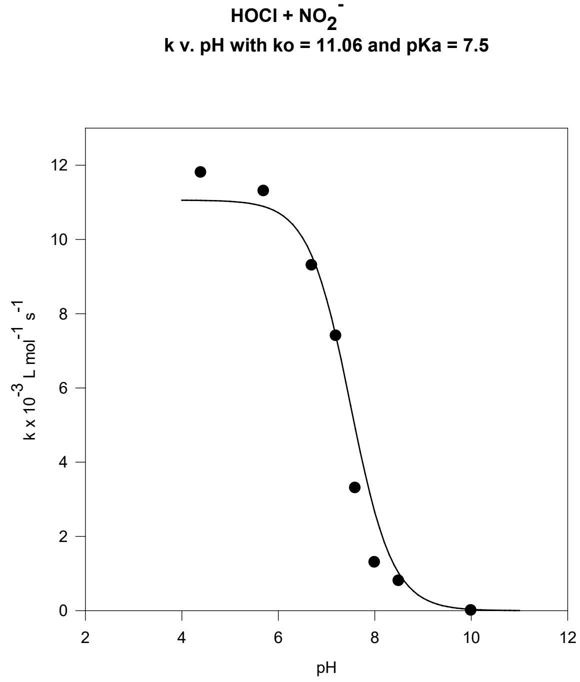
(5) $NO_2Cl + H_2O \rightarrow NO_3^- + Cl^- + 2H^+$

or

($NO_2Cl \rightarrow NO_2^+ + Cl^-$

$NO_2^+ + OH^- \rightarrow NO_3^- + H^+$)

Stopped-flow spectrophotometric studies at high (0.05 mol L^{-1}) nitrite concentration support the unreactivity of ClO^-.[16] An unweighted fit to these data at 25 ºC,[20] taking $pK_a(HOCl) = 7.5$, results in a rate constant of about 1.1×10^4 L mol^{-1} s^{-1} for the reaction of HOCl with NO_2^-.



In this study, there was not a systematic variation of the nitrite concentration. Therefore, the reaction could just as well have involved the equilibrium formation of nitryl chloride, with rate-limiting secondary reactions.

A study of the reaction in acid, $[H^+] = 0.174$ to 0.979 mol L^{-1}, and high chloride concentration, $[Cl^-] = 1.875$ mol L^{-1}, revealed an inverse acid dependence.[17] This was interpreted to indicate that NO_2^- was much more reactive than HONO (pK_a (HONO) = 3.20). An alternate explanation, however, would be that HOCl is more reactive that Cl_2, particularly since an inverse dependence on $[Cl^-]^2$ was also observed. On the other hand, the data of Panasenko[20] does suggest a slight additional positive dependence on acid concentration below pH 6.

The reaction was also studied by bubbling chlorine through a nitrite solution over the pH range 3.4 to 11.5.[4] The reaction was too fast to follow in acid or neutral conditions, but was sufficiently slow over the pH range 9.5 to 11.6. Based on the pH behavior, it was concluded the reaction takes place predominantly between the neutral molecules. Experiments over the temperature range 17.5 to 21.2 ºC indicated some positive temperature dependence, but not sufficient to derive a meaningful activation energy. An earlier study by Lister and Rosenblum at pH 13.1 to 13.6 and a temperature range of 50 to 70 ºC was interpreted to support the conclusion that the reactions takes place between the nitrite ion and the hypochlorous acid molecule.[15] These results suggest a temperature dependence of about 3200 K, including a correction for the heat of hydrolysis of hypochlorite.

The most extensive kinetic measurements on this reaction were done by Lahoutifard, et al.,[12] at 298 K, who measured rate constants over the pH range 5–11, varying nitrite, hypochlorite, ionic strength, and supporting electrolyte. Their results support the contention that the initial reaction between hypochlorite and nitrite involves the reversible formation of nitryl chloride and that the kinetics are controlled by its subsequent fate. Because of this, they were unable to derive a rate constant for the initial reaction, only an equilibrium constant, but they did report rate constants for the two subsequent reactions of nitryl chloride. As a separate part of the study, Lahoutifard, et al. measured the hypochlorous acid hydrolysis constant, K_a, and the water constant, K_w, as a function of ionic strength in both NaCl and Na_2SO_4 solutions. These results are presented in the table below.

	Na_2SO_4 (μ = 1.0 M)	NaCl (μ = 1.0 M)	NaCl (μ = 0.01 M)
K_{eq}	$(1.1 \pm 0.1) \times 10^{-4}$	$(8.8 \pm 0.8) \times 10^{-4}$	$(2.0 \pm 0.2) \times 10^{-4}$
k ($ClNO_2 + NO_2^-$)	$(13 \pm 1) \times 10^3$	$(8 \pm 0.7) \times 10^3$	$(2.9 \pm 0.2) \times 10^3$
k ($ClNO_2 + H_2O$), s^{-1}	81 ± 7	4.8 ± 0.4	79 ± 7
K ($ClO^- + H^+ \leftrightarrow HOCl$), M	1.28×10^7	1.99×10^7	0.89×10^7
pK_w	12.95	13.68	13.75

Back to Table

H3. **NO_2^- + HOBr.** The reactions of hypobromide solutions with nitrite were followed spectrophotometrically after either conventional or stopped-flow mixing by Lahoutifard, et al.[13] Both HOBr solutions free of additional bromide or in its presence were used. The ionic strength was adjusted with either Na_2SO_4 or NaCl. In the presence of 1.0 mol L^{-1} Na_2SO_4, 1.0 mol L^{-1} NaCl, and 0.1 mol L^{-1} NaCl, respectively, the equilibrium constants, $K_{eq}(NO_2^- + HOBr \leftrightarrow BrNO_2 + OH^-) = (5.6 \pm 1.1) \times 10^{-6}$, $(14 \pm 3) \times 10^{-6}$, and $(10 \pm 2) \times 10^{-6}$ and the rate constants, $k(BrNO_2 + NO_2^- \rightarrow N_2O_4 + Br^-) = (14 \pm 3) \times 10^3$, $(3.8 \pm 0.8) \times 10^3$, and $(5.5 \pm 1.1) \times 10^3$ L mol^{-1} s^{-1}.

This study has been criticized by Becker, et al.,[2] who point out that large concentrations of chloride will lead to a much more complicated system containing, for example, BrCl and HOCl. Lahoutifard and Scott[14] have replied to these comments, arguing that the bromide concentrations in most of their kinetic studies were sufficient to prevent this problem. Certainly, at this point these results need to be viewed with some suspicion, particularly those at higher Cl^- concentration.

In a stopped-flow study of the reaction between bromine and nitrous acid at high acidity (pH <2.4), a quadratic dependence on HONO was observed.[21] Also, both H^+ and added Br^- showed a retarding effect and the effect of Br_2 on the rate demonstrated saturation. It was suggested that concurring reactions involving either N_2O_3 (formed by $2HONO \leftrightarrow N_2O_3 + H_2O$) or NO_2^- reacting with Br_2

$$Br_2 + N_2O_3 \rightarrow BrN_2O_3^+ + Br^-$$

$$Br_2 + NO_2^- \rightarrow BrNO_2 + Br^-.$$

An alternate explanation would be that HOBr is more reactive than Br_2 and is the more important reactant in this system. Back to Table

H4. **Br_2^- + NO_2^-.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} Br^- solution containing NO_2^- following the decay of Br_2^- at 360 nm.[19] Temperature was varied from 5–79 ºC. $E_a = 14.3 \pm 0.4$ kJ mol^{-1}. Back to Table

H5. **$Cl_2^- + HSO_3^-$.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} Cl^- solution containing HSO_3^- following the decay of Cl_2^- at 350 nm.[19] Temperature was varied from 5–80 ºC. $E_a = 9.0 \pm 0.3$ kJ mol^{-1}. A 298 K value of $k = 1.7 \times 10^8$ L mol^{-1} s^{-1} at zero ionic strength was reported from the flash photolysis of persulfate solutions containing Cl^-.[9] Back to Table

H6. **$Br_2^- + HSO_3^-$.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} Br^- solution containing HSO_3^- following the decay of Br_2^- at 360 nm.[19] Temperature was varied from 5–75 ºC. $E_a = 6.5 \pm 0.8$ kJ mol^{-1}. Back to Table

H7. **$I_2^- + HSO_3^-$.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} I^- solution containing HSO_3^- following the decay of I_2^- at 380 nm.[19] Temperature was varied from 5–79 ºC. $E_a = 24.8 \pm 2.1$ kJ mol^{-1}. Back to Table

H8. **$Cl_2^- + SO_3^{2-}$.** Flash photolysis at 279 K of a persulfate solution containing Cl^-.[9] Rate constant corrected to zero ionic strength. Back to Table

H9. **$Br_2^- + SO_3^{2-}$.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} Br^- solution containing SO_3^{2-} following the decay of Br_2^- at 360 nm.[19] Temperature was varied from 1–76 ºC. $E_a = 5.4 \pm 1.0$ kJ mol^{-1}. Back to Table

H10. **$I_2^- + SO_3^{2-}$.** Pulse radiolysis of N_2O-saturated 0.1 mol^{-1} L^{-1} I^- solution containing SO_3^{2-} following the decay of I_2^- at 380 nm.[19] Temperature was varied from 4–79 ºC. $E_a = 11.8 \pm 0.4$ kJ mol^{-1}. Back to Table

H11. **NH_3 + HOCl.** Rate constant measured over the temperature range 5–35 ºC and pH 6–12 by stopped-flow spectrophotometry, monitoring ClO^- at 294 nm and NH_2Cl at 243 nm.[18] The observed reaction is strongly pH dependent, with a maximum rate at pH 8.5, where the product $[HOCl]\cdot[NH_3]$ is also maximum. This points to these two as the reactive species, but the ions NH_4^+ and ClO^- cannot be excluded by kinetic considerations, alone. Qiang and Adams argue, however, that the observed unreactivity of NH_4^+ toward O_3, as opposed to NH_3, supports the conclusion that the neutral species are correct. Another stopped-flow study resulted in $k = 1.9 \times 10^6$ L mol^{-1} s^{-1}, in good agreement.[8] Back to Table

H12. **NH_3 + HOBr/BrO^-.** Calculated from a stopped-flow study at various pH values from 6.5 to 13 and 24 ± 2 ºC.[8] Back to Table

6.10.1 Notes: Tri-halo compounds

I1. **$Cl_2 + Cl^- \leftrightarrow Cl_3^-$.** From a pulse radiolysis study of the disappearance of Cl_2^- and formation of Cl_3^-, monitored spectroscopically.[3] The mechanism included the self-reaction of Cl_2^-, for which a rate constant of 1.5×10^9 L mol^{-1} s^{-1} at 5 mol L^{-1} NaCl was calculated, which is in the range of other reported values.[10] An equilibrium constant of $K_{eq} = 0.18$ M^{-1} was reported, the same as the average of values determined earlier at 25.0 ± 0.1 ºC.[8]

I2. **$Br_2 + Br^- \leftrightarrow Br_3^-$.** From a pulse radiolysis study of the disappearance of Br_2^- and formation of Br_3^-, monitored spectroscopically.[2] Results lead to $K_{eq} = 17.5$ M^{-1}, close to the value reported by Wang, et al. for 25.0 ± 0.1 ºC, $K_{eq} = 16.1 \pm 0.3$ M^{-1}.[8]

I3. **$Cl_2 + Br^- \leftrightarrow Cl_2Br^-$ $K_{eq} = 6.7 \pm 1.3 \times 10^5$ M^{-1}.** From a spectroscopic measurement of the pulse radiolysis-induced oxidation of chloride in the presence of added bromide.[4] In a pulsed-accelerated flow determination, a forward rate constant $k_f = (7.7 \pm 1.3) \times 10^9$ L mol^{-1} s^{-1} was reported at 25 ± 0.1 ºC and $\mu = 1.0$ M, in good agreement.[8]

I4. **$Br + Cl^- \leftrightarrow Cl_2Br^-$.** The equilibrium constant $K_{eq} = 6.0 \pm 0.3$ M^{-1} was derived in a spectrophotometric investigation of solutions of BrCl in the presence of added chloride ions at 25 ± 0.1º C and $\mu = 1.0$ M.[8] The value was used in a simulation of the pulse radiolysis-induced oxidation of chloride in the presence of added bromide to derive the forward and reverse rate constants.[4]

I5. **$Cl_2Br + Br^- \rightarrow ClBr_2^- + Cl^-$.** From a spectroscopic measurement of the pulse radiolysis-induced oxidation of chloride in the presence of added bromide.[4]

I6. A spectrophotometric investigation of solutions of BrCl in the presence of added chloride ions yielded the following equilibrium constants at 25 ± 0.1 ºC and $\mu = 1.0$ M:[8]

$ClBr + Br^- \leftrightarrow ClBr_2^-$ $K_{eq} = (1.8 \pm 0.2) \times 10^4$ M^{-1}

$Br_2 + Cl^- \leftrightarrow ClBr_2^-$ $K_{eq} = 1.3 \pm 0.3$ M^{-1}

I7. **$ClI + Cl^- \leftrightarrow Cl_2I^-$.** Equilibrium constant determined by a spectrophotometric titration of a Cl_2I^- solution by HCl.[9] $K_{eq} = 77 \pm 6\ M^{-1}$at 25 ± 0.1 ºC and $\mu = 0.5$ and 1.0 M. For $HOI + 2Cl^- \leftrightarrow Cl_2I^-$, $K_{eq} = 9.4 \times 10^5\ M^{-1}$at 25 °C and $\mu = 0.5$.

I8. **$BrI + Br^- \leftrightarrow Br_2I^-$.** Equilibrium constant determined by a spectrophotometric titration of a Br_2I^- solution by HBr.[7] $K_{eq} = 286 \pm 50\ M^{-1}$at 25 °C and $\mu = 1.0$ M.

I9. **$BrI + I^- \leftrightarrow BrI_2^-$.** The rate constants for this reaction were determined as the rate-limiting step in the overall reaction $Br_2I^- + I^- \leftrightarrow BrI_2^- + Br^-$ using the pulse-accelerated flow method in 1 M H^+ and at 25 °C. The rate was proportional to I^- and inversely to Br^-, indicating that I^- does not react directly with Br_2I^-, but through a multi-step mechanism involving BrI.[7]

I10. **$I_2 + Cl^- \rightarrow ClI_2^-$; $K_{eq} = 1.59\ M^{-1}$ $I_2 + Br^- \rightarrow BrI_2^-$; $K_{eq} = 12.2\ M^{-1}$.** Equilibrium constants determined from measurements of the solubility of I_2 in solution containing the halide ion.[5] For $I_2 + I^- \rightarrow I_3^-$, $K_{eq} = 740\ M^{-1}$, in good agreement with the value recommended here.

I11. **$I_2 + I^- \rightarrow I_3^-$** Log $K_{eq} = 2.8580 - 1.170 \times 10^{-2}(T - 25) - 3.77 \times 10^{-5}(T - 25)^2\ M^{-1}$ or, at 25 ºC, $K_{eq} = 721\ M^{-1}$. Taken from a spectrophotometric measurements from 15 to 35º C by Daniele,[1] reported by Ramette and Sanford,[6] who also discussed other earlier studies.

7. THERMODYNAMIC PARAMETERS

Table of Contents

7.1 Introduction

Table 6-2 lists selected entropy and enthalpy of formation values at 298 K for a number of atmospheric species. As much as possible, the values were taken from primary evaluations that develop a recommended value from the original studies. Otherwise, the values were selected from the original literature, which is referenced in the table. Often, the enthalpy of formation and the entropy values are taken from different sources, usually due to a more recent value for the enthalpy of formation. The cited error limits are from the original references and therefore reflect often widely varying criteria. Some enthalpy values have been adjusted to reflect the value of a reference compound selected for this table; these are mentioned in the Notes. Values that are calculated or estimated are also indicated in the Notes, along with information on the level of theory. Results other than those recommended are also often mentioned in the Notes, including recommendations from previous versions of this Table. These should provide a better perspective on the selected value. All values in the Table are in SI (Joule) units. In the notes, some values are reported in calorie units (1 cal = 4.184 J).

In order to make the utilization of Table 6-2 more convenient, the species are grouped according to some defining characteristic. Each of these groupings has a number linked to that group in the Table. Each group, in turn, has a linked Note associated with it, in which the group's species are listed sequentially, followed by comments. At the end of each Note, the applicable references are given. Below is a list of these various groups and their group numbers. Formulas are presented in the order: C H O N F Cl Br I S Hg.

7.2 Table 7-1. Glossary of Groupings

$H_{0-2} O_{0-3}$	1	$C_1 H_1 Br_{1-3} Cl_{1-3}$	46
H_2O complexes	2	$C_1 H_1 Br_{1,2} Cl_{1,2} F_{1,2}$	47

7.4 Notes for Table 7-2

Note 1: *Simple compounds of H and O*

Back to Table

H	Enthalpy value is from the optimization of Ruscic et al.[19] and is almost the same as the CODATA Key Value,[3] but with a smaller error limit. Entropy value from CODATA.[3]
H_2	CODATA Key Value.[3]
O(^{3}P)	Enthalpy value is from the optimization of Ruscic et al.[19] CODATA Key Value[3] of $\Delta_f H^\circ_{298}$ = 249.18±0.10 kJ mol^{-1} was used in previous evaluation. Entropy value is from CODATA.
O(^{1}D)	Based on a transition to the weighted midpoint of the O^{3}P J-levels.[15]
O_2	CODATA Key Value.[3]
$O_2(^1\Delta_g)$	Spectroscopic value from Huber and Herzberg.[12]
$O_2(^1\Sigma_g^+)$	Spectroscopic value from Huber and Herzberg.[12]
O_3	Enthalpy value is from the optimization of Ruscic, et al.[21] Entropy from Gurvich et al. review, which also gave the previously-listed enthalpy of 141.8±2 kJ mol^{-1}.[10]
OH	Enthalpy value is an update[19] to the recommendation of the IUPAC Task Group.[20] It is an optimization, based on photoionization measurements. Values based on Birge-Sponer extrapolations of OH vibrational levels are 2.1 kJ mol^{-1} higher. The entropy is taken from Gurvich et al.[10] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ$ = 36.90±0.16 kJ mol^{-1}.[4] Uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables ver. 1.20.
H_2O	The enthalpy and entropy values are the result of an optimization in the Active Thermochemical Tables (ATcT).[18] Previous values of –241.826±0.040 kJ mol^{-1} and 188.835±0.010 J mol^{-1} K^{-1} are CODATA Key Values.[3] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ$ = –239.18±0.23 kJ mol^{-1}.[4] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.
HO_2	The enthalpy and entropy values are the result of an optimization by Ruscic, et al. as part of the Active Thermochemical Tables project (ATcT).[20] We accept the larger uncertainty recommended by Burgess, however.[1] The previous Table values, $\Delta_f H^\circ_{298}$ = 11.92±0.22 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 14.85±0.22 kJ mol^{-1}, were from an optimization of a local thermochemical network consisting of 14 experimental and 7 theoretical reaction enthalpies, and grounded in very well established reference enthalpies.[8] Most theoretical values from the literature were rejected in favor of determinations at a higher level of theory. In this study, computed values of $\Delta_f H^\circ_{298}$ = 11.88±0.33 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 14.81±0.33 kJ mol^{-1} were obtained from a composite quantum chemical method discussed in the study, roughly 0.5 kJ mol^{-1} lower than earlier values. An earlier Table enthalpy value at 298 K of 13.4±2.1 kJ mol^{-1} was based upon a negative ion thermodynamic cycle,[17] which was in good agreement with the photoionization result of 13.8±3.3 kJ mol^{-1}.[14] An earlier network optimization of *ab initio* reaction enthalpies resulted in a value of $\Delta_f H_0^\circ$ = 15.09±0.23 kJ mol^{-1}.[4] The uncertainty corresponds to the 95% confidence limit.
H_2O_2	Taken from the review of Burgess.[1] Previous enthalpy values, $\Delta_f H^\circ_{298}$ = –135.9±0.2 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –129.9±0.2 kJ mol^{-1}, were based on the enthalpy of formation of liquid H_2O_2 and the enthalpy of vaporization.[7] The entropy is also from the Dorofeeva, et al., review. A CCSD(T) calculation of the atomization energy, employing the cc-pVnZ basis sets (n=T,Q,5,6) led to $\Delta_f H^\circ_{298}$ = -32.28 kcal mol^{-1} and $\Delta_f H_0^\circ$ = -30.83 kcal mol^{-1}.[6]
HO_3	Taken from the review of Burgess.[1] Previous enthalpy values, $\Delta_f H^\circ_{298}$ = 18.1±6.2 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 21.8±6.3 kJ mol^{-1}, were based on the enthalpy for the reaction HOOOH + FOO → HOOF + HOOO at the CCSD(T)/CBS(Q5) level of theory is 9.50 kcal mol^{-1}. Adjusted for the Table reference values, this gives the cited enthalpy of formation. The minimum was found to be the *trans* configuration at the CCSD(T)/CBS(Q5) level of theory, with the *cis* configuration 0.5 kcal mol^{-1} higher in energy.[9] Note that the enthalpy values obtained from the atomization energy were higher, due, apparently, to higher order correlation effects.[9] A more recent calculation employing the 2-electron reduced density

matrix method suggests that the *cis* isomer is 1.84 kcal mol^{-1} higher in energy than the trans isomer with a aug-cc-pVQZ basis set.[11] The selected value is supported by another analysis using the isodesmic reaction HO_2 + FOO → HO_3 + FO which leads to a value of $\Delta_f H_{298}°$ = 6.3 kcal mol^{-1}.[6] An older theoretical study, using both atomization energies and the reaction HOOO + HOH → HOOOH + OH, resulted in $\Delta_f H_{298}°$ = 7.1±2 kcal mol^{-1} (not adjusted).[5] The enthalpy of formation derived from an estimate of the ionization energy of HO_3, which comes from a study of the electron transfer reactions between HO_3^+ and a series of neutral substrates, was $\Delta_f H_{298}°$ = -1±5 kcal mol^{-1}.[22] The stability of HO_3 has been supported by a neutralization-reionization mass spectrometry experiment, which led to a lifetime of >1 μs,[2] and an infrared action spectrum, which leads to an upper limit for the HO-O_2 bond strength of 6.12 kcal mol^{-1}.[16]

HO_3H Enthalpy value based on the atomization energy calculated by CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level.[9] The listed value and uncertainty are those given by Burgess, who corrected the ZPE slightly.[1] Previous enthalpy values, $\Delta_f H^\circ_{298}$ = −90.0 kJ mol^{-1} and $\Delta_f H_0°$ = −81.10kJ mol^{-1}, were based on a CCSD(T) calculation of the atomization energy, employing the cc-pVnZ basis sets (n=T,Q,5,6).[6] Reaction enthalpy for the reaction 2 HOOH → HOOOH + HOH was calculated to be −15.5 kcal mol^{-1} using the G2 method, leading to $\Delta_f H^\circ_{298}$ = -22.7 kcal mol^{-1}.[13]

HO_4H CCSD(T) calculation of the atomization energy, employing the cc-pVnZ basis sets (n = T,Q,5,6).[6]

Note 2: *Water complexes*

Back to Table

H_2O•H_2O The enthalpy and entropy values are the result of an optimization in the Active Thermochemical Tables (ATcT).[1]

OH•H_2O The structure was optimized with A' symmetry at the CCSD(T(/aug-cc-pVTZ level and a binding energy of 5.88 kcal mol^{-1} calculated, resulting in the listed formation enthalpy.[2] In another calculation, the binding energy for the hydrogen-bonded complex was calculated by optimizing the structure using the PM3 method followed by HF/6-31G* self-consistent field optimization. A G3 calculation leads to a reaction enthalpy of −4.49 kcal mol^{-1} for the formation of the complex.[3]

HO_2•H_2O Derived from the recommended equilibrium constant for the formation of the complex (Table 3-1, Note 4).

O_3•H_2O Structures were optimized using the QCISD approach, using the 6-311G(2df,2p) and G+ with aug-cc-pVDZ and aug-cc-pVTZ basis sets. Single point calculations were carried out using the CCSD(T) method with the same basis sets. The lowest energy complexes have van der Waals structures, not hydrogen-bonding, with the two terminal oxygens of ozone interacting with the oxygen atom of water. The calculated bond dissociation enthalpy is 1.58 kcal mol^{-1}. The structure involving the central oxygen atom of ozone has a slightly weaker bond, but, due to ZPE corrections, a slightly lower enthalpy.[4]

CH_2O•H_2O Obtained from a binding energy of 3.5 kcal mol^{-1}, calculated using B3LYP and the 6-311++G(3df,2pd) basis set.[5]

OCl•OH_2 Obtained from a dissociation energy of 2.70 kcal mol^{-1}, calculated at the MP2//aug-cc-pVTZ level of theory with a quadruple-ζ basic set. Values of 1.70–1.79 kcal mol^{-1} were calculated using B3LYP with triple to quintuple-ζ bases sets. B3LYP//aug-cc-pVTZ was also used to calculate BDEs for hydrates with up to six water molecules.[6]

ClO•HOH Obtained from a dissociation energy of 1.55 kcal mol^{-1}, calculated at the MP2//aug-cc-pVTZ level of theory with a quadruple-ζ basic set. Value of 1.06–1.23 kcal mol^{-1} were calculated using B3LYP with triple to quintuple-ζ bases sets. B3LYP//aug-cc-pVTZ was also used to calculate BDEs for hydrates with up to six water molecules.[6]

OBr•OH_2 Obtained from a dissociation energy of 3.48 kcal mol^{-1}, calculated at the MP2//aug-cc-pVTZ level of theory. A value of 2.54 kcal mol^{-1} was calculated using B3LYP, which was also used to calculate BDEs for hydrates with up to four water molecules.[7]

BrO•HOH Obtained from dissociation energy of 1.70 kcal mol^{-1}, calculated at the MP2//aug-cc-pVTZ level of theory. A value of 1.58 kcal mol^{-1} was calculated using B3LYP, which was also used to calculate BDEs for hydrates with up to four water molecules.[7]

Note 3: *Simple compounds of N and H*

Back to Table

N(^{4}S) The enthalpy value is the result of an optimization in the Active Thermochemical Tables (ATcT).[12] Previous value of 472.420±0.050 kJ mol^{-1} derived from a PFI-PEPICO TOF study.[14] Entropy from CODATA Key Values.[4]

N_2 CODATA Key Values.[4]

NH Enthalpy from review of Anderson.[1] Entropy and enthalpy difference (0.05 kJ mol^{-1}) from JANAF.[3] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ$ = 359.17±0.17 kJ mol^{-1}.[5] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.[12] A value of $\Delta_f H_{298}^\circ$ = 361 kJ mol^{-1} was calculated for triplet NH by an atomization procedure at the CBS-QB3 level of theory and for singlet NH, a value of 531 kJ mol^{-1} was calculated.[2]

NH_2 Recommended values from the IUPAC Task Group.[11] Enthalpy is a weighted average of four measurements since 1982. Previous recommendation was 186±1 kJ mol^{-1}.[1] Entropy was taken from a computed anharmonic potential surface,[9] and is close to the JANAF value of 194.71±0.05 kJ mol^{-1}.[3] A value of $\Delta_f H_{298}^\circ$ = 188 kJ mol^{-1} was calculated for NH_2 by an atomization procedure at the CBS-QB3 level of theory.[2]

NH_3 CODATA Key Value.[4] The JANAF Tables give $\Delta_f H_0^\circ = -38.91$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -45.90$ kJ mol^{-1}, and S° = 192.774 J K^{-1}mol^{-1}.[3] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ = -38.52 \pm 0.26$ kJ mol^{-1}.[5] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

N_2H Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[10] A value of $\Delta_f H_{298}^\circ$ = 249 kJ mol^{-1} was calculated for NH_2 by an atomization procedure at the CBS-QB3 level of theory.[2]

NNH_2 Isodiazene. Enthalpy calculated by an atomization procedure at the CBS-QB3 level of theory. B3LYP geometries were verified by MP2/6-311++G(3df,3dp) calculations.[2] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ$ = 309.0±3.5 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 301.9±3.6 kJ mol^{-1}.[13]

***trans*-N_2H_2** Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[10] Previous value, 212±10 kJ mol^{-1}, taken from the Gurvich et al. review.[8] (The same value was used for the equilibrium mixture.) A value of $\Delta_f H_{298}^o$ = 202 kJ mol^{-1} was calculated for *trans*-N_2H_2 by an atomization procedure at the CBS-QB3 level of theory.[2] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = 210.0±2.9 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 202.8±2.9 kJ mol^{-1}.[13]

***cis*-N_2H_2** Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[10] Previous enthalpy value, 248±12 kJ mol^{-1}, based on enthalpy of conversion of the *trans* to *cis* isomers, 36±12 kJ mol^{-1}.[8] A value of $\Delta_f H_{298}^o$ = 223 kJ mol^{-1} was calculated for *cis*-N_2H_2 by an atomization procedure at the CBS-QB3 level of theory.[2] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = 231.7±3.2 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 224.6±3.2 kJ mol^{-1}.[13]

N_2H_3 Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[10] A value of $\Delta_f H_{298}^o$ = 226 kJ mol^{-1} was calculated for N_2H_3 by an atomization procedure at the CBS-QB3 level of theory.[2]

NH_3NH, iminoammonium ylide

Enthalpy calculated by an atomization procedure at the CBS-QB3 level of theory. B3LYP geometries were verified by MP2/6-311++G(3df,3dp) calculations.[2]

N_2H_4, hydrazine

Enthalpy values taken from a re-evaluation of the Active Thermochemical Tables.[7] A computational study in which four composite methods were used on 45 isogyric reactions, led to a recommended value of $\Delta_f H_{298}^o$ = 97.7±2.0 kJ mol^{-1}.[6] An enthalpy value of 23.1 kcal mol^{-1} (96.7 kJ mol^{-1}) was obtained using a geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[10] The previous recommendation and the entropy value, $\Delta_f H_{298}^o$ = 95.2±0.5 kJ mol¯1, were taken from the review of Gurvich et al.[8] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = 115.4±2.0 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 100.8±2.0 kJ mol^{-1}.[13]

Note 4: *Simple compounds containing N and O*

Back to Table

NO Enthalpy value is an update[7] to the recommendation of the IUPAC Task Group, which is from an optimization based on experimental data.[8] Previous enthalpy value, 91.29±0.17 kJ mol^{-1} from review of Anderson.[3] Much of the difference can be ascribed to the change in the enthalpy for N. Entropy from JANAF.[4]

N_2O Taken from review of Gurvich et al.[6] The JANAF Tables give $\Delta_f H_0^\circ$ = 85.48 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 82.05 kJ mol^{-1}, and S° = 219.957 J $\text{K}^{-1}\text{mol}^{-1}$.[4]

NO_2 The enthalpy value is from an optimization based on experimental data.[8] Entropy from Gurvich et al.[6]

NO_3 Enthalpy derived from a molecular beam photofragmentation translational spectroscopic study, adjusted to Table values for O and NO_2.[5] Entropy from review of Abramowitz, et al.[1]

N_2O_3 Taken from review of Gurvich et al.[6] The JANAF Tables give $\Delta_f H_0^\circ$ = 89.6 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 82.8 kJ mol^{-1}, and S° = 308.539 J $\text{K}^{-1}\text{mol}^{-1}$.[4]

N_2O_4 Taken from review of Gurvich et al.[6] The JANAF Tables give $\Delta_f H_0^\circ$ = 18.7 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 9.1 kJ mol^{-1}, and S° = 304.376 J $\text{K}^{-1}\text{mol}^{-1}$.[4]

N_2O_5 Selected enthalpy value derived from a third-law calculation on the equilibrium constant for the reaction, $NO_2 + NO_3 \leftrightarrow N_2O_5$, presented in Table 3-1, note 11. Entropy value was calculated by Alecu and Marshall,[2] as discussed in Table 3-1. Previous values ($\Delta_f H_{298}^\circ$ = 13.3 kJ mol^{-1}, and S° = 355.7 J mol^{-1}) and enthalpy difference taken from review of Gurvich et al.[6] The JANAF Tables give $\Delta_f H_0^\circ$ = 12.7 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 11.3 kJ mol^{-1}, and S° = 346.548 J $\text{K}^{-1}\text{mol}^{-1}$.[4]

Note 5: *Compounds containing N, H, and O*

Back to Table

HNO Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[4] Previous enthalpy, 107.1±2.5 kJ mol^{-1}, from review of Anderson.[1] Entropy from Gurvich et al., who cites an enthalpy of 102 kJ mol^{-1}.[7] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = 109.7±3.6 kJ mol^{-1} and $\Delta_f H^o_{298}$ = 107.2±3.6 kJ mol^{-1}.[13]

HON Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[4]

NH_2O Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[4]

NH_2OH Calculated using isodesmic reactions at several levels of theory and several basis sets.[12] Previous value of –9.6±2.2 kcal mol^{-1} based on average of theoretical and experimental values.[1] Entropy from Gurvich et al.[7] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = −32.0±3.0 kJ mol^{-1} and $\Delta_f H^o_{298}$= −41.9±3.1 kJ mol^{-1} for *trans*-hydroxylamine and $\Delta_f H_0^o$ = −14.2±3.0 kJ mol^{-1} and $\Delta_f H^o_{298}$= −24.2±3.0 kJ mol^{-1} for *cis*-hydroxylamine.[13]

NH_3O Ammonia oxide. Enthalpy values for this isomer of hydroxylamine were calculated by using several composite models, CBS-QB3, CBS-APNO, G3, and G4.[13]

HNOH Geometry optimized at the frozen core CCSD(T) level of theory with aug-cc-pVDZ and aug-cc-pVTZ basis sets; the CCSD(T) energy extrapolated to the CBS limit.[4]

NH_2NO_2 The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[14] The previous value, $\Delta_f H^o_{298}$ = −26±10 kJ mol^{-1}, was based on measurements of the enthalpy of formation of the crystalline substance and an estimated value of the enthalpy of sublimation, 60.7±10 kJ mol^{-1}.[7]

HONO Thermodynamic properties for the equilibrium mixtures of isomers from Gurvich et al. review.[7]

***trans*-HONO**

Taken from review of Gurvich et al.[7] Values calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions are $\Delta_f H_{298}^o$ = −18.90±0.05 kcal mol^{-1} and S^o = 57.89 cal K^{-1} mol^{-1}.[2] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = −73.2±4.0 kJ mol^{-1} and $\Delta_f H^o_{298}$= −78.5±3.9 kJ mol^{-1}.[13]

***cis*-HONO** Enthalpy value obtained on basis of enthalpy of conversion of trans-HONO into cis-HONO, 1.7±0.4 kJ mol^{-1}.[7] Values calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions are $\Delta_f H_{298}^o$ = −18.40±0.05 kcal mol^{-1} and S^o = 57.64 cal K^{-1} mol^{-1}.[2] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o$ = −70.9±4.3 kJ mol^{-1} and $\Delta_f H^o_{298}$ = −76.4±4.3 kJ mol^{-1}.[13]

***trans*-HOON, hydroperoxynitrene or nitrosyl O-oxide**

The O-O dissociation energy was calculated at the CCSDTQ/aug-cc-pVTZ level of theory as 39.0 kJ mol^{-1}. This was corrected to 298 K by −5.7 kJ mol^{-1} to give the selected enthalpy value. The *cis* isomer was calculated to be 6.4–8.5 kJ mol^{-1} less stable.[15]

HNO_2, nitryl hydride

Calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions.[2]

$HONO_2$ Nitric acid. Taken from the updated NIST-JANAF Tables.[5] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ = -137.4 \pm 6.2$ kJ mol^{-1} and $\Delta_f H^\circ_{298} = -129.0 \pm 6.3$ kJ mol^{-1}.[13]

***cis,cis*-HOONO**

Derived from a third-law analysis of the equilibrium constant for HO + NO_2 ↔ *c,c*-HOONO (Table 3-1, Note 1). Previous enthalpy value of –5.7 kcal mol^{-1} and values for the *cis,perp*- and *trans,perp*-HOONO calculated at the MP2 level of theory.[10] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets, led to $\Delta_f H_0^\circ = -6.4 \pm 2.0$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -15.5 \pm 2.0$ kJ mol^{-1}, and $S = 271.0 \pm 2.0$ J K^{-1} mol^{-1}.[14] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ = 6.2 \pm 6.1$ kJ mol^{-1} and $\Delta_f H_{298}^\circ = 0.3 \pm 5.9$ kJ mol^{-1} for peroxynitrous acid.[13] It was noted that the two lowest energy conformations did not converge, however

***trans, perp*-HOONO**

Derived from the dissociation energy for *t,p*-HOONO and reported molecular constants (Table 3-1, Note 1). Enthalpy values for the *cis,cis*-, *cis,perp*-, and *trans,perp*-HOONO have also been calculated at the MP2 level of theory.[10]

HO_2NO_2 Derived from a third-law analysis of the equilibrium constant for HO_2NO_2 ↔ HO_2 + NO_2.[6] Previous recommended enthalpy value of –12.7±0.6 kcal mol^{-1} from Regimbal and Mozurkewich.[11] A value of $\Delta_f H^\circ_{298} = -52.3$ kJ mol^{-1} was obtained from a computational study in which equilibrium structures optimized at the MP2 level with the 6-311G(d,p) basis set and enthalpy values calculated by both atomization energies and through use of isodesmic reactions at the G3, G3B3, and G4 methods.[3] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets, led to $\Delta_f H_0^\circ = -41.3 \pm 2.4$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -52.4 \pm 2.4$ kJ mol^{-1}, and $S = 296.2 \pm 2.0$ J K^{-1} mol^{-1}.[14] The enthalpy difference was used to calculate the 0 K value in the Table.

NH_4NO_3 Enthalpy obtained from a third-law analysis of the sublimation pressure of NH_4NO_3 over the range 321−360 K. The entropy was calculated from molecular constants taken from the literature.[8] A high-level theoretical calculation, CCSD(T) extrapolated to the aug-cc-pV∞Z basis set, gives $\Delta_f H_0^\circ = -221.1 \pm 3$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -230.6 \pm 3$ kJ mol^{-1}, and $S = 342.4$ J $K^{-1} mol^{-1}$.[9]

Back to Table

C Enthalpy from an active thermochemical tables optimization.[9] The previous enthalpy of ΔH_f(298 K) = 716.68±0.45 kJ mol^{-1} and ΔH_f(0 K) = 711.19±0.45 kJ mol^{-1} and the entropy are CODATA Key Values.[2] The JANAF Tables give $\Delta_f H_0^o$ = 711.2 kJ mol^{-1}, $\Delta_f H_{298}^o$ = 716.7 kJ mol^{-1}, and S^o = 158.100 J K^{-1} mol^{-1}.[1] The cited enthalpy is identical to that for the triplet carbon atom, ^3C. The singlet carbon atom, ^1C, is higher at ΔH_f(298 K) = 838.478±0.050 kJ mol^{-1},[9] and is completely unimportant under atmospheric conditions.

CH Enthalpy from an active thermochemical tables optimization,[9] which is very slightly different from the recommendation, ΔH_f(298 K) = 595.8±0.6 kJ mol^{-1}, from an IUPAC Task Group, used previously.[10] An earlier recommendation of ΔH_f(298 K) = 597.37±1.3 kJ mol^{-1} was from Gurvich et al.[6] The preferred value corresponds to the theoretical value of Császár et al.,[4] which is in agreement with the experimental values but is considered to be of higher accuracy. The entropy was taken from Gurvich et al.[6] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^o$ = 592.62±0.24 kJ mol^{-1}.[3] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20. The cited enthalpy is identical to that for doublet methyidyne, ^2CH. Quartet methylidyne, ^4CH, is higher at ΔH_f(298 K) = 667.88±0.59 kJ mol^{-1},[9] and is completely unimportant under atmospheric conditions.

$CH_2(^3B_1)$ Enthalpy from an active thermochemical tables optimization,[9] which is very slightly different from the recommendation from IUPAC Task Group[10] and its update.[11] Entropy value from the ICPAC Task Group.[10] Previous recommendations of ΔH_f(298 K) = 390.4±0.8 kJ mol^{-1} and S(298 K) = 194.90 J K^{-1} mol^{-1} were from experiments of Ruscic et al.[12] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0°$ = 390.86±0.29 kJ mol^{-1}.[3] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20. Ruscic. et al.,[9] also include information on "regular methylene", or methylene thermally equilibrated over all available electronic states. At atmospheric temperatures, this is essentially equal to the value for triplet methylene.

$CH_2(^1A_1)$ Enthalpy from an active thermochemical tables optimization,[9] which is very slightly different from the recommendation from IUPAC Task Group[10] and its update.[11] Entropy value from the ICPAC Task Group.[10] Previous recommendation of ΔH$_f$(298 K) = 428.0±0.8 kJ mol^{-1} was from Jacox.[7] The preferred value is based on the enthalpy of formation of triplet methylene and a separation between the singlet and triplet sates of 3147±5 cm^{-1}.

CH_3 Enthalpy from an active thermochemical tables optimization,[9] which is slightly different, but with a much smaller error limit, than the earlier recommendation, ΔH$_f$(298 K) = 146.7±0.3 kJ mol^{-1}, taken from IUPAC Task Group.[10] Entropy value differs only slightly from an earlier recommended value of 193.96 J K^{-1} mol^{-1} from Gurvich et al.[6] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0°$ = 149.66±0.34 kJ mol^{-1}.[3] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

CH_4 Enthalpy from an active thermochemical tables optimization, [9] which is slightly different from the earlier optimization value of ΔH$_f$(298 K) = −74.549±0.060 kJ mol^{-1}.[13] Enthalpy from flame calorimetry –74.48±0.41 kJ mol^{-1} used previously.[8] Entropy from Frenkel et al.[5] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0°$ = –66.35±0.46 kJ mol^{-1}.[3] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

Note 7: *Compounds containing one C, 0-4 H, and one or more O*

Back to Table

CO Enthalpy from an active thermochemical tables optimization,[23] which is slightly different than the CODATA Key Value, $\Delta_f H^\circ_{298} = -110.53 \pm 0.17$ kJ mol^{-1}, previously recommended.[3] The entropy value is still from CODATA. Atomization energies calculated using CCSD(T) with aug cc-pVnZ (n = D − 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = -27.0 \pm 0.2$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -26.2 \pm 0.2$ kcal mol^{-1}.[12] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ = -114.09 \pm 0.32$ kJ mol^{-1}.[4] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

CO_2 CODATA Key Value.[3] The active thermochemical tables optimization gives $\Delta_f H^\circ_{298} = -393.474 \pm 0.014$ kJ mol^{-1} and $\Delta_f H_0^\circ = -393.108 \pm 0.014$ kJ mol^{-1}.[25] Atomization energies calculated using CCSD(T) with aug cc-pVnZ (n=D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = -93.7 \pm 0.2$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -93.8 \pm 0.2$ kcal mol^{-1}.[12] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ = -392.98 \pm 0.40$ kJ mol^{-1}.[4] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

HCO, formyl

Enthalpy from an active thermochemical tables optimization.[23]The previous recommendation, $\Delta_f H_{298}^\circ = 44.15 \pm 0.43$ kJ mol^{-1}, was from reversible reactions of I and Br with CH_2O,[1] using present values for HI and HBr. Entropy taken from Gurvich et al.[13] Atomization energies calculated using CCSD(T) with aug cc-pVnZ (n=D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = 10.4 \pm 0.2$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = 10.5 \pm 0.2$ kcal mol^{-1}.[12]

COH, isoformyl

Enthalpy from an active thermochemical tables optimization.[23]

HCOH Enthalpy from an active thermochemical tables optimization.[23] The cited enthalpy is almost identical to that for the *trans* singlet hydroxymethylene, *t*-^{1}HCOH, ΔH_f(298 K) = 108.64±0.33 kJ mol^{-1}. The *cis* singlet, *c*-^{1}HCOH, is higher at ΔH_f(298 K) = 127.11±0.33 kJ mol^{-1}.[23] The triplet, which is in a gauche configuration, is much higher at ΔH_f(298 K) = 216.1±1.1 kJ mol^{-1}.

CH_2O Enthalpy from an active thermochemical tables optimization.[23] The previous recommendation, $\Delta_f H_{298}^\circ = -108.99 \pm 1.76$ kJ mol^{-1}, was obtained by using experimental reaction enthalpies taken from the literature.[7] This value was confirmed by three computational approaches involving enthalpies of the same reaction, isodesmic reaction enthalpies, and atomization energies, using a range of high-level computational techniques. An earlier recommended value, $\Delta_f H_{298}^\circ = -108.7 \pm 0.50$ kJ mol^{-1}, was taken from review of Gurvich et al., as is the present entropy value.[13] A CCSD(T) calculation with the aug-cc-pVnZ (n = D,T,Q,5) basis set extrapolated to the CBS limit gave $\Delta_f H_0^\circ = -104.2 \pm 2.1$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -107.95 \pm 2.1$ kJ mol^{-1}, and $S = 218.57$ J K^{-1} mol^{-1}.[20] A computation using the focal-point analysis approach resulted in $\Delta_f H_0^\circ = -105.42 \pm 0.33$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -109.23 \pm 0.33$ kJ mol^{-1}.[5]

***trans*-HOCO**

The enthalpy and entropy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[21] The previous $\Delta_f H_{298}^{\circ}$ = –187.9±2.1 was obtained from atomization energies calculated using CCSD(T) with aug cc-pVnZ (n=D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit.[12] An earlier computational study using G3 and CBS-QB3 methods gave $\Delta_f H^{\circ}_{298}$ = –43.3±2 kcal mol^{-1}.[10] These results are in agreement with photoionization lower limit of –46.5 kcal mol^{-1}.[26]

cis-HOCO The enthalpy and entropy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[21] The previous $\Delta_f H_{298}^{\circ}$ = –175.7±2.1 was obtained from atomization energies calculated using CCSD(T) with aug cc-pVnZ (n=D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit; $\Delta_f H_0^{\circ}$ = –41.0±0.5 kcal mol^{-1}. (Result presented in text as an energy difference of 2.9 kcal mol^{-1} over the t*rans* form.)[12] An earlier computational study using G3 and CBS-Qb3 methods gave $\Delta_f H^{\circ}_{298}$ = –41.4±2 kcal mol^{-1}.[10]

HC(O)O Enthalpy obtained from atomization energies calculated using CCSD(T) with aug cc-pVnZ (n = D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit.[12] An earlier study using vibrational frequencies calculated at the HF/6-31G(D) level and total energies evaluated at the G2(MP2) level, also making use of isodesmic reactions, gave $\Delta_f H^{\circ}_{298}$ = –30 kcal mol^{-1} and the quoted entropy value.[31] A CCSD(T)-CBS (W1U) calculation gives $\Delta_f H^{\circ}_{298}$ = –129.4±12.6 kJ mol^{-1}.[11]

C(O)OH Vibrational frequencies calculated at the HF/6-31G(D) level and total energies evaluated at the G2(MP2) level, also making use of isodesmic reactions.[31] Enthalpy calculated using the atomization energy method at the CBS-Q level gave –41.62 kcal mol^{-1}.[28]

HC(O)OH Enthalpy taken from NBS Tables;[30] entropy calculated based on structure optimized at MP2/6-31G(D) and frequencies calculated at HF6/31G(D) level.[31] See also discussion of enthalpy in Yu et al.[31] $\Delta_f H_{298}^{\circ}$ = –90.5 kcal mol^{-1} also obtained by calculating optimized geometry at the CCSD(T)/aVTZ level with the aug-cc-pVTZ basis set; CCSD(T) energy extrapolated to the CBS limit.[22] Atomization energies calculated using CCSD(T) with aug cc-pVnZ (n = D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^{\circ}$ = –88.9±0.4 kcal mol^{-1} and $\Delta_f H^{\circ}_{298}$ = –90.7±0.4 kcal mol^{-1}.[12] Microwave intensity measurements have determined that the *cis* rotamer of HC(O)OH to be 16.3±0.4 kJ mol^{-1} higher in energy than the *trans* rotamer.[14]

***trans*-and *cis*-HC(O)OO**

Photoelectron spectroscopy of the peroxyformate anion was used to obtain the electron affinity of the peroxyformate radical. Through a thermochemical cycle, this leads to the O-H bond dissociation energy, which combined with the calculated enthalpy of the acid, yields the enthalpy of formation. BDEs for both the *cis* and *trans* conformers of the acid could be determined, both leading to the lower-energy *trans* conformer of the radical.[29]

***trans*-HC(O)OOH**

Enthalpy obtained from the calculated heat of an isodesmic reaction, at the G3B3MP2 level of theory.[29] This value is slightly lower than $\Delta_f H^{\circ}_{298}$ = –285.3±2.5 kJ mol^{-1} ($\Delta_f H_0^{\circ}$ = –275.7 kJ mol^{-1}) obtained from atomization energies calculated using CCSD(T) with aug cc-pVnZ (n = D – 7) basis sets, using frozen-core CCSD(T) optimized geometries and extrapolated to the complete basis set limit.[12] The present value was chosen as it is conformer specific; the 0 K value is based on the Feller et al.[12] enthalpy difference.

***cis*-HC(O)OOH**

The enthalpy value is derived from the value for the *trans* conformer, which is calculated at the G3B3MP2 level of theory, to be 14.2 kJ mol^{-1} lower in energy than the *cis* conformer.[29]

CH_2OO, formaldehyde carbonyl oxide (Criegee intermediate)

Optimized geometry calculated at the CCSD(T)/aVTZ level with the aug-cc-pVTZ basis set; CCSD(T) energy extrapolated to the CBS limit.[22]

CH_2O_2, dioxirane

Optimized geometry calculated at the CCSD(T)/aVTZ level with the aug-cc-pVTZ basis set; CCSD(T) energy extrapolated to the CBS limit.[22]

CH_3O Enthalpy from an active thermochemical tables optimization,[23] which is slightly different than the previous recommendation taken from IUPAC Task Group, ΔH_f(298 K) = 21.0±2.1 kJ mol^{-1}.[24] The recommendation is supported by one recent high-level theoretical study. This value is significantly higher than that recommended here earlier, 17.15±3.8 kJ mol^{-1} from the evaluation of Berkowitz et al.,[2] and most other previous recommendations. The recommended entropy is also somewhat different that the previously recommended value of 232.86 J K^{-1} mol^{-1}.[13] Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ$ = 7.4 kcal mol^{-1} and $\Delta_f H^\circ_{298}$ = 5.5 kcal mol^{-1}.[19] The entropy value is taken from the IUPAC Task Group.[24]

CH_3O_2 Based on a re-analysis of previous equilibrium data on R + O_2 ↔ RO_2 from the same laboratory.[16] In a computational study, $\Delta_f H^\circ_{298}$ = 8.8 kJ mol^{-1} was determined using G3B3 and CBS-APNO methods with isodesmic reactions to minimize systematic errors, where the geometry was optimized at the B3LYP/cc-pVTZ+d level of theory. This work also provided the recommended entropy.[6]

CH_2OH Enthalpy from an active thermochemical tables optimization,[23] which is slightly different from the recommendation taken from IUPAC Task Group, ΔH_f(298 K) = −17.0±0.7 kJ mol^{-1}.[24] (Note that an earlier value listed in this Table, $\Delta_f H_{298}^\circ$ = −11.5±1.3 kJ mol^{-1}, inadvertently was actually $\Delta_f H_0^\circ$ for 0 K.) The entropy value reported by Johnson and Hudgens was accepted and is included here with their error limits.[15] Results of Dóbé, et al.[8] give –16.6±1.3 kJ mol^{-1}. Atomization energies calculated using CCSD(T) with cc-pVnZ (n=D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ$ = –2.3 kcal mol^{-1} and $\Delta_f H^\circ_{298}$ = –3.8 kcal mol^{-1}.[19]

CH_3OH Enthalpy from an active thermochemical tables optimization.[23] The previous enthalpy of ΔH_f(298 K) = –201.0±0.6 kJ mol^{-1} was taken from review of Gurvich et al.,[13] as is the entropy value. Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ$ = –45.7 kcal mol^{-1} and $\Delta_f H^\circ_{298}$ = –48.3 kcal mol^{-1}.[19]

$CH_3OH{\bullet}HO_2$

Estimated from studies on the decay of HO_2 in the presence of CH_3OH, with supporting *ab initio* calculations (Table 3-1, Note 5).

CH_2OOH Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[28] This radical is unstable to decomposition to CH_2O + OH.

CH_3OOH Geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level. The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate the enthalpy of formation at 298 K.[17] This was adjusted to the radical values from the present Table. Reaction enthalpies determined using the G2 method indicated ΔH°_{298}(CH_3OO–H) is 1.6 kcal mol^{-1} lower than ΔH°_{298}(HOO–H), or 85.9 kcal mol^{-1} (359.4 kJ mol^{-1}), leading to the previous enthalpy value of –132.2 kJ mol^{-1}.[18] An earlier recommended enthalpy value (–139.0±8.1 kJ mol^{-1}) was computed on the assumption that the dissociation energy for ROO–H is 366±3 kJ mol^{-1} (Stocker and Pilling, unpublished work).[16] Enthalpy calculated using the atomization energy method at the CBS-Q level gave –30.75 kcal mol^{-1} (−128.7 kJ mol^{-1}).[28] The entropy and enthalpy difference is from the updated JANAF Table.[9] An entropy value of 273.4 J K^{-1} mol^{-1} was calculated based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[28] Calculations using the CBS-QB3 and CBS-APNO model chemistries on three isodesmic reactions led to $\Delta_f H^\circ_{298} = -129.5\pm0.9$ kJ mol^{-1}.[27]

CH_3O_3 and CH_3O_4

Bond dissociation energies were calculated for $CH_3OOOOCH_3$ at the G3B3 and CBS-APNO levels of theory, using isodesmic and bond dissociation work reactions. The molecular geometry was optimized at the B3LYP/cc-pVTZ+d level of theory.[6]

Back to Table

CN Enthalpy from an active thermochemical tables optimization.[12]The previous recommendation, $\Delta_f H_{298}^o$ = 440±5 kJ mol^{-1}, and the entropy value, were from the review of Gurvich, et al.[6]

HCN Enthalpy from an active thermochemical tables optimization, augmented by HEAT-456QP calculations using the aug-cc-pCVXZ basis sets, X+Q,6, and 6.[10]The previous recommendation, $\Delta_f H_{298}^o$ = 132±4 kJ mol^{-1}, and the entropy value, were from the review of Gurvich, et al.[6] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ$ = 131.8±2.4 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 131.7±2.4 kJ mol^{-1}.[14]

HNC Enthalpy from an active thermochemical tables optimization, augmented by HEAT-456QP calculations using the aug-cc-pCVXZ basis sets, X+Q,6, and 6.[10] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ$ = 192.1±1.5 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 192.7±1.5 kJ mol^{-1}.[14]

NCN Enthalpy from an active thermochemical tables optimization.[5] Entropy value also listed in a summary table.

C_2N_2 From the review of Gurvich et al.[6]

CH_2NH, Methylenimine

Enthalpy values obtained from computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[14]

CH_3NH Obtained from a computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies.[13]

CH_2NH_2 Based on recommendation of McMillen et al.,[9] adjusted for enthalpy for CH_3NH_2 used here (–5.6 kcal mol^{-1} vs. –5.5 kcal mol^{-1}). Calculations at the G2(MP2) level lead to an enthalpy of 147 kJ mol^{-1}.[16] A computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies resulting in $\Delta_f H^\circ_{298}$ = 150.2 kJ mol^{-1} and S_{298} = 236.2 J K^{-1}mol^{-1}.[13]

CH_3NH_2 Enthalpy from review of Pedley;[11] entropy value from the Thermodynamics Research Center Data Series.[4] Values of $\Delta_f H^\circ_{298}$ = −21.8±1.5 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –7.0±1.5 kJ mol^{-1} have been derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory.[2] A computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies resulted in $\Delta_f H^\circ_{298}$ = –19.7 kJ mol^{-1} and S_{298} = 242.0 J K^{-1}mol^{-1}.[13] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ$ = −5.4±2.0 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= −20.2±2.0 kJ mol^{-1}.[14]

CH_2CN Based on an analysis of the negative ion cycle.[8]

CH_3CN Enthalpy at 298 K by combustion calorimetry;[1] 0 K value based on measured vibrational frequencies.[8] Entropy from NBS Tables.[15]

CH_2N_2 Enthalpy value calculated from the atomization energy at the G3 level of theory. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[7]

CH_2N_2 Enthalpy from a CCSD(T) calculation of the atomization energy.[3]

Note 9: *Compounds containing one C and H, N, and O*

Back to Table

CH_2NO From computed G2 heats of reaction.[11]

NH_2CO This is the more stable isomer of CH_2NO (above), which is formed by the association of CH_2 with NO. The enthalpy and entropy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[8] The previous $\Delta_f H_{298}°$ = –15.1±4 was from computed G2 heats of reaction.[11]

NCO Enthalpy from D(H-NCO) = 4.9±0.01 eV,[9] using present value for HNCO. Entropy from Gurvich et al.[6]

HCNO, Fulmic acid

Enthalpy values obtained from a computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[12]

HONC, Isofulmic acid

Enthalpy values obtained from a computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[12]

HOCN, Cyanic acid

Enthalpy values obtained from a computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[12]

HNCO, isocyanic acid

The dissociative photoionization of urea was investigated by iPEPICO.[2] The lowest energy channel, $CO(NH_2)_2 + h\nu \rightarrow NH_3^+ + HNCO + e^-$, was measured accurately and the appearance energy of the second channel, $CO(NH_2)_2 + h\nu \rightarrow NH_2 + H_2NCO^+ + e^-$, was measured with somewhat lower precision. These were used together with W1 and CBS-APNO calculations on three isodesmic reactions for $CO(NH_2)_2$ and two isoelectonic reactions for HNCO to determine the enthalpy values for both HNCO and $CO(NH_2)_2$. The previous value, $\Delta_f H_{298}^o = -104 \pm 12$ kJ mol^{-1} from threshold photodissociation of HNCO by measuring $NH(a^1\Delta)$ threshold and fragment energy, adjusted for the present enthalpy of NH.[13] Entropy from NBS Tables.[15] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^o = -117.6 \pm 0.8$ kJ mol^{-1} and $\Delta_f H_{298}^o = -119.7 \pm 0.8$ kJ mol^{-1}.[12]

$HCONH_2$, Formamide

From review of Pedley et al.[10]

CH_2NO_2 Recommendation from the Thermodynamics Research Center Data Series.[5] A calculation of the atomization energy at the G3 level of theory leads to $\Delta_f H_{298}^o = 31.5$ kcal mol^{-1}. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[7]

CH_3NO_2 Enthalpy from Pedley,[10] entropy from Frenkel et al.[5] Enthalpy value calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions is $\Delta_f H_{298}^o = -17.67 \pm 0.27$ kcal mol^{-1}, which becomes -17.73 ± 0.27 kcal mol^{-1} using the reference enthalpy for *cis*-HONO from this Table.[1] A calculation of the atomization energy at the G3 level of theory leads to $\Delta_f H_{298}^o = -17.5$ kcal mol^{-1}. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[7] A value of $\Delta_f H_{298}^o = -73.2$ kJ mol^{-1} was calculated at the G4 level of theory, making use of isodesmic reactions.[4]

CH_3ONO Taken from review of Stull et al.[14] Enthalpy value calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions is $\Delta_f H_{298}^o = -15.64 \pm 0.10$ kcal mol^{-1}, which becomes -15.81 ± 0.10 kcal mol^{-1} using the reference enthalpy for *cis*-HONO from this Table.[1] A calculation of the atomization energy at the G3 level of theory leads to $\Delta_f H_{298}^o = -15.4$ kcal mol^{-1}. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[7]

CH_3ONO_2 Enthalpy from Pedley,[10] entropy from Stull et al.[14]

$CH_3O_2NO_2$ Equilibrium structures optimized at the MP2 level with the 6-311G(d,p) basis set and enthalpy values calculated by both atomization energies and through use of isodesmic reactions at the G3, G3B3, and G4 methods.[3]

$C(NO_2)_4$ Enthalpy value calculated from the atomization energy at the G3 level of theory. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[7] (see addition and corrections)

$(NH_2)_2CO$, Urea

The dissociative photoionization of urea was investigated by iPEPICO.[2] The lowest energy channel, $CO(NH_2)_2 + h\nu \rightarrow NH_3^+ + HNCO + e^-$, was measured accurately and the appearance energy of the second channel, $CO(NH_2)_2 + h\nu \rightarrow NH_2 + H_2NCO^+ + e^-$, was measured with somewhat lower precision. These were used together with W1 and CBS-APNO calculations on three isodesmic reactions for $CO(NH_2)_2$ and two isoelectonic reactions for HNCO to determine the enthalpy values for both HNCO and $CO(NH_2)_2$. The previous value, $\Delta_f H_{298}^o = -245.8 \pm 2.0$ kJ mol^{-1} from Pedley et al.,[10] depended on a value of the sublimation energy that appears to be too low.[2]

Note 11: *Compounds containing two C and 0 - 4 H* Back to Table

C_2, ethynylene

Enthalpy from an active thermochemical tables optimization.[14] The slightly-different previous enthalpy value of $\Delta H_f(298\ K) = 828.73 \pm 0.29\ kJ\ mol^{-1}$ was from an earlier optimization in the Active Thermochemical Tables (ATcT).[15] The entropy value is from JANAF.[4] The cited enthalpy is close to the value for singlet ethynylene, $^1C_2$, $\Delta H_f(298\ K) = 826.78 \pm 0.27\ kJ\ mol^{-1}$. The triplet ethynylene, $^3C_2$, is higher at $\Delta H_f(298\ K) = 864.08 \pm 0.27\ kJ\ mol^{-1}$.[14]

C_2H Enthalpy from an active thermochemical tables optimization.[14] The previous enthalpy of $\Delta H_f(298\ K) = 565.3 \pm 3.9\ kJ\ mol^{-1}$ was from the review of Berkowitz, Ellison, and Gutman.[1]

$\Delta_f H_0^o$ = 134.1±0.7 kcal mol^{-1}. Entropy from Gurvich et al.[7] High level *ab initio* calculations result in an enthalpy value of 567.4±1.5 kJ mol^{-1}.[17]

C_2H_2 Enthalpy from an active thermochemical tables optimization.[14] The previous enthalpy of ΔH_f(298 K) = 227.4±0.8 kJ mol^{-1} was from the review of Gurvich et al.[7] Pedley gives the enthalpy as 228.2±0.7 kJ mol^{-1}.[12] The JANAF Tables give $\Delta_f H_0^o$ = 227.3 kJ mol^{-1}, $\Delta_f H_{298}^o$ = 226.7 kJ mol^{-1}, and S^o = 200.958 J K^{-1} mol^{-1}.[4] The critical evaluation by the Thermodynamic Research Center at NIST recommends $\Delta_f H^o_{298}$ = 226.4 kJ mol^{-1}.[20] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^o$ = 228.67±0.35 kJ mol^{-1}.[5] The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

H_2CC, vinylidene

Enthalpy from an active thermochemical tables optimization.[14] The previous enthalpy of ΔH_f(298 K) = 428±17 kJ mol^{-1} was based on a series of negative ion photoelectron spectroscopic measurements combined with proton-transfer kinetics.[6] CCSD(T) calculations, extrapolated to the CBS level, lead to $\Delta_f H_0^o$ = 98.6 kcal mol^{-1} and $\Delta_f H^o_{298}$= 98.8 kcal mol^{-1}.[11]

CH_3C, ethylidyne

Enthalpy from an active thermochemical tables optimization.[14] The cited enthalpy is identical to that for doublet ethylidyne, $^2CH_3C$. Quartet ethylidyne, $^4CH_3C$, is higher at ΔH_f(298 K) = 636.07±1.20 kJ mol^{-1},[14] and is completely unimportant under atmospheric conditions.

C_2H_3, CH_2CH, vinyl

Enthalpy from an active thermochemical tables optimization.[14] The previous enthalpy of ΔH_f(298 K) = 295.4±1.7 kJ mol^{-1} was derived from a third-law analysis of the reaction $Cl + C_2H_4 \leftrightarrow HCl + C_2H_3$.[8] A second-law analysis gives 69.1±1.6 kcal mol^{-1}. The recommendation of Tsang is 71.5±1 kcal mol^{-1}.[19] See also discussion by Lago and Baer.[9] Negative ion photoelectron spectroscopy combined with proton-transfer kinetics leads to a value of $\Delta_f H^o_{298}$= 71.6±0.8 kcal mol^{-1}.[6] A calculation at the HEAT345-Q level of theory gives recommended values of $\Delta_f H_0^o$ = 301.5±1.3 kJ mol^{-1} and $\Delta_f H_{298}^o$ = 297.3±1.3 kJ mol^{-1}.[18] This enthalpy difference provides the 0 K value in the Table. The entropy value was taken from the evaluation of Tsang.[19]

CH_3CH, ethylidene

Enthalpy from an active thermochemical tables optimization.[14] The cited enthalpy is very close to the value for triplet ethylidene, $^3CH_3CH$, ΔH_f(298 K) = 354.45±0.82 kJ mol^{-1}. The singlet ethylidene, $^1CH_3CH$, is higher at $\Delta_f H^o_{298}$= 366.70±0.86 kJ mol^{-1}.[14]

C_2H_4 Enthalpy from an active thermochemical tables optimization,[14] which is slightly different, but with a smaller error limit, than the earlier recommendation, $\Delta_f H^o_{298}$= 52.4±0.5 kJ mol^{-1} from the review of Gurvich et al.[7] The JANAF Tables give $\Delta_f H_0^o$ = 60.0 kJ mol^{-1}, $\Delta_f H_{298}^o$ = 52.5 kJ mol^{-1}, and S^o = 219.330 J K^{-1} mol^{-1}.[4] The critical evaluation by the Thermodynamic Research Center at NIST recommends $\Delta_f H^o_{298}$ = 52.5±0.5 kJ mol^{-1}, where the uncertainty represents the 95% confidence level.[20]

C_2H_5 Enthalpy from an active thermochemical tables optimization.[14] The previous enthalpy of $\Delta_f H^o_{298}$ = 120.9±1.7 kJ mol^{-1} and ΔH_f(0 K) = 131.8±1.7 kJ mol^{-1} are from the review of Berkowitz, Ellison, and Gutman.[1] A recent evaluation recommended $\Delta_f H^o_{298}$ = 119.9±3.1 kJ mol^{-1}, where the error limit is a standard deviation of the results considered.[3] Entropy from Gurvich et al.[7] Enthalpy of 120.7±1.0 kJ mol^{-1} has been derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory. $\Delta_f H_0^o$ = 132.3±1.0 kJ mol^{-1}.[2] A re-analysis of the thermal decomposition of C_2H_5I, making use of calculated molecular parameters, led to a value of $\Delta_f H_{298}^o$ = 124±3 kJ mol^{-1}.[16] The reaction enthalpy for $C_2H_5 + HI \rightarrow C_2H_6 + I$ was calculated using CCSD optimizations and CCSD(T) single-point energies, with small energetic corrections.[10] A value of $\Delta_r H^o_{298}$ = −125.45 kJ mol^{-1} vs. the value of −124.45 kJ mol^{-1} calculated using the formation enthalpies in this Table.

C_2H_6 Enthalpy from an active thermochemical tables optimization,[14] which is slightly different and with a smaller error limit, than the earlier recommendation, $\Delta_f H^\circ_{298} = -83.85\pm0.29$ kJ mol^{-1} from a flame calorimetry measurement.[13] A recent evaluation recommended $\Delta_f H^\circ_{298} = -80.41\pm1.26$ kJ mol^{-1}, where the error limit is a standard deviation of the results considered.[3] The critical evaluation by the Thermodynamic Research Center at NIST recommends $\Delta_f H^\circ_{298} = -84.0\pm0.9$ kJ mol^{-1}, where the uncertainty represents the 95% confidence level.[20] Entropy from Gurvich et al.,[7] who gives $\Delta_f H_{298}^\circ = -84.00\pm0.40$ kJ mol^{-1} and $\Delta_f H_0^\circ = -68.38\pm0.40$ kJ mol^{-1}.

Note 12: *Compounds containing two C, one O, and 1-6 H*

Back to Table

CHCO Based on the recommended dissociation energy for CH_2CO of 105.3±2.1 kcal mol^{-1}.[1] High level *ab initio* calculations result in an enthalpy of 173.8±1.5 kJ mol^{-1}.[20]

CH_2CO From photoionization or CH_2CO and a subsequent optimization of a local thermochemical network.[17] Calculations on several isodesmic reactions using CBS-QB3, CBS-APNO, and G3 methods led to a value of $\Delta_f H_{298}^{o} = -48.2 \pm 2.6$ kJ mol^{-1}.[18]

CH_3CO Recommendation taken from IUPAC Task Group.[16] Enthalpy is a weighted average of the experimental results, with amplified uncertainties assigned to the most negative values. This recommendation is only slightly lower that the value –10.0±1.2 kJ mol^{-1} previously recommended here.[1]

C_2H_2OH Calculated from the heat of reactions for OH + C_2H_2 of −146±10 kJ mol^{-1}.[7]

$CH_2C(O)H$, vinoxy radical

Enthalpy values calculated at the HEAT345-Q level of theory.[21] Previous enthalpy value an average of the a value obtained from the gas-phase basicity and proton affinity determined by a kinetic method (9.9±3.9 kJ mol^{-1}) and a reexamination of the results of Holmes, et al.[11] on the dissociation of ethyl acetate after electron ionization (15.9±5.6 kJ mol^{-1}).[3] This value is supported by several computational studies.[5,9,10,12] Previous recommendation, 10.5±9.2 kJ mol^{-1}, was from an analysis of gas-phase acidity and electron affinity studies.[1] A G3MP2B3 calculation led to $\Delta_f H_{298}^{o}$ = 13.45 kJ mol^{-1} and the selected entropy value.[12]

$CH_3C(O)H$

Enthalpy from Pedley,[15] entropy from Frenkel et al.[6] A critical evaluation by the Thermodynamics Research Center at NIST resulted in $\Delta_f H^{o}_{298} = -165.3$ kJ mol^{-1}.[22]

Vinyl alcohol and corresponding radicals (CH_2CHOH, CH_2COH, $CHCHOH$)

Molecular geometry optimized at the B3LYP/6-31G(d,p) level of theory. The enthalpy was determined using CBS-Q, CBS-APNO, and G3 methods with isodesmic reactions to minimize systematic errors. Entropies calculated by using the SMCPS program. The enthalpy values for both conformers of vinyl alcohol are within about 5 kJ mol^{-1} the average of the experimental values, which are based on ionization techniques.[4]

CH_3CH_2O Recommendation taken from IUPAC Task Group.[16] Enthalpy is based on a collision-induced dissociation measurement, which lies between the theoretical results and most of the previous recommendations, including that previously included here, $\Delta_f H_{298}^{o}$ = –15.5±3.3 kJ mol^{-1}.[1] Ruscic et al. note that their new preferred value corresponds to an O–H bond dissociation energy for ethanol more in line with that in methanol. Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^{o}$ = 0.8 kcal mol^{-1} and $\Delta_f H^{o}_{298}$ = –2.7 kcal mol^{-1}.[13]

CH_2CH_2OH

Calculated from the heat of reaction for the addition of OH to C_2H_4 of -123 ± 6 kJ mol^{-1}.[7] Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = -3.1$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -6.2$ kcal mol^{-1}.[13] The enthalpy of formation was also calculated from a set of isodesmic and isogyric reactions at the CBS-QB3 level of theory to be $\Delta_f H^\circ_{298} = -28.7\pm2.2$ kJ mol^{-1}. Calculations with B3LYP/cc-pVTZ were about 6 kJ mol^{-1} more negative.[2]

CH_3CHOH

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[19] Enthalpy recommended in the review of McMillen and Golden is -15.2 ± 1 kcal mol^{-1}.[14] Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = -9.8$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -13.1$ kcal mol^{-1}.[13]

C_2H_5OH Taken from review of Gurvich, et al.[8] Atomization energies calculated using CCSD(T) with cc-pVnZ (n = D, T, and Q) basis sets, using (U)MP2/aug-cc-pVTZ optimized geometries and extrapolated to the complete basis set limit, led to enthalpies of $\Delta_f H_0^\circ = -52.1$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -56.4$ kcal mol^{-1}.[13] A critical evaluation by the Thermodynamics Research Center at NIST resulted in $\Delta_f H^\circ_{298} = -235.3$ kJ mol^{-1}.[22]

CH_3OCH_2 Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[19] Recommendation in the review of McMillen and Golden, adjusted to allow for present enthalpy of CH_3COCH_3, is -3 ± 1 kcal mol^{-1}.[14]

CH_3OCH_3 Enthalpy from Pedley,[15] entropy from Frenkel et al.[6] Enthalpy calculated using the atomization energy method at the CBS-Q level gave -43.98 kcal mol^{-1}.[19] A critical evaluation by the Thermodynamics Research Center at NIST resulted in $\Delta_f H^\circ_{298} = -184.0$ kJ mol^{-1}.[22]

Note 13: *Compounds containing two C, two O, and 1-6 H*

Back to Table

$(CHO)_2$, glyoxal

The lowest energy conformer is the *trans* isomer. From the updated JANAF Tables, based on measurements of the heat of combustion.[2]

***cy*-$(C_2H_2O)O$, oxiranone (an α-lactone of ethylene oxide)**

Ab initio calculations utilizing isodesmic reactions.[9]

CH_3CHOOH

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-

31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12] This radical is unstable towards dissociation.

$C_2H_5O_2$ Based on a re-analysis of previous equilibrium data on $R + O_2 \leftrightarrow RO_2$ from the same laboratory.[5]

C_2H_5OOH Reaction enthalpy for the reaction $CH_3CH_2OO + CH_3OOH \rightarrow CH_3CH_2OOH + CH_3OO$ calculated to be 0.5 kcal mol^{-1} using the QCISD(T)/6-31G**// MP2/6-31G* method.[6] Previous enthalpy value (−175.4±12.9 kJ mol^{-1}) was computed on the assumption that the dissociation energy for ROO-H is 366±3 kJ mol^{-1} (Stocker and Pilling, unpublished work).[5] Pedley gives a value of –198.9±58.7 kJ mol^{-1}.[8] Enthalpy calculated using the atomization energy method at the CBS-Q level gave –38.78 kcal mol^{-1}.[12] Calculations using the CBS-QB3 and CBS-APNO model chemistries on three isodesmic reactions led to $\Delta_f H^o_{298} = -163.7\pm0.9$ kJ mol^{-1}.[11] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12]

CH_3OCO, radical from methyl formate

An average of two isodesmic reactions calculated at the G3MP2//B3LYP/6-31G(d) level.[10] Enthalpy calculated using the atomization energy method at the CBS-Q level gave $\Delta_f H_{298}^o$ = –37.87 kcal mol^{-1}.[12] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12]

$CH_2OC(O)H$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12]

$CH_3OC(O)H$, methyl formate

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[13] Previous enthalpy value of −357.4±0.7 kJ mol^{-1} taken from review of Pedley.[8] An average of three isodesmic reactions calculated at the G3MP2//B3LYP/6-31G(d) level, supported by G3 and B3LYP calculations gives $\Delta_f H_{298}^o$ = –82.3±0.49 kcal mol^{-1}.[10] Enthalpy calculated using the atomization energy method at the CBS-Q level gave $\Delta_f H_{298}^o$ = –85.87 kcal mol^{-1}.[12] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12]

CH_3COO Vibrational frequencies calculated at the HF/6-31G(D) level and total energies evaluated at the G2(MP2) level, also making use of isodesmic reactions.[15]

$CH_2(OH)CO$ and $CH(OH)C(O)H$

Enthalpy derived from isodesmic reactions calculated by the B3LYP/6-31G(d,p) and G3 methods. Reported results were adjusted for enthalpy values of reference compounds in this Table.[3]

$CH_2(OH)C(O)H$, glycoaldehyde

Enthalpy derived from isodesmic reactions calculated by the B3LYP/6-31G(d,p) and G3 methods. Reported results were adjusted for enthalpy values of reference compounds in this Table.[3]

$CH_2C(O)OH$

Enthalpy based on CID studies of the acetate radical anion yielding D(H-CH2COOH) = 95.3±2.9 kcal mol^{-1}.[14] Entropy based on vibrational frequencies calculated at the HF/6-31G(D) level.[15] Isodesmic reactions at the G2(MP2) level give –243 kJ mol^{-1}.

$CH_3C(O)O$

Derived from a hybrid experimental/CBS-Q approach.[7]

$CH_3C(O)OH$, acetic acid

Enthalpy from Pedley[8], entropy from Chao.[1]

$CH_2C(OH)_2$, ethene, 1-diol

Enthalpy obtained from three isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[10]

$CH_2(OH)CH_2OH$, 1,2-ethanediol

Enthalpy from Pedley,[8] entropy from Frenkel et al.[4]

$C(OH)_2C(O)H$, radical from ethanal, 2-diol

Calculated from two isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[10]

$CH(OH)_2C(O)H$, ethanal, 2-diol

Calculated from two isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[10]

C(O)HC(O)H, ethanedial (glyoxal)

From the review of Pedley.[8]

CH_2OOCH_3

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12] This radical is unstable towards decomposition.

CH_3OOCH_3

Enthalpy from updated JANAF Tables, based on calorimetric measurements.[2] Enthalpy calculated using the atomization energy method at the CBS-Q level gave $\Delta_f H_{298}^{o} = -29.17$ kcal mol^{-1}.[12] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[12]

Note 14: *Alkylcarbonate radicals*

Back to Table

Alkylcarbonate radials

Formation enthalpies for these short-lived radicals were studied by the CBS-Q method, with geometry optimization at the MP2/6-31G(d) level. Enthalpies from both atomization and bond-separation reactions were calculated. The differences were 4 kJ mol^{-1} or less, so the values were averaged for inclusion in the Table. The decomposition of the radicals was investigated by charge-reversal and neutralization-reionization mass spectrometry. For these ROC(O)O radicals, hydrogen-atom migration was important for R = CH_3 and C_2H_5, whereas decarboxylation was more important for R = H, *i*-C_3H_7, and *t*-C_4H_9.[1]

Note 15: *Compounds with two C and more than 2 O*

Back to Table

$CH_3C(O)O_2$

Derived from a hybrid experimental/CBS-Q approach.[3]

$CH_2(OH)C(O)OH$, glycolic acid

From the updated JANAF Tables, estimated based on additivity methods.[2]

$CH_2(OH)OOCH_2OH$, dioxybismethanol

Taken from the review of Pedley[4]

$(HOCO)_2$, oxalic acid

Updated JANAF Tables, based on the enthalpy of combustion of the solid and the enthalpy of vaporization.[2]

$CH_3O_4CH_3$, dimethyl tetroxide

Molecular geometry optimized at the B3LYP/cc-pVTZ+d level of theory. The enthalpy was determined using G3B3 and CBS-APNO methods with isodesmic reactions to minimize systematic errors. Several bond dissociation energies were also reported.[1]

$C(OH)_2C(O)H$, radical from ethanal, 2-diol

Calculated from two isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[5]

$CH(OH)_2C(O)H$, ethanal, 2-diol

Calculated from two isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[5]

Note 16: *Compounds with two C, one N, and 0-5 O*

Back to Table

NCCN, Cyanogen

Enthalpy and entropy values taken from the review of Gurvich.[4] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ$ = 307.8±4.2 kJ mol^{-1} and $\Delta_f H^\circ_{298}$= 310.0±4.2 kJ mol^{-1}.[9]

CNCN, Isocyanogen

Enthalpy values obtained from a computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[9]

CNNC, Diisocyanogen

Enthalpy values obtained from a computational study of atomization involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4.[9]

$C_2H_5NO_2$ Calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions. Value reported is $\Delta_f H_{298}^\circ$ = −25.06±0.07 kcal mol^{-1}, which is adjusted using the reference enthalpy for *cis*-HONO from this Table.[1] A calculation of the atomization energy at the G3 level of theory leads to $\Delta_f H_{298}^\circ$ = −24.7 kcal mol^{-1}. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[5]

C_2H_5ONO Calculated using G3, CBS-QB3, and CBS-APNO methods applied to atomization, isomerization, and work reactions. Value reported is $\Delta_f H_{298}^\circ$ = −23.58±0.12 kcal mol^{-1}, which is adjusted using the reference enthalpy for *cis*-HONO from this Table.[1] A calculation of the atomization energy at the G3 level of theory leads to $\Delta_f H_{298}^\circ$ = −22.9 kcal mol^{-1}. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[5]

$C_2H_5O_2NO_2$

Equilibrium structures optimized at the MP2 level with the 6-311G(d,p) basis set and enthalpy values calculated by both atomization energies and through use of isodesmic reactions at the G3, G3B3, and G4 methods.[3]

$CH_3C(O)O_2NO_2$

Derived from a hybrid experimental/CBS-Q approach.[6]

$CH_3CHN(O)OH$

Enthalpy value calculated from the atomization energy at the G3 level of theory. Calculations also carried out at the G2, G2M(CC5), B3LYP, MW1B95, and MPWB1K levels.[5]

$C_2H_5NH_2$, ethylamine

From the review of Pedley.[7] Values of $\Delta_f H_{298}^\circ$ = −50.1±1.5 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –28.6±1.5 kJ mol^{-1} have been derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory.[2]

$(CH_3)_2N$ Obtained from a computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies.[8]

CH_3NHCH_2

Obtained from a computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies.[8]

CH_3NHCH_3, dimethylamine

From the review of Pedley.[7] A computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies resulted in $\Delta_f H^\circ_{298} = -16.0$ kJ mol^{-1} and the listed entropy value.[8] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ = 5.1\pm3.0$ kJ mol^{-1} and $\Delta_f H^\circ_{298} = -16.1\pm3.0$ kJ mol^{-1}.[9]

CH_3CONH_2, acetamide

From the review of Pedley.[7]

Note 17: *C3 hydrocarbons*

Back to Table

C_3H_4, propadiene

Enthalpy from Pedley.[4]

C_3H_4, propyne

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[11] The previous enthalpy value, $\Delta_f H^\circ_{298} = 184.9\pm0.7$ kJ mol^{-1}, from Pedley.[4]

***cy*-C_3H_3, 3-cyclopropenyl radical**

The 3-cyclopropenium cation was reacted with a series of reagents to establish the ionization energy of the radical as 6.00±0.17 eV or 578.9±16.4 kJ mol^{-1}.[9] This, combined with the enthalpy of formation of the reaction of 1076.5±3.3 kJ mol^{-1}, leads to the reported value. High level G3 and W1 calculation lead to similar values.

***cy*-C_3H_4, cyclopropene**

Enthalpy from Pedley.[4]

C_3H_5 From a second-law analysis of $C_3H_5 + HBr \leftrightarrow C_3H_6 + Br$.[6] A calculation at the HEAT345-Q level of theory gives recommended values of $\Delta_f H_0^\circ = 180.3\pm1.8$ kJ mol^{-1} and $\Delta_f H_{298}^\circ = 168.6\pm1.8$ kJ mol^{-1}.[8] This enthalpy difference provides the 0 K value in the Table.

C_3H_6 Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[11] The previous enthalpy value, $\Delta_f H^\circ_{298}$ = 20.0±0.7 kJ mol^{-1}, from Pedley[4]. Entropy value from Chao.[3]

***n*-C_3H_7** Enthalpy derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory.[1] Previous value of $\Delta_f H_{298}^\circ$ = 100±2 kJ mol^{-1} estimated by Tsang.[10]

***i*-C_3H_7** From a second-law analysis of iso-C_3H_7 + HBr ↔ iso-C_3H_8 + Br.[7] An enthalpy of $\Delta_f H_{298}^\circ$ = 88.5±1.0 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 106.2±1.0 kJ mol^{-1} has been derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory.[1]

C_3H_8 Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[11] The previous enthalpy value, $\Delta_f H^\circ_{298}$ = –104.68±0.50 kJ mol^{-1}, from a combustion calorimetry study.[5] Entropy from ideal gas properties calculations.[2]

Note 18: *Compounds containing 3 C 1-8 H, and 1 O*

Back to Table

1-C_3H_7OH Enthalpy taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[16] Previous value, $\Delta_f H_{298}^\circ$ = −255.1±0.4 kJ mol^{-1}, from review of Pedely et al.[12] Entropy value from evaluation of Chao, et al.[3]

2-C_3H_7OH Enthalpy taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[16] Previous value, $\Delta_f H_{298}°$ = −272.6±0.5 kJ mol^{-1}, from review of Pedely et al.[12] Entropy value from evaluation of Chao, et al.[3]

C_2H_5CO CBS-4 and G2(MP2,SVP) methods used to obtain thermodynamic properties. Value listed is recommendation based on theoretical and experimental results. Entropy at the G2(MP2(full)//MP2(full)/6-31G(d) level treating internal rotations as harmonic oscillators.[17]

$C_2H_5C(O)H$

Enthalpy taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[16] The previous enthalpy value, $\Delta_f H^\circ_{298}$ = −185.6±0.8 kJ mol^{-1}, from Pedley.[12] Entropy from Frenkel et al.[7]

CH_2CHOCH_3 and C_3H_5O

Methyl vinyl ether and corresponding radicals. Molecular geometry optimized at the B3LYP/6-31G(d,p) level of theory. The enthalpy was determined using CBS-Q, CBS-APNO, and G3 methods with isodesmic reactions to minimize systematic errors. Entropies calculated by using the SMCPS program.[4]

$CH_3C(O)CH_2$

Enthalpy value an average of the a value obtained from the gas-phase basicity and proton affinity determined by a kinetic method (−34.6±8.4 kJ mol^{-1}) and a reexamination of the results of Holmes et al.[9] on the dissociation of 2-propenyl acetate and acetylacetone after electron ionization (−33.1 and −30.3 kJ mol^{-1}).[2] This value is supported by several computational studies.[5,8,10] The previous recommendation, −28.1±3.1 kJ mol^{-1}, was derived from forward and reverse rate constants for the reaction $CH_3C(O)CH_2 + HBr \leftrightarrow CH_3C(O)CH_3 + Br$.[6] The reverse rate constant requires an extrapolation from high temperatue for the reference reaction. An earlier photobromination determination of the reverse reaction results in an enthalpy value of −24.3±5.8 kJ mol^{-1}.[11] Density functional and ab initio calculations at the CBS-QB3 level of theory, using a series of isodesmic reactions, led to $\Delta_f H^\circ_{298}$ = −24.3±5.8 kJ mol^{-1}.[5] The entropy value is from G3MP2B3 calculation.[10]

$CH_3C(O)CH_3$

Enthalpy from review of Pedley;[12] entropy value from Frenkel.[7]

CH_3CHOCH_3 and $CH_3CH_2OCH_2$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[15]

$CH_3CH_2OCH_3$, methoxyethane (methyl ethyl ether)

Enthalpy from Pedley et al.[12] An identical value was recommended by the Thermodynamics Research Center at NIST.[16] Enthalpy calculated using the atomization energy method at the CBS-Q level gave −52.20 kcal mol^{-1}.[15] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[15]

$CH_2CC(O)H$, radical from propenal

Enthalpy obtained from four isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[13]

CH_2CHCO, radical from propenal

CBS-4 and G2(MP2,SVP) methods used to obtain thermodynamic properties. Value listed is recommendation based on theoretical and experimental results. Entropy at the G2(MP2(full)//MP2(full)/6-31G(d) level treating internal rotations as harmonic oscillators.[17]

CH_3CHCO, methyl ketene

Reaction enthalpies for two isodesmic reactions were calculated at the CBS-QB3, CBS-APNO, and G3 levels.[14] Preferred values for the reference compounds from this Table were employed.

$CH_2CHC(O)H$, propenal, acrolein

Enthalpy obtained from W1 atomization energy calculations. Geometric properties evaluated at the B3LYP/cc-pVTZ+d level of theory, with the rotation about the C-C bond treated as a hindered rotation.[1] The previous enthalpy value, $\Delta_f H^\circ_{298}$ = −74.3±1.7 kJ mol^{-1}, was determined in the same laboratory from two isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[13]

Note 19: *Compounds containing 3 C 1-8 H, and 2 O*

Back to Table

$C_3H_5O_2$ Equilibrium constants for the reaction $C_3H_5 + O_2 \leftrightarrow C_3H_5O_2$ were determined over the temperature range 320–420 K and fit to a van't Hoff plot. Combining the results with previous results led to $\Delta_r H^\circ_{298} = -75.6\pm2.3$ kJ mol^{-1} and $\Delta_r S = -129.9\pm3.1$ J K^{-1}mol^{-1}.[5]

$CH_2CHOOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4-6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±2.8 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol^{-1}, ranged from ±6.7 to 14 kJ mol^{-1}.[6]

$C_2H_5C(O)OH$

Enthalpy taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$CH_3CH(OH)CH_2OH$, 1,2-propanediol

From review of Pedley et al.[4]

C_3H_5OOH Enthalpy based on calculations made using the CBS-QB3 and CBS-APNO model chemistries on two isodesmic reactions.[8]

$CH_2OC(O)CH_3$ and $CH_3OC(O)CH_3$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9] An enthalpy value of $\Delta_r H^\circ_{298} = -413.5$ kJ mol^{-1} for methyl ethanoate, $CH_3CH_2OC(O)H$, was recommended by the Thermodynamics Research Center at NIST.[10]

$CH_3OCH_2OCH_3$, dimethoxymethane

From the review of Pedley et al.[4]

$CH_3CH_2OC(O)$, $CH_3CHOC(O)H$, $CH_3CH_2OC(O)H$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9] An enthalpy value of $\Delta_r H^\circ_{298} = -398.5\pm8.5$ kJ mol^{-1} for ethyl methanoate, $CH_3CH_2OC(O)H$, was recommended by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$CH_2(OH)C(O)CH_3$, hydroxyacetone

Enthalpy derived from isodesmic reactions calculated by the B3LYP/6-31G(d,p) and G3 methods. Reported results were adjusted for enthalpy values of reference compounds in this Table.[1]

$CH_3CHOOCH_3$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9] This radical is unstable towards dissociation

$CH_3CH_2OOCH_3$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9]

$(CH_3)_2CHOO$

Based on a re-analysis of previous equilibrium data on R + $O_2 \leftrightarrow RO_2$ from the same laboratory.[2]

$(CH_3)_2COOH$

Calculated using the complete basis set method, CBS-Q. Enthalpies calculated using the atomization energy method. Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9]

$(CH_3)_2CHOOH$

Reaction enthalpy for the reaction $(CH_3)_2CHOO + CH_3OOH \rightarrow (CH_3)_2CHOOH + CH_3OO$ calculated to be 0.6 kcal mol^{-1} using the QCISD(T)/6-31G**// MP2/6-31G* method.[3] Enthalpy calculated using the atomization energy method at the CBS-Q level gave –48.1 kcal mol^{-1}.[9] Entropy based on geometric properties optimized at the MP2/6-31G(d') level and vibrational frequencies at the HF/6-31G(d') level.[9]

$CH_3C(OH)_2C(O)OH$

Enthalpy obtained from three isodesmic reactions at the G3MP2//B3LYP/6-31G(d) level of theory.[7]

$CH_2(OH)CH(OH)CH_2OH$, 1,2,3-propanetriol

Taken from the review of Pedley et al.[4]

$CH_2CHOOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4–6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±2.8 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol–1, ranged from ±6.7 to 14 kJ mol^{-1}.[6]

Back to Table

$C_3H_7NH_2$ Enthalpy derived from a threshold PEPICO study of alkyl amines and the use of two isodesmic reaction networks, connected through the TPEPICO dissociation energies, and with reaction heats calculated at the CBS-APNO and W1U levels of theory.[2]

$(CH_3)_2NCH_2$

Obtained from a computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies.[6]

$(CH_3)_3N$, trimethylamine

From the review of Pedley et al.[5] A computational analysis involving B3LYP/6-31G(2df,p) for geometric factors and G4 for atomization energies resulted in $\Delta_f H^\circ_{298} = -25.56$ kJ mol^{-1} and the listed entropy value.[6] A computational study involving the use of several composite models, CBS-QB3, CBS-APNO, G3, and G4, led to values of $\Delta_f H_0^\circ = 1.5 \pm 4.2$ kJ mol^{-1} and $\Delta_f H^\circ_{298} = -26.1 \pm 4.3$ kJ mol^{-1}.[7]

$(CH_3)_3NO$, trimethylene-*N*-oxide

Enthalpy from heat of combustion of solid and estimated sublimation enthalpy.[1]

$C_3H_7O_2NO_2$

Equilibrium structures optimized at the MP2 level with the 6-311G(d,p) basis set and enthalpy values calculated by both atomization energies and through use of isodesmic reactions at the G3, G3B3, and G4 methods.[3]

NCC(O)CN, oxopropanedinitrile

From the updated JANAF Tables, based on calorimetric measurements.[4]

***trans*-C_4H_8, *trans*-2-butene**

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$CH_3C(CH_3)CH_2$, *2*-methylpropene

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$CH_3CH(CH_3)CH_3$, *2*-methylpropane

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

***n*-C_4H_{10}** Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10] The previous enthalpy value, $\Delta_f H^\circ_{298}$ = -125.65 ± 0.67 kJ mol^{-1}, from a combustion calorimetry study.[7] Entropy by ideal gas properties calculations.[4]

$CH_3CH(CH_3)C(O)OH$, $C_3H_7C(O)OH$

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$C_2H_5OC(O)CH_3$, ethyl acetate

Taken from a critical evaluation by the Thermodynamics Research Center at NIST, where the uncertainty represents the 95% confidence level.[10]

$(CH_3)_2CCO$, dimethyl ketene

Reaction enthalpies for three isodesmic reactions were calculated at the CBS-QB3, CBS-APNO, and G3 levels.[9] The preferred value for ketene from this Table was employed.

$(CH_3)_3CO$, *tert*-Butoxyl

Earlier photoacoustic calorimetry results were combined with redetermined values of the enthalpy of formation and vaporization of di-1,1-dimethylethyl peroxide (using combustion calorimetry, ebulliometry, and heat capacity measurements) to derive this improved enthalpy of formation.[2]

$(CH_3)_3COO$

Based on a re-analysis of previous equilibrium data on $R + O_2 \leftrightarrow RO_2$ from the same laboratory.[5]

$(CH_3)_3COOH$

Enthalpy based on the gas-phase acidity and electron affinity from a negative ion photoelectron spectral study, leading to a BDE(O-H) of 85±2 kcal mol^{-1} (83±2 kcal mol^{-1} at 0 K).[1] Reaction enthalpy for the reaction $(CH_3)_3COO + CH_3OOH \rightarrow (CH_3)_3COOH + CH_3OO$ was calculated to be 1.3 kcal mol^{-1} using the QCISD(T)/6-31G**// MP2/6-31G* method, leading to $\Delta_f H^\circ_{298}$ = -56.8 kcal mol^{-1}.[6]

$(CH_3COO)_2$, diacetyl peroxide

From updated JANAF Tables, based on a calorimetric measurement on the liquid and an assumed enthalpy of vaporization.[3]

trans-$CH_3CHCHOOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4-6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±2.8 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol^{-1}, ranged from ±4.2 to 10.3 kJ mol^{-1}.[8]

cis-$CH_3CHCHOOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4-6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±2.0 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol^{-1}, ranged from ±4.0 to 8.0 kJ mol^{-1}.[8]

$CH_2C(CH_3)OOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4-6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±1.8 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol^{-1}, ranged from ±3.8 to 7.8 kJ mol^{-1}.[8]

$CH_2CHCH_2OOCH_3$

Thermodynamic parameters were determined at the B3LYP/6-311G(d,p) level of theory, with the enthalpy the average of 4-6 isodesmic reactions. The standard deviation of the enthalpy from the average of the isodesmic reactions was ±1.1 kJ mol^{-1}, but the estimated error limits for the individual isodesmic reactions, which take into account the uncertainty in each reactant and an estimated uncertainty due to thermal energy of 0.46 kJ mol^{-1}, ranged from ±3.2 to 7.4 kJ mol^{-1}.[8]

Note 22: *Inorganic compounds containing F*

Back to Table

F Enthalpy value is from the optimization in the Active Thermochemical Tables (ATcT).[16] CODATA Key Value[4] of $\Delta_f H^\circ_{298}$ = 79.38±0.30 kJ mol^{-1} was used in previous evaluation. Entropy value is from CODATA.

F_2 CODATA Key Value.[4]

HF CODATA Key Value.[4] The active thermochemical tables optimization gives an enthalpy value of –272.775±0.24 kJ mol^{-1}.[17] The most recent NIST-JANAF review gives and enthalpy of –273.3000±0.70 kJ mol^{-1} and an entropy of 173.778±0.005 J K^{-1} mol^{-1}.[18] A network optimization of *ab initio* reaction enthalpies results in a value of $\Delta_f H_0^\circ$ = –272.82±0.35 kJ mol^{-1}.[5] The uncertainty corresponds to the 95% confidence limit. The reference atomic values were taken from the Active Thermochemical Tables, ver. 1.20.

HOF Enthalpy value at 0 K from a re-evaluation of the photoionization studies, along with the newer enthalpy for OH and a more recent ionization energy for OH.[15] Previous values of $\Delta_f H^\circ_{298}$ = −98.3±4.2 kJ mol^{-1} and $\Delta_f H_0^\circ$ = −95.4±4.2 kJ mol^{-1} from JANAF review from 1972.[3] A calculation of the isodesmic reaction HOF + OH → FO + H_2O at the W4.2 level of theory leads to $\Delta_f H^\circ_{298}$ = −87.2±0.6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = −84.3±0.6 kJ mol^{-1}, in good agreement.[13]

FO Atomization energy was calculated using the Wn family of computational methods. Small increases in the atomization energy were found going from W2.2 to W4.4. These results led to $\Delta_f H^\circ_{298}$ = 110.58±0.46 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 109.96±0.46 kJ mol^{-1}.[13] Atomization energy calculated at the CCSD(T)(FC) level through aug-cc-PV7Z basis sets led to $\Delta_f H^\circ_{298}$ = 110.88±0.84 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 110.04±0.84 kJ mol^{-1}.[9] These were averaged to give the Table values. The previous table values of $\Delta_f H^\circ_{298}$ = 109±10 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 108±10 kJ mol^{-1} were from the NIST-JANAF thermochemical tables for the oxygen fluorides[2] and were based on mass spectrometric and thermal decomposition studies of FOF. The atomization energy calculated with CCSD(T) using aug-cc-pVnZ (n=D-6) basis sets, approaching the complete basis set limit, resulted in $\Delta_f H^\circ_{298}$ = 27.9±0.4 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 27.6±0.4 kcal mol^{-1}.[7] The entropy value is from JANAF.[2]

FOF NIST-JANAF thermochemical tables for the oxygen fluorides.[2] Enthalpy based on a series of calorimetric studies. Atomization energy calculated at the CCSD(T)(FC) level through aug-cc-PV7Z basis sets led to $\Delta_f H^\circ_{298}$ = 24.7±1.3 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 26.8±1.3 kJ mol^{-1}.[9] The atomization energy calculated with CCSD(T) using aug-cc-pVnZ (n=D-6) basis sets, approaching the complete basis set limit, resulted in $\Delta_f H^\circ_{298}$ = 6.6±0.5 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 7.1±0.5 kcal mol^{-1}.[7] An extrapolation of a CCSD(T) calculation with aug-cc-pVTZ and aug-cc-pVQZ basis sets lead to $\Delta_f H^\circ_{298}$ = 24.4±4 kJ mol^{-1}.[12]

OFO Atomization energy calculated at the CCSD(T)(FC) level through aug-cc-PV7Z basis sets led to the listed enthalpy.[9] The previous Table values of $\Delta_f H^\circ_{298}$ = 380±20 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 381±20 kJ mol^{-1} were from the NIST-JANAF thermochemical tables for the oxygen fluorides and was based on a calculated value of enthalpy difference between OFO and FOO at 0 K of 356 kJ mol^{-1}.[2] The entropy value is also from the JANAF Table and is based on the earlier computational results.

FOO From an analysis of studies of the equilibrium F + O_2 ↔ FOO (Table 3-1, Note 10). NIST-JANAF thermochemical tables for the oxygen fluorides, based on several experimental values, primarily from kinetic studies recommends $\Delta_f H^\circ_{298}$ = 25.4±2 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 27.2±2 kJ mol^{-1}.[2] This is also the source of the entropy value. A determination of the atomization energy gave $\Delta_f H^\circ_{298}$= 5.8±0.3 kcal mol^{-1},[8] whereas a UCCSDT calculation led to $\Delta_f H^\circ_{298}$= 6.5±1 kcal mol^{-1}.[6] Atomization energy was calculated using the Wn family of computational methods. Significant increases in the atomization energy were found going from W2.2 to W4.4. These results led to $\Delta_f H^\circ_{298}$ = 24.6±0.7 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 26.4±0.7 kJ mol^{-1}.[13] Atomization energy calculated at the CCSD(T)(FC) level through aug-cc-PV7Z basis sets led to $\Delta_f H^\circ_{298}$ = 26.8±2.9 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 28.9±2.9 kJ mol^{-1}.[9]

HOOF Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized through the CCSD(T)/aV(T+d)Z level.[10]

FOOF NIST-JANAF thermochemical tables for the oxygen fluorides.[2] Value adopted for enthalpy is that recommended by Lyman[14] based on a calorimetric measurement on the decomposition into O_2 and F_2. The atomization energy calculated with CCSD(T) using aug-cc-pVnZ (n=D-6) basis sets, approaching the complete basis set limit, resulted in $\Delta_f H^\circ_{298}$ = 40.2±3.8 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 43.9±3.8 kJ mol^{-1}.[7] Atomization energy was calculated using the Wn family of computational methods. Significant increases in the atomization energy were found going from W2.2 to W4.4. These results led to $\Delta_f H^\circ_{298}$ = 32.8±0.75 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 37.24±0.75 kJ mol^{-1}.[13] Atomization energy calculated at the CCSD(T)(FC) level through aug-cc-PV7Z basis sets led to $\Delta_f H^\circ_{298}$ = 26.8±2.9 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 31.0±2.9 kJ mol^{-1}.[9] An extrapolation of a CCSD(T) calculation with aug-cc-pVTZ and aug-cc-pVQZ basis sets lead to $\Delta_f H^\circ_{298}$ = 34.8±4 kJ mol^{-1}.[12]

FOOOF, for the C_2 conformer

Based on an extrapolation of a CCSD(T) calculation with aug-cc-pVTZ and aug-cc-pVQZ basis sets. For the C_s conformer, $\Delta_f H^\circ_{298}$ = 111.3±4 kJ mol^{-1} and S = 204.3 J K mol^{-1} K^{-1}.[12]

FNO The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[20] The previous value, $\Delta_f H^\circ_{298}$ = −65.7 kJ mol^{-1}, was taken from review of Stull, et al.[19] The JANAF Tables give $\Delta_f H_0^\circ$ = –63.3 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = –65.7 kJ mol^{-1}, and S° = 248.082 J mol^{-1} K^{-1}.[3]

***cis, trans*-FONO**

The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[20] The previous value, $\Delta_f H^\circ_{298}$ = 67 kJ mol^{-1}, was estimated.[1]

FNO_2 The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[20] The previous value, $\Delta_f H^\circ_{298}$ = −79 kJ mol^{-1}, was taken from review of Stull et al.[19]

$FONO_2$ The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[20] The previous value, $\Delta_f H^\circ_{298}$ = 15±3 kJ mol^{-1}, was taken from review of Gurvich et al.[11] The JANAF estimate from 1963 gave an enthalpy of 10±2 kJ mol^{-1}.[3]

NF_2 Enthalpy value from a reanalysis of the data used by JANAF, combined with the newer enthalpy value for NF_3.[21]

NF_3 A study of the combustion of rhombic sulfur in NF_3 to generate SF_6 and N_2 using $\Delta_f H^\circ_{298}(SF_6)$ = –1220.8±0.8 kJ mol^{-1} results in the enthalpy of NF_3.[21]

Back to Table

CF Thermodynamic properties from Gurvich et al. review.[6] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ =243.3±0.8 kJ mol^{-1}, $\Delta_f H^o_{298}$ =247.0±0.8 kJ mol^{-1}, and S = 212.9±1.5 J K^{-1} mol^{-1}.[5] A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 and vQz-F12 basis sets led to $\Delta_f H_0^o$ = 243.8±1.0 kJ mol^{-1} and $\Delta_f H^o_{298}$= 247.9±1.0 kJ mol^{-1}.[1]

CHF Calculated for the X^1A' state. Enthalpy from a CCSD(T) calculation with the aug-cc-pVnZ (n=D,T,Q,5) basis set extrapolated to the CBS limit and entropy from a MP2/aVTZ calculation.[9] Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_2F_2 + 2CH_3Y \rightarrow CFY(^1A_1) + 3CH_4$ results in $\Delta_f H^o_{298}$ = 146 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[15] Previous recommendation, $\Delta_f H^o_{298}$ = 143±13.0 kJ mol^{-1}, based on combining experimental chloride dissociation energies from the parent anion, prior experimental measurements, and G2 calculations.[12] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ =148.9±1.2 kJ mol^{-1}, $\Delta_f H^o_{298}$ = 149.0±1.2 kJ mol^{-1}, and S = 223.1±1.5 J K^{-1} mol^{-1}.[5]

CH_2F Derived from the kinetics and equilibria of the iodination reaction $CH_3F + I_2 \leftrightarrow CH_2FI + HI$.[11] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of –29.0±4.1 kJ mol^{-1}.[16] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ = −27.9±1.6 kJ mol^{-1}, $\Delta_f H^o_{298}$ = −31.2±1.6 kJ mol^{-1}, and S = 232.5±1.5 J K^{-1} mol^{-1}.[5] This enthalpy difference was used to calculate the 0 K value in the Table.

CH_3F Enthalpies of reaction calculated (and averaged) at the MCG3//MCQCISD level of theory (up to 6-311++G(3d2f,2df,2p) basis set) for the homolytic fragmentation to the alkyl radical and fluoride atom, and for the atomization reaction. Enthalpy also calculated for the heterolytic fragmentation into the alkyl cation and fluoride anion for support.[7] Previous value, $\Delta_f H^o_{298}$ = -238±8 kJ mol^{-1}, estimated in review of Rodgers et al.[13] Luo and Benson recommend -55.9±1 kcal/mol.[8] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ = −228.5±2.0 kJ mol^{-1}, $\Delta_f H^o_{298}$= −236.9±2.0 kJ mol^{-1}, and S = 222.5±1.5 J K^{-1} mol^{-1}.[5] This enthalpy difference was used to calculate the 0 K value in the Table.

CF_2 Calculated for the X^1A' state. Enthalpy from a CCSD(T) calculation with the aug-cc-pVnZ (n=D,T,Q,5) basis set extrapolated to the CBS limit and entropy from a MP2/aVTZ calculation.[9] $\Delta_f H_0^o$ = –46.0±0.8 kcal mol^{-1}. Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_2F_2 + 2CH_3Y \rightarrow CFY(^1A_1) + 3CH_4$ results in $\Delta_f H^o_{298}$ = -196 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[15] Previous recommendation, –44.0±2 kcal mol^{-1}, based on combining experimental chloride dissociation energies from the parent anion, prior experimental measurements, and G2 calculations.[12] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ = −193.6±1.2 kJ mol^{-1}, $\Delta_f H^o_{298}$= −193.2±1.2 kJ mol^{-1}, and S = 240.6±1.5 J K^{-1} mol^{-1}.[5] A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 and vQz-F12 basis sets led to $\Delta_f H_0^o$ = −193.2±1.3 kJ mol^{-1} and $\Delta_f H^o_{298}$= −190.4±1.3 kJ mol^{-1}.[1]

CHF_2 Derived from the kinetics and equilibria of the iodination reaction $CH_3F + I_2 \leftrightarrow CH_2FI + HI$.[11] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of –241.2±4.1 kJ mol^{-1}.[16] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o$ = −239.4±2.6 kJ mol^{-1}, $\Delta_f H^o_{298}$= −243.0±2.6 kJ mol^{-1}, and S = 255.8±6.5 J K^{-1} mol^{-1}.[5] The enthalpy difference was used to calculate the 0 K value in the Table.

CH_2F_2 From review by Rodgers et al.[13] Pedley gives –452.3±0.9 kJ mol^{-1}.[10] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -442.6\pm2.0$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -450.5\pm2.0$ kJ mol^{-1}, and $S = 246.3\pm1.5$ J K^{-1} mol^{-1}.[5] The enthalpy difference was used to calculate the 0 K value in the Table.

CF_3 Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[14] Entropy from recommendation of Gurvich et al.[6] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of –465.9±4.1 kJ mol^{-1}.[16] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -464.8\pm1.6$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -467.6\pm1.6$ kJ mol^{-1}, and $S = 264.1\pm1.5$ J K^{-1} mol^{-1}.[5] A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 and vQz-F12 basis sets led to $\Delta_f H_0^\circ = -468.4\pm1.6$ kJ mol^{-1} and $\Delta_f H^\circ_{298} = -469.3\pm1.6$ kJ mol^{-1}.[1]

CHF_3 Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[14] Entropy from recommendation of Gurvich et al.[6] An enthalpy calculation from the atomization energy was obtained starting with a 'best estimated' structure from extensive calculations and analysis, followed by CCST with aug-cc-pVQZ and aug-cc-pV5Z basis sets, and CCSD(T) with aug-cc-pVTZ and aug-cc-pVQZ basis sets. Values of $\Delta_f H_0^\circ = -165.18$ kcal mol^{-1} and $\Delta_f H^\circ_{298} = -166.86$ kcal mol^{-1} were obtained.[2] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -687.7\pm2.0$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -694.9\pm2.0$ kJ mol^{-1}, and $S = 259.2\pm1.5$ J K^{-1} mol^{-1}.[5]

CF_4 CODATA Key Value.[4] The JANAF Tables give $\Delta_f H_0^\circ = -927.2$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -933.2$ kJ mol^{-1}, and $S^\circ = 261.419$ J mol^{-1}.[3] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -927.8\pm2.0$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -933.8\pm2.0$ kJ mol^{-1}, and $S = 260.9\pm1.5$ J K^{-1} mol^{-1}.[5] A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 and vQz-F12 basis sets led to $\Delta_f H_0^\circ = -930.7\pm2.0$ kJ mol^{-1} and $\Delta_f H^\circ_{298} = -934.2\pm2.0$ kJ mol^{-1}.[1]

Back to Table

CFH_2O and CFH_2OH

The enthalpies of formation are based on isodesmic reactions calculated at the MP2/6-31G(d,p) level of theory.[16]

FCO The enthalpy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[14] The previous $\Delta_f H_{298}^{\circ} = -174.1 \pm 2$ was from a CCSD(T) calculation with the aug-cc-pVnZ (n=D,T,Q,5) basis set extrapolated to the CBS limit.[13] The entropy value is from a MP2/aVTZ calculation.[13] The decomposition rate constant for $FCO \rightarrow F + CO$,[9] combined with the rate constant $k = 2.4 \times 10^{-22}$ cm^6 s^{-1} [18] for the reverse reaction, results in an upper limit of $\Delta_f H_{298}^{\circ} < -153.1$ kJ mol^{-1}.[9] A. CCSD(T) calculation gives $\Delta_f H_{298}^{\circ} = -42.0 \pm 0.5$ kcal mol^{-1}.[4]

FCO_2, fluoroformyloxyl radical

Calculated at the CCSD(T) level of theory. CFO value from same work is -42.0 ± 0.5 kcal mol^{-1}, which differs from value in Table.[4]

CHFO The enthalpy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[14] The previous $\Delta_f H_{298}^{\circ} = -381.2 \pm 2$ was from a CCSD(T) calculation with the aug-cc-pVnZ (n = D,T,Q,5) basis set extrapolated to the CBS limit.[13] The entropy value is from a MP2/aVTZ calculation.[13] The earlier enthalpy value, -91.6 kcal mol^{-1}, was from an G2(MP2) calculation,[17] and the earlier entropy was from Gurvich et al.[8]

CF_2HFO and CF_2HOH

The enthalpies of formation are based on isodesmic reactions calculated at the MP2/6-31G(d,p) level of theory.[16]

CF_2O The enthalpy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set,[14] supported by several earlier computational studies discussed in that paper.[3,7,13] The previous $\Delta_f H_{298}^{\circ} = -623.8 \pm 5.9$ was a lower limit from a photoionization study.[1] Entropy from Gurvich et al.[8] Pedley review gives an enthalpy value of -639.8 ± 1.4 kJ mol^{-1}.[15] A CCSD(T) calculation with the aug-cc-pVnZ (n=D,T,Q,5) basis set extrapolated to the CBS limit gave $\Delta_f H_0^{\circ} = -143.9 \pm 0.5$ kcal mol^{-1}, $\Delta_f H_{298}^{\circ} = -144.7 \pm 0.5$ kcal mol^{-1}, and $S = 61.87$ cal K^{-1}mol^{-1}.[13]

CF_3O Re-analysis of data of Batt and Walsh, using new value for CF_2O.[1] The enthalpy of formation, $\Delta_f H_{298}^{\circ} = -154.5$ kcal mol^{-1} based on an isodesmic reaction calculated at the MP2/6-31G(d,p) level of theory.[16]

CF_2O_2 Determined on the basis of extensive ab initio calculations.[11] Isomeric forms F_2COO and FC(=O)OF are calculated to have enthalpies of –60 and –104 kcal mole^{-1}, respectively.

CF_3O_2 Two values for the C-O bond dissociation energy in CF_3O_2 are given in Lightfoot, et al., -144±3.3 and –141±10 kJ mol^{-1} at 0 K and adjusted to 298 K.[12] The value given is an average of the two resulting enthalpies.

CF_3OH Proton affinity obtained by using transitional energy threshold measurements on protonated trifluoromethanol. This was used in a thermochemical cycle to derive the enthalpy of formation.[6] Previous value was based on a photoionization study, where a lower limit of $\Delta_f H^\circ_{298} >$ –908.8±0.9 kJ mol^{-1} was presented.[2] The enthalpy of formation, $\Delta_f H_{298}{}^\circ$ = –933.4 kJ mol^{-1}, based on an isodesmic reaction calculated at the MP2/6-31G(d,p) level of theory.[16]

CF_3OF Based on photoionization of CF_3OF and an analysis of the CF_3^+ and CF_2O^+ fragments.[2] A G2 calculation led to an enthalpy of –774.5 kJ mol^{-1}.[5]

CH_2FOOH, CHF_2OOH, and CF_3OOH

Geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level. The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate the enthalpy of formation at 298 K.[10] This was adjusted to the radical values from the present Table.

CH_2CHF Enthalpy from review of Pedley.[16]

CH_2CH_2F and CH_3CHF

Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. For CH_2CH_2F, the value given is for the global minimum configuration. A local minimum with C_s symmetry is slightly higher in enthalpy, with $\Delta_f H_{298}°$ = −58.7±2.8 kJ mol^{-1}. Previous values of the enthalpy, $\Delta_f H_{298}°(CH_2CH_2F)$ = −59.4±8 kJ mol^{-1} and $\Delta_f H_{298}°(CH_3CHF)$ = −70.3±8 kJ mol^{-1}, were from photobromination studies.[14] The previous entropy value, $S(CH_2CH_2F)$ = 279.7 J K^{-1} mol^{-1} and $S(CH_3CHF)$ = 274.0 J K^{-1} mol^{-1}, were determined at the UHF/6-31G* level of theory.[3]

CH_3CH_2F Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous value of $\Delta_f H_{298}^o$ = –278.2±1.7 kJ mol^{-1} was based on enthalpies of reaction calculated at the MCG3//MCQCISD level of theory (up to 6-311++G(3d2f,2df,2p) basis set) for the homolytic fragmentation to the alkyl radical and fluoride atom, and for the atomization reaction and averaged. Enthalpy also calculated for the heterolytic fragmentation into the alkyl cation and fluoride anion for support.[11] Previous entropy S^o = 265.1 J mol^{-1} from Gurvich et al. review.[9]

C_2F_2 Enthalpy values obtained from a computational study with CCSD(T)(FC) geometry optimization with the aug-cc-pVnZ(n = D, T, Q, 5-7) basis sets, checked by a CCSD(T)-F12 calculation followed by atomization energy calculation at the CCSD(T) level extrapolated to the complete basis set limit.[6] Note that these values are from a published correction: doi:10.1021/jp202158j. A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 basis set led to $\Delta_f H_0^o$ = 5.0±2.0 kJ mol^{-1} and $\Delta_f H^o_{298}$= 9.0±2.0 kJ mol^{-1}.[1]

CH_2CF_2 Enthalpy from review of Pedley.[16] A computational study with CCSD(T)(FC) geometry optimization with the aug-cc-pVnZ(n = D, T, Q, 5-7) basis sets, checked by a CCSD(T)-F12 calculation followed by atomization energy calculation at the CCSD(T) level extrapolated to the complete basis set limit, resulted in $\Delta_f H_0^o$ = −343.1±2.5 kJ mol^{-1} and $\Delta_f H^o_{298}$= −350.2±2.5 kJ mol^{-1}.[6] Note that these values are from a published correction: doi:10.1021/jp202158j.

***cis* and *trans* CHCHF**

Enthalpy values obtained from a computational study with CCSD(T)(FC) geometry optimization with the aug-cc-pVnZ(n = D, T, Q, 5-7) basis sets, checked by a CCSD(T)-F12 calculation followed by atomization energy calculation at the CCSD(T) level extrapolated to the complete basis set limit.[6] Note that these values are from a published correction: doi:10.1021/jp202158j.

CH_3CF_2 Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.

CH_3CHF_2, 1,1-difluoroethane

Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous value of $\Delta_f H_{298}^o$ = –497.0±8.3 kJ mol^{-1} was from a review by Pedley.[16]

***anti*- and *gauche*-CH_2FCH_2F, 1,2-difluoroethanes**

The conformationally averaged values are $\Delta_f H_{298}^o$ = –446.9±3.4 kJ mol^{-1} and S^o = 296.8±2.8 J mol^{-1}. Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous enthalpy of $\Delta_f H_{298}^o$ = –232±25 kJ mol^{-1} was based on an analysis of the thermal elimination of HF from CH_2FCH_2F, which led to a C-C bond dissociation energy of 88±2 kcal mol^{-1}.[10]

CH_2FCHF Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. The enthalpy value given is for the global minimum synclinal configuration. A local minimum with antiperiplanar symmetry is slightly higher in enthalpy, with $\Delta_f H_{298}^o = -229.8\pm2.8$ kJ mol^{-1}. Previous thermodynamic properties, $\Delta_f H_{298}^o = -235.5$ kJ mol^{-1} and S = 293.3 J K^{-1} mol^{-1}, were determined at the UHF/6-31G* level, utilizing isodesmic/homodesmic reactions for enthalpy of formation.[5]

CHF_2CH_2 Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. The value given is for the global minimum configuration. A local minimum, with C_s symmetry, is slightly higher with $\Delta_f H_{298}^o = -281.7\pm2.8$ kJ mol^{-1}. Previous thermodynamic properties, $\Delta_f H_{298}^o = -277$ kJ mol^{-1} and S = 297.8 J K^{-1} mol^{-1}, were determined at the UHF/6-31G* level, utilizing isodesmic/homodesmic reactions for enthalpy of formation.[3]

CH_3CF_2 The dissociation energy of CH_3CF_2-H of 99.5±1 kcal mol^{-1} was derived from a study of the equilibrium $CH_3CF_2H + I_2 \leftrightarrow CH_3CF_2I + HI$.[17] Entropy calculated from molecular properties computed at the UHF/6-31* level of theory.[4]

CH_3CHF_2 Taken from a Thermodynamics Research Center review.[2]

***anti*- and *gauche*-CH_2FCHF_2, 1,1,2-trifluoroethanes**

The conformationally averaged values are, $\Delta_f H_{298}^o = -661\pm3.4$ kJ mol^{-1} and $S^o = 316.9\pm2.0$ J mol^{-1}. Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous value of $\Delta_f H_{298}^o = -665\pm4$ kJ mol^{-1} was based on the heat of hydrogenation of CF_2CFCl.[12] Pedley gives an enthalpy value of –730.7±20.8 kJ mol^{-1}.[16]

CH_2CF_3 Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. The previous value, $\Delta_f H_{298}^o = -517.1\pm5$ kJ mol^{-1}, was calculated from the dissociation energy of CF_3CH_2-H, derived from a study of the equilibrium $CF_3CH_3 + I_2 \leftrightarrow CF_3CH_2I + HI$.[19] The previous entropy value, $S^o = 306.8$ J mol^{-1}, was calculated from molecular properties computed at the UHF/6-31* level of theory.[3]

CH_3CF_3, 1,1,1-trifluoroethane

Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous values of $\Delta_f H_{298}^{o}$ = –445.6±1.7 kJ mol^{-1} and S^o = 287.3 J mol^{-1} were from the Thermodynamics Research Center review.[2] Pedley review gives –744.6±1.7 kJ mol^{-1}.[16]

CF_2CF_2 Enthalpy from review of Pedley.[16] A computational study with CCSD(T)(FC) geometry optimization with the aug-cc-pVnZ(n = D, T, Q, 5-7) basis sets, checked by a CCSD(T)-F12 calculation followed by an atomization energy calculation at the CCSD(T) level extrapolated to the complete basis set limit, resulted in $\Delta_f H_0^o$ = −669.4±3.3 kJ mol^{-1} and $\Delta_f H_{298}^{o}$= −672.8±3.3 kJ mol^{-1}.[6] Note that these values are from a published correction: doi:10.1021/jp202158j. A simulation of the atomization reaction using the CCSD(T) method with the vTz-F12 basis set led to $\Delta_f H_0^o$ = −671.2±4.0 kJ mol^{-1} and $\Delta_f H_{298}^{o}$= −672.0±4.0 kJ mol^{-1}.[1]

***anti*- and *gauche*-CHF_2CHF_2, 1,1,2,2-tetrafluoroethanes**

The conformationally averaged values are $\Delta_f H_{298}^{o}$ = −877.6±3.8 kJ mol^{-1} and S^o = 323.2±4.7 J mol^{-1}. Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous ,$\Delta_f H_{298}^{o}$ = –860±24 kJ mol^{-1} calculated based on the C-C bond strength estimate of 91.4±3.7 kcal mol^{-1}.[13] Previous S^o = 320.3 J mol^{-1} from Thermodynamics Research Center review.[7]

$CHFCF_3$ Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. The previous value, $\Delta_f H_{298}^{o}$ = –690 kJ mol^{-1}, was derived from isodesmic reactions and adjusted down by 2 kJ mol^{-1} to reflect the enthalpy value for CH_2FCF_3 in this Table.[5] The previous entropy, S^o = 326.2 J mol^{-1}, was calculated from molecular properties computed at the UHF/6-31* level of theory.

CH_2FCF_3, 1,1,1,2-tetrafluoroethane

Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous values of $\Delta_f H_{298}^{o}$ = –896±8 kJ mol^{-1} (estimated) and S^o = 316.2 J mol^{-1} were from the Thermodynamics Research Center review.[2]

CF_2CF_3 Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)), corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect.[8] The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon. The previous value, $\Delta_f H_{298}^{o}$ = –891±5 kJ mol^{-1}, was calculated from the dissociation energy of C_2F_5-I of 52.5±1 kcal mol^{-1}, derived from a study of the reaction of pentafluoroethyl iodide with HI.[20]

CHF_2CF_3, pentafluoroethane

Conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15] Previous values of $\Delta_f H_{298}^o = -1105 \pm 5$ kJ mol^{-1} and S^o = 333.7 J mol^{-1} were from the Thermodynamics Research Center review.[2] Pedley review gives an enthalpy value of -1100.4 ± 4.1 kJ mol^{-1}.[16]

C_2F_6, hexafluoroethane

Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[18] Entropy from recommendation of Chen, et a.[2] A study in which conformers and rotational barriers determined at the CCSD)T)/cc-pVTZ level of theory and the resulting equilibrium structure optimized at the CCSD(T)/cc-pVQZ level. The total electronic energy was calculated at the complete basis set limit (extrapolated from aug-cc-pVXZ (X = T, Q, 5)) energies, corrected for correlation contributions, the core correlation, the zero-point energy, diagonal Born-Oppenheimer contributions, and the scalar relativistic effect led to $\Delta_f H_{298}^o = -1339.8 \pm 3.2$ kJ mol^{-1} and $S^o = 331.0 \pm 1.5$ J mol^{-1}. The heat of formation was computed from the calculated enthalpies by using the elemental reaction approach, taking the gaseous atom as the standard state for carbon.[15]

Back to Table

CH_2FCH_2OH

The enthalpy of formation was calculated from a set of isodesmic and isogyric reactions at the CBS-QB3 level of theory and refers to the *gauche* configuration. Calculations with B3LYP/cc-pVTZ were in good agreement.[2]

CH_2FCOOH

The enthalpy of formation was calculated from a set of isodesmic and isogyric reactions at the CBS-QB3 level of theory. Calculations with B3LYP/cc-pVTZ were in good agreement.[2]

CF_3CO CBS-4 and G2(MP2,SVP) methods used to obtain thermodynamic properties. In addition, enthalpy was derived from isodesmic reaction calculations. Value listed is recommendation based on theoretical and experimental results. Entropy at the G2(MP2(full)//MP2(full)/6-31G(d) level treating internal rotations as harmonic oscillators.[8]

$CF_3C(O)H$ Thermodynamic properties calculated at the G2(MP2(full)//MP2(full)/6-31G(d) level of theory. Enthalpy from atomization energy and entropy calculated treating internal rotations as harmonic oscillators. Similar values obtained at the CBS-4//HF/3021G* level.[8]

$CH_3C(O)F$, acetyl fluoride

Enthalpy value from review of Pedley.[4]

$CF_3C(O)F$ Thermodynamic properties calculated for five isodesmic reactions at the MP2//6-31G(d) level of theory. In the same study, $\Delta H_f° = -614 \pm 7$ kJ mol^{-1} for CF_2O and $\Delta H_f° = -381 \pm 2$ kJ mol^{-1} for CHFO were calculated, both close to the recommended values.[7]

$CF_3C(O)OH$, trifluoroacetic acid

Enthalpy value from review of Pedley.[4]

CF_3OCO_2 An average of a result from an isodesmic reaction and an atomization energy, both calculated at the CBS-4 level of theory.[3]

CF_3OOCF_3

A thermal decomposition study from 575 to 900 K led to a BDE(O-O) of 47.5±0.5 kcal mol^{-1}.[5] An MP2//6-31G(d,p) calculation utilizing isodesmic and isogyric reactions resulted in –343±3 kcal mol^{-1}.[6] A CBS-QB3 calculation led to a BDE(O-O) of 209.4 kJ mol^{-1}, and thus an enthalpy of –1479 kJ mol^{-1}.[1]

Note 28: *Compounds containing more than two C and one or more F*

Back to Table

***iso*-C_3H_7F** Enthalpies of reaction calculated at the MCG3//MCQCISD level of theory (up to 6-311++G(3d2f,2df,2p) basis set) for the homolytic fragmentation to the alkyl radical and fluoride atom, and for the atomization reaction and averaged. Enthalpy also calculated for the heterolytic fragmentation into the alkyl cation and fluoride anion for support[2] $\Delta_f H^\circ_{298}$ = -318.8±4.2 kJ mol^{-1} estimated by Luo and Benson.[3]

***tert*-C_4H_9F** Enthalpies of reaction calculated at the MCG3//MCQCISD level of theory (up to 6-311++G(3d2f,2df,2p) basis set) for the homolytic fragmentation to the alkyl radical and fluoride atom, and for the atomization reaction and averaged. Enthalpy also calculated for the heterolytic fragmentation into the alkyl cation and fluoride anion for support.[2] $\Delta_f H^\circ_{298}$ = -363.6±4.2 kJ mol^{-1} estimated by Luo and Benson.[3]

$CF_3C(O)OCH_3$

The free energy of formation of methyl trifluoroacetate in solution was determined by measuring the equilibrium constant for the reaction of trifluoroacetic acid with methanol. The solubility was estimated from a linear free-energy relationship and the vapor pressure estimated from the boiling point, leading to a value of the free energy of formation in the gas phase. Combining this with the estimate of the standard entropy, also listed, leads to the cited value.[1] A density-functional calculation at the MPWB1K//6-31+G(d,p) level with two isodesmic reactions, led to $\Delta_f H^\circ_{298} = -1020$ kJ mol^{-1}.[4]

Note 29: *Inorganic compounds containing Cl*

Back to Table

Cl Enthalpy value is from the optimization of Ruscic et al.[20] Entropy is a CODATA Key Value[4] as was the previous enthalpy value of $\Delta_f H^\circ_{298}$ = 121.301±0.008 kJ mol^{-1}.

Cl_2 CODATA Key Value[4]

HCl CODATA Key Value.[4] The active thermochemical tables optimization gives an enthalpy value of –92.1763±0.0063 kJ mol^{-1}.[20] The most recent NIST-JANAF review gives and enthalpy of –92.31±0.10 kJ mol^{-1} and an entropy of 186.901±0.005 J K^{-1} mol^{-1}.[22]

ClO Both JANAF[3] and Gurvich et al.[9] use the dissociation energy from Coxon and Ramsay[5] of 265.380±0.036 kJ mol^{-1}. The present recommendation is a recalculation using reference values from this Table. The entropy is a statistical mechanical calculation[1] using data from JANAF. The previous value of 101.63±0.1 kJ mol^{-1} was from the JANAF recommendation.[3] A CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy leads to an enthalpy of formation of 24.8 kcal mol^{-1} at both 0 K and at 298 K.[16] Another CCSD(T) calculation of the dissociation energy, both directly and through a negative ion thermochemical cycle, led to enthalpy values of $\Delta_f H_0^\circ$ = 24.1±0.3 and $\Delta_f H^\circ_{298}$ =24.1±0.3 and 24.2±0.3 kcal mol^{-1}.[18] Atomization energy was calculated using the Wn family of computational methods. A slight increase in the atomization energy was found going from W2.2 to W4.4. These results led to $\Delta_f H^\circ_{298}$ = 101.2±0.4 kJ mol^{-1} and a 0 K value only 0.04 kJ mol^{-1} higher.[12]

ClOO Enthalpy and entropy values are from an analysis of equilibrium constant measurements (see Table 3-1, Note 11). More recent measurements over the temperature range 212–245 K[24] support these values. Previous enthalpy value of 98±4 kJ mol^{-1} and entropy value of 269.32±0.5 J K^{-1} mol^{-1} from JANAF. Enthalpy for the reaction HOOCl + FOO → HOOF + ClOO at the CCSD(T)/CBS(Q5) level of theory, adjusted for the Table value for FOO, leads to $\Delta_f H^\circ_{298}$ = 103.9±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 104.7±6 kJ mol^{-1}.[8] Atomization energy was calculated using the Wn family of computational methods. Significant increases in the atomization energy were found going from W2.2 to W4.4. These results led to $\Delta_f H^\circ_{298}$ = 101.7±0.7 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 103.3±0.7 kJ mol^{-1}.[12]

ClOOH Isodesmic reaction calculations done at MP2, CCSD, and CCSD(T) level with ANO basis sets to determine enthalpy of formation.[14]

OClO Near-threshold fragmentation studies led to a dissociation energy to O + ClO of 247.3±0.5 kJ mol^{-1}.[6] This leads to an enthalpy of formation at 0 K of 100.6±0.6 kJ mol^{-1}. A computational study gives, at 0 K, 102.2±6.5 kJ mol^{-1}.[13] Previous 298 K enthalpy of formation, 94.6±1.2, derived from equilibrium constant for ClO + ClO ↔ Cl + OClO.[17] Entropy and enthalpy function are from JANAF.[3] A CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy leads to an enthalpy of formation of 24.5 kcal mol^{-1} at 0 K and 23.9 at 298 K.[16] An atomization energy calculated at the W4 level of theory led to $\Delta_f H^\circ_{298}$ = 99.0±0.7 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 101.5±0.7 kJ mol^{-1}.[12]

ClO_3 A calculation of the isodesmic reaction ClO_3 + ClO → 2OClO at the W4.2 level of theory provided the selected enthalpy values.[12] The previous values, $\Delta_f H^\circ_{298}$ = 194±12 kJ mol^{-1} and

$\Delta_f H_0^\circ$ = 200±12 kJ mol^{-1} were the JANAF recommendations, which were based on limited kinetic and theoretical studies.[3] A more recent density functional/G3 calculation led to a 298 K enthalpy of 43.1 kcal mol^{-1} (= 180.3 kJ mol^{-1}).[23]

ClClO A CCSD(T), extrapolated to the complete basis set limit, for the atomization energy leads to the recommended enthalpy of formation and a value of 32.2 kcal mol^{-1} at 0 K. For the ^{1}A' state. $\Delta_f H^\circ_{298}$ = 52.4±1 kcal mol^{-1} for the ^{3}A" state.[16] The previous recommendation, 90±30 kJ mol^{-1}, from the JANAF evaluation,[3] was based on an interpretation of the infrared spectrum and suggested that ClClO was less stable than ClOCl by ~9 kJ mol^{-1}. Several computational studies cited in the JANAF review indicated that the stability difference was considerably greater, typically about 60 kJ mol^{-1}. The present recommendation leads to a stability difference of 52 kJ mol^{-1}. Entropy and enthalpy difference calculated by a statistical mechanical calculation using vibrational frequencies from the WebBook and PM3 rotational moments.[1]

ClOCl Enthalpy value based on experimental reports on the equilibrium constant for the reaction $H_2O + Cl_2O \leftrightarrow 2HOCl$ and the recommended enthalpy of formation for HOCl.[10] Gurvich et al. recommended an enthalpy of formation at 298 K of 79±10 kJ mol^{-1}.[9] A CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy leads to an enthalpy of formation of 19.3 kcal mol^{-1} at 0 K and 18.9 at 298 K.[16]

ClOOCl Selected enthalpy value derived from a third-law calculation on the equilibrium constant for the dimerization reaction, ClO + ClO ↔ ClOOCl, presented in Table 3-1, note 20. Entropy value calculation is also discussed in Table 3-1. Previous Table value of $\Delta_f H^\circ_{298}$, 127.6±2.9 kJ mol^{-1}, was from the equilibrium constant of Nickolaisen, et al.[17] and the entropy was the JANAF recommendation.[3] A study of the fragmentation threshold of ClO^+ from the photoionization of ClOOCl yielded a 0 K enthalpy of 134.07±2.8 kJ mol^{-1} and a 298 K value of 130.87±2.8 kJ mol^{-1}.[19] A CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy leads to an enthalpy of formation of 32.9 kcal mol^{-1} at 0 K and 31.6 at 298 K.[16] A calculation using the isodesmic reactions $ClOOCl + H_2O \rightarrow H_2O_2 + Cl_2O$ and $ClOOCl + 2HOCl \rightarrow H_2O_2 + 2Cl_2O$ at the W4.2 level of theory leads to $\Delta_f H^\circ_{298}$ = 131.8±1.3 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 135.1±1.3 kJ mol^{-1}.[12]

$ClClO_2$ Derived from a CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy.[16] See Table 3-1, note 21 for a more complete discussion. The previous value, 154.2 kJ mol^{-1} (36.9 kcal mol^{-1}), was calculated at Gaussian-2 level of theory.[15] Entropy from JANAF evaluation.[3] The same value resulted from a statistical mechanical calculation.

ClOClO Derived from a CCSD(T) calculation, extrapolated to the complete basis set limit, for the atomization energy[16] combined with G2 composite calculations.[26] See Table 3-1, note 20b for a more complete discussion. The previous value, 175.5 kJ mol^{-1} (41.9 kcal mol^{-1}), was calculated at Gaussian-2 level of theory[15] and the previous entropy (309±2 kJ mol^{-1}) was from the JANAF evaluation.[3]

Cl_2O_3 Selected enthalpy and entropy values derived from a third-law calculation on the equilibrium constant for the reaction, $ClO + OClO \leftrightarrow Cl_2O_3$, presented in Table 3-1, note 15. Previous values in Table, $\Delta_f H$ = 35.8±1.5 kcal mol^{-1} and ΔS = 94±5 cal K^{-1} mol^{-1}, were taken from a single study.[2] The most stable structure among the Cl_2O_3 isomers is calculated to be ClOCl(O)O.[27] A density functional/G3 calculation led to a 298 K enthalpy of 31.7 kcal mol^{-1}.[23]

HOCl Enthalpy value from an evaluation of the experimental data.[10] Entropy and the enthalpy difference from JANAF evaluation.[3] An enthalpy value of –18.1±0.3 kcal mol^{-1} has been calculated by coupled-cluster theory with correlation consistent basis sets and corrections for core-valence, relativistic, and anharmonic effects.[7] A calculation of the isodesmic reaction $HOF + OH \rightarrow FO + H_2O$ at the W4.2 level of theory leads to $\Delta_f H^\circ_{298}$ = −76.1±0.6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = −73.4±0.6 kJ mol^{-1}.[12] A re-evaluation of the spectroscopic results, along with a newer value for the OH enthalpy, has led to a recommended value of $\Delta_f H_0^\circ$ = −73.99±0.12 kJ mol^{-1}.[11]

HOClO A calculation of the isodesmic reaction HOClO + ClO → HOCl + OClO at the W4lite level of theory provided the selected enthalpy values.[12]

$HOClO_2$ The total atomization energy was calculated at the W2.2 level of theory and then corrected to provide an estimated W4lite value, leading to the selected enthalpy values.[12]

$HOClO_3$ The total atomization energy was calculated at the W2.2 level of theory, leading to the selected enthalpy values.[12]

ClF Taken from review of Gurvich et al.[9] The JANAF Tables give $\Delta_f H_0^o$ = −50.2±0.4 kJ mol^{-1}, $\Delta_f H_{298}^o$ = −50.3±0.4 kJ mol^{-1}, and S^o = 217.938 J mol^{-1}.[3] A study in which the total atomization energy was calculated using a composite electronic structure approach based on CCSD(T) and extrapolated to the complete basis set limit with a two-point extrapolation scheme, Q5. Additional corrections included zero-point energy, core-valence effect, for scalar relativistic effects, and spin-orbit corrections, gave $\Delta_f H_{298}^o$ = −54.8 kJ mol^{-1}.[25]

ClOF, ClO_2F Enthalpy values derived from a weighted average of two isodesmic reactions and the atomization reaction, calculated at the CCSD(T) level of theory.[21] Previous values of $\Delta_f H_{298}^o$ = 24.3 kJ mol^{-1} and $\Delta_f H_{298}^o$ = −34.3kJ mol^{-1} were from the total atomization energy, which was calculated using a composite electronic structure approach based on CCSD(T) and extrapolated to the complete basis set limit with a two-point extrapolation scheme, Q5. Additional corrections included zero-point energy, core-valence effect, for scalar relativistic effects, and spin-orbit corrections.[25] Entropy values were from statistical mechanics calculations.[21] Thermodynamic parameters were also reported for $ClFO_3$, ClF_3O, ClF_2O_2, and ClF_5O.

Back to Table

ClNO Taken from review of Gurvich et al.[4] The JANAF Tables give $\Delta_f H_0^\circ$ = 53.6 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 51.7 kJ mol^{-11}, and S° = 261.680 J mol^{-1}.[2]

$ClNO_2$ The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 52.7±0.5 kJ mol^{-1}, was taken from review of Gurvich et al.[4] The JANAF Tables give $\Delta_f H_0^\circ$ = 17.5 kJ mol^{-1}, $\Delta_f H_{298}^\circ$ = 12.1 kJ mol^{-1}, and S° = 272.187 J mol^{-1}.[2]

***cis*-ClONO** The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 64.6 kJ mol^{-1}, was predicted based on isodesmic reactions at the CCSD(T) level of theory.[5]

***trans*-ClONO**

The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 75.3 kJ mol^{-1}, was predicted based on isodesmic reactions at the CCSD(T) level of theory.[5]

***cis, perp*-ClO$_2$NO**

Enthalpy calculated at MP2 level of theory using basis sets ranging from 6-31G(d) to 6-311G(2df,2p).[7] A G3//B3LYP study gave enthalpies at 0 K and 298 K of 32.5 and 31.5 kcal mol^{-1}, respectively.[6]

***trans, perp*-ClO$_2$NO**

Enthalpy calculated at MP2 level of theory using basis sets ranging from 6-31G(d) to 6-311G(2df,2p).[7] A G3//B3LYP study gave enthalpies at 0 K and 298 K of 34.4 and 33.2 kcal mol^{-1}, respectively.[6]

ClONO$_2$ The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 22.9±2.0 kJ mol^{-1}, was derived from a study of the thermal dissociation of ClONO$_2$.[1] Enthalpy values obtained from the atomization energy obtained using the G3//B3LYP level of theory are $\Delta_r H_0{}^\circ$ = 7.0 kcal mol^{-1} and $\Delta_r H_{298}{}^\circ$ = 5.5 kcal mol^{-1}.[6]

***cis,perp*-ClOONO**

The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 132 kJ mol^{-1}, was obtained from the atomization energy obtained using the G3//B3LYP level of theory.[6]

***trans, perp*-ClOONO**

The equilibrium geometry was calculated at the CCSD(T)/cc-pVQZ level of theory, while the energy was calculated by summing various contributions calculated at the CCSC(T) level with the use of various basis sets.[8] The previous value, $\Delta_f H^\circ_{298}$ = 132 kJ mol^{-1}, was obtained from the atomization energy obtained using the G3//B3LYP level of theory.[6]

***trans, perp*-OClONO**

Value obtained from the atomization energy obtained using the G3//B3LYP level of theory.[6]

O$_2$ClONO$_2$ Based on a study of the recombination of OClO and NO$_3$, leading to a bond strength of 18±3 kcal mol^{-1}.[3]

NH$_2$Cl, NHCl$_2$, NCl$_3$, chloramines

Geometries were optimized at the (AE)-CCSD(T)/AVQZ level of theory and zero-point energies computed at the B2PLYPD/AVQZ level. For the electronic energies, a calculational protocol termed TA14 was adapted from the W3, W4, and FPD protocols. Enthalpies of formation were determined from the total atomization energies.[9]

Note 31: *Compounds containing one C and one or more Cl and H*

Back to Table

CCl Geometry optimization was carried out at the CCSD(T) level of theory with the cc-pZQZ basis set. Enthalpy was calculated using the HEAT protocols, which involves summing a number of individual CCSD(T) energies with the basis set limited HF energy, along with other contributions.[1]

CHCl Calculated for the X^1A' state. The triplet-singlet energy gap is estimated to be 2170±40 cm^{-1}. Enthalpy determined by calculating the enthalpy of the reaction $CH_2 + HCl \rightarrow HCCl + H_2$. Calculations involved the focal-point approach, based on methods up to CCSDTQ and basis sets ranging from aug-cc-pVDZ to aug-cc-pV6Z, extrapolated to the complete basis set limit.[12] Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \leftrightarrow CXY(^1A_1) + 2CH_4$ results in $\Delta_f H^\circ_{298}$ = 320 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[9] Previous recommendation was based on combining experimental chloride dissociation energies from the parent anion, prior experimental measurements, and G2 calculations.[7] Entropy values from Gurvich et al. review.[2] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ$ = 320.1±2.3 kJ mol^{-1}, $\Delta_f H^\circ_{298}$= 320.3±2.3 kJ mol^{-1}, and S = 234.6±1.5 J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CH_2Cl Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[11] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of 117.0±4.1 kJ mol^{-1}.[10] A dissociative photoionization study of CH_2ClBr results in an enthalpy of 110.7 kJ mol^{-1}.[5] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ$ = 119.4±2.7 kJ mol^{-1}, $\Delta_f H^\circ_{298}$= 116.0±2.7 kJ mol^{-1}, and S = 236.3±1.5 J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CH_3Cl Enthalpy from Manion evaluation.[6] Entropy from Thermodynamics Research Center evaluation.[8] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ$ = −74.3±3.1 kJ mol^{-1}, $\Delta_f H^\circ_{298}$= −82.6±3.1 kJ mol^{-1}, and S = 234.0±1.5 J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CCl_2 Calculated for the X^1A' state. The triplet-singlet energy gap is estimated to be 7045±60 cm^{-1}. Enthalpy determined by calculating the enthalpy of the reaction $CH_2 + 2HCl \rightarrow CCl_2 + 2H_2$. Calculations involved the focal-point approach, based on methods up to CCSDTQ and basis sets ranging from aug-cc-pVDZ to aug-cc-pV6Z, extrapolated to the complete basis set limit.[12] Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ results in $\Delta_f H^\circ_{298}$ = 230 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[9] Previous recommendation (55.0±2.0 kcal mol^{-1}) based on combining experimental chloride dissociation energies from the parent anion, prior experimental measurements, and G2 calculations.[7] Entropy values from Gurvich et al. review.[2] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = 229.0\pm1.9$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = 230.1\pm1.9$ kJ mol^{-1}, and $S = 264.5\pm1.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CHCl$_2$ Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[11] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of 91.1 ± 4.1 kJ mol^{-1}.[10] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = 91.2\pm4.8$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = 88.8\pm5.8$ kJ mol^{-1}, and $S = 280.7\pm6.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CH$_2$Cl$_2$ Enthalpy from Manion evaluation.[6] Entropy from Thermodynamics Research Center evaluation.[8] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -86.5\pm4.2$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -93.7\pm4.2$ kJ mol^{-1}, and $S = 269.7\pm1.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CCl$_3$ A third-law determination based on the reaction $CCl_3 + Br_2 \leftrightarrow CCl_3Br + Br$, re-evaluating the kinetics of the reverse reaction and using spectroscopic data to calculate the entropy.[4] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of 72.2 ± 4.1 kJ mol^{-1}.[10] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = 73.7\pm4.9$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = 73.1\pm4.9$ kJ mol^{-1}, and $S = 301.3\pm1.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CHCl$_3$ Enthalpy from Manion evaluation.[6] Entropy from Thermodynamics Research Center evaluation.[8] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = 94.6\pm5.3$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -99.7\pm5.3$ kJ mol^{-1}, and $S = 294.8\pm1.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table.

CCl$_4$ Enthalpy from Manion evaluation.[6] Entropy from Thermodynamics Research Center evaluation.[8] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^\circ = -88.8\pm6.4$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -91.0\pm6.4$ kJ mol^{-1}, and $S = 308.6\pm1.5$ J K^{-1} mol^{-1}.[1] The enthalpy difference was used to calculate the 0 K value in the Table. Experimental data from threshold PEPICO studies of halogenated methanes were combined with *ab initio* calculations of isodesmic and exchange reactions into a thermochemical network, leading to $\Delta_f H_0^\circ = -94.0\pm3.2$ kJ mol^{-1}.[3]

Back to Table

$CClH_2O$ and $CClH_2OH$

The enthalpies of formation based on isodesmic reactions calculated at the MP2/6-31G(d,p) level of theory.[11]

CClO Second- and third-law analyses of the equilibration kinetics for the reaction Cl + CO ↔ ClCO led to $\Delta_r H^\circ_{298}$ = -7.7±0.6 kcal mol^{-1}, $\Delta_r H_0^\circ$ = -6.9±0.7 kcal mol^{-1}, and $\Delta_r S^\circ_{298}$ = -23.8±2.0 cal mol^{-1} K^{-1}.[9] See also Table 3-1, Note 12. (Previous enthalpy value had a sign error.) A shock-tube study of the thermal decomposition of $COCl_2$ led to a value of $\Delta_r H_0^\circ$ = -6.3±1.0 kcal mol^{-1}.[7] Entropy value cited derived by using standard statistical mechanic methods.[9]

CHClO The enthalpy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[8] The previous $\Delta_f H_{298}^\circ$ = –164±20 kJ mol^{-1} was estimated in the Gurvich et al. review.[3] Entropy was based on spectroscopic studies.[3]

CH_2OCl Molecular properties determined at the MP2/6-31G(p,d), B3LYP/6-31G(d,p), and MP2/6-31G(d) level with single-point energy calculations at B3LYP/6-311+G(3df,2p) levels. Enthalpy based on four isodesmic reactions calculated at the CBS-Q//MP2/6-31(G(d,p) level.[1]

CH_3OCl Molecular properties determined at the B3LYP/6-31G(d,p) level, with single-point calculations at this and the B3LYP/6-311+G(3df,2p), QCISD(T)/6-31G(d,p), and CBS-Q levels. Enthalpies determined using several working reactions.[4]

CH_2ClO_2 Based on a re-analysis of previous equilibrium data on R + O_2 ↔ RO_2 from the same laboratory.[5]

CH_2ClOOH

Molecular geometries determined at the B3LYP/6-31G(d,p) level of theory and electronic energies obtained through single-point calculations at the CBSQ level. Enthalpy of formation determined using five reaction schemes, three of which were isodesmic.[13] A study in which geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level.[6] The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate $\Delta_f H^\circ_{298}$ = –174 kJ mol^{-1}, after adjustment to the values for CH_3 and HO_2 from the present Table.

CCl_2O Taken from "The Chemical Thermodynamics of Organic Compounds".[12] Pedley review gives an enthalpy value of −219.1±0.5 kJ mol^{-1}.[10]

CCl$_2$HO and CCl$_2$HOH

The enthalpies of formation are based on isodesmic reactions calculated at the MP2/6-31G(d,p) level of theory.[11]

CHCl$_2$O$_2$ Based on a re-analysis of previous equilibrium data on R + O$_2$ ↔ RO$_2$ from the same laboratory.[5]

CH$_2$ClOCl Molecular properties determined at the B3LYP/6-31G(d,p) level, with single-point calculations at this and the B3LYP/6-311+G(3df,2p), QCISD(T)/6-31G(d,p), and CBS-Q levels. Enthalpies determined using several working reactions.[4]

CHCl$_2$OOH

Molecular geometries determined at the B3LYP/6-31G(d,p) level of theory an d electronic energies obtained through single-point calculations at the CBSQ level. Enthalpy of formation determined using five reaction schemes, three of which were isodesmic.[13]

CHCl$_2$OCl

Molecular properties determined at the B3LYP/6-31G(d,p) level, with single-point calculations at this and the B3LYP/6-311+G(3df,2p), QCISD(T)/6-31G(d,p), and CBS-Q levels. Enthalpies determined using several working reactions.[4]

CCl$_3$O and CCl$_3$OH

Enthalpies of formation are based on isodesmic reactions calculated at the MP2/6-31G(d,p) level of theory.[11]

CCl$_3$O$_2$ Based on a re-analysis of previous equilibrium data on R + O$_2$ ↔ RO$_2$ from the same laboratory.[5]

CCl$_3$OOH Molecular geometries determined at the B3LYP/6-31G(d,p) level of theory an d electronic energies obtained through single-point calculations at the CBSQ level. Enthalpy of formation determined using five reaction schemes, three of which were isodesmic.[13]

CCl$_3$OCl Molecular properties determined at the B3LYP/6-31G(d,p) level, with single-point calculations at this and the B3LYP/6-311+G(3df,2p), QCISD(T)/6-31G(d,p), and CBS-Q levels. Enthalpies determined using several working reactions.[4] $\Delta_f H^\circ_{298}$ = -146.6 kJ mol^{-1} from a G2 calculation of the total energy of formation from the gas-phase elements.[2]

Back to Table

CHFCl Enthalpy derived from an analysis of thermochemical and kinetic data on the bromination of CH_2FCl.[12] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of -63.8±4.1 kJ mol^{-1}.[11] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o = -64.6\pm3.7$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = -67.8\pm4.7$ kJ mol^{-1}, and $S = 273.5\pm6.5$ J K^{-1} mol^{-1} (used in the Table).[3] The enthalpy difference was used to calculate the 0 K value in the Table.

CH_2FCl Geometry optimization was carried out at the CCSD(T) level of theory with the cc-pZQZ basis set. Enthalpy was calculated using the HEAT protocols, which involves summing the CCSD(T) energy extrapolated to the complete basis set limit, along with several other contributions.[3] Previous enthalpy from Pedley review[7] and entropy from Thermodynamics Research Center review.[1]

CFCl Recommendation based on combining experimental chloride dissociation energies from the parent anion, prior experimental measurements, and G2 calculations.[8] Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ results in $\Delta_f H^\circ_{298} = 29.4$ kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[10] Entropy values from Gurvich et al. review.[4] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o = 32.2\pm2.3$ kJ mol^{-1}, $\Delta_f H^\circ_{298} = 32.0\pm2.3$ kJ mol^{-1}, and $S = 258.9\pm1.5$ J K^{-1} mol^{-1}.[3] The enthalpy difference was used to calculate the 0 K value in the Table.

CF_2Cl Geometry optimization was carried out at the CCSD(T) level of theory with the cc-pZQZ basis set. Enthalpy was calculated using the HEAT protocols, which involves summing the CCSD(T) energy extrapolated to the complete basis set limit, along with several other contributions.[3] A photobromination study leads to D($CClF_2$-H) = 100.7±2 kcal mol^{-1}.[6] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of –274.7±4.1 kJ mol^{-1}.[11]

$CFCl_2$ Geometry optimization was carried out at the CCSD(T) level of theory with the cc-pZQZ basis set. Enthalpy was calculated using the HEAT protocols, which involves summing the CCSD(T) energy extrapolated to the complete basis set limit, along with several other contributions.[3] An enthalpy of –89.1±10 kJ mol^{-1} was derived from an analysis of thermochemical and kinetic data on the bromination of CH_2FCl.[12] A QCISD(T)/6-311+G(3df,2p) isodesmic study resulted in an enthalpy of –94.3±4.1 kJ mol^{-1}.[11]

$CHFCl_2$ Geometry optimization was carried out at the CCSD(T) level of theory with the cc-pZQZ basis set. Enthalpy was calculated using the HEAT protocols, which involves summing the CCSD(T) energy extrapolated to the complete basis set limit, along with several other contributions.[3] Previous enthalpy value, from the Thermodynamics Research Center review,[1] was estimated.

CHF_2Cl Enthalpy from Pedley[7] review and entropy from Thermodynamics Research Center review.[1] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to

$\Delta_f H_0^o = -475.7 \pm 3.1$ kJ mol^{-1}, $\Delta_f H^o_{298} = -482.2 \pm 3.1$ kJ mol^{-1}, and $S = 280.5 \pm 1.5$ J K^{-1} mol^{-1}.[3] The enthalpy difference was used to calculate the 0 K value in the Table.

$CFCl_3$ Enthalpy based on equilibrium measurements for the reaction $CClF_3 + 2CCl_4 \leftrightarrow 3CCl_3F$ leading to a heat of reaction of 10.59 kcal mol^{-1}, changed to reflect present enthalpy values.[2] Pedley review gives an enthalpy value of -268.3 ± 8.4 kJ mol^{-1}.[7] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o = -286.0 \pm 5.3$ kJ mol^{-1}, $\Delta_f H^o_{298} = -282.7 \pm 5.3$ kJ mol^{-1}, and $S = 308.6 \pm 1.5$ J K^{-1} mol^{-1}.[3] The enthalpy difference was used to calculate the 0 K value in the Table. Experimental data from threshold PEPICO studies of halogenated methanes were combined with *ab initio* calculations of isodesmic and exchange reactions into a thermochemical network, leading to $\Delta_f H_0^o = -285.2 \pm 3.2$ kJ mol^{-1}.[5]

CF_2Cl_2 Enthalpy based on equilibrium measurements for the reaction $2CClF_3 + CCl_4 \leftrightarrow 3CCl_2F_2$ leading to a heat of reaction of 7.59 kcal mol^{-1}, changed to reflect present enthalpy values.[2] Pedley review gives an enthalpy value of -477.4 ± 7.2 kJ mol^{-1}.[7] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o = -487.9 \pm 4.2$ kJ mol^{-1}, $\Delta_f H^o_{298} = -492.1 \pm 4.2$ kJ mol^{-1}, and $S = 300.2 \pm 1.5$ J K^{-1} mol^{-1}.[3] The enthalpy difference was used to calculate the 0 K value in the Table. Experimental data from threshold PEPICO studies of halogenated methanes were combined with *ab initio* calculations of isodesmic and exchange reactions into a thermochemical network, leading to $\Delta_f H_0^o = -487.8 \pm 3.4$ kJ mol^{-1}.[5]

CF_3Cl Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[9] Entropy from recommendation of the Thermodynamics Research Center.[2] A computational study with geometry optimization carried out at the CCSD(T) level of theory with the cc-pZQZ basis set, followed by an enthalpy calculation using the HEAT protocols, led to $\Delta_f H_0^o = -703.4 \pm 3.1$ kJ mol^{-1}, $\Delta_f H^o_{298} = -708.6 \pm 3.1$ kJ mol^{-1}, and $S = 284.7 \pm 1.5$ J K^{-1} mol^{-1}.[3] The enthalpy difference was used to calculate the 0 K value in the Table. Experimental data from threshold PEPICO studies of halogenated methanes were combined with *ab initio* calculations of isodesmic and exchange reactions into a thermochemical network, leading to $\Delta_f H_0^o = -702.1 \pm 3.5$ kJ mol^{-1}.[5]

Note 34: *Compounds containing one C and one or more Cl, F, and O* Back to Table

CFClO The enthalpy values are taken from a CCSDT(Q) calculation, with structure optimized using the cc-pVQZ basis set.[7] Previous enthalpy value of –429±20 kJ mol^{-1} estimated in the Gurvich et al. review.[5] The recommended entropy is taken from the Gurvich et al. review.

CF_3OCl Based on photoionization study. Enthalpy presented as lower limit.[1] A G2 calculation led to an enthalpy of –768.3 kJ mol^{-1}.[4]

CCl_3OF Derived from a G2 calculation of the total energy of formation from the gas-phase elements.[3]

***cis*- and *trans*-FC(O)OCl**

Enthalpy computed at the G3//B3LYP/6-311++G(3df,3pd) level of theory with both atomization energies and isodesmic reactions.[2]

CHClFOOH and CCl_2FOOH

Geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level. The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate the enthalpy of formation at 298 K.[6] This was adjusted to the radical values from the present Table.

C_2HCl Enthalpy from Manion evaluation based on calculations involving isodesmic reactions.[4]

C_2H_3Cl Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of 37.2±1.2 kJ mol^{-1}.[7]

CH_2CH_2Cl Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[10]

CH_3CHCl Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[9]

CH_3CH_2Cl Enthalpy from Manion evaluation.[4] Entropy from a Thermodynamics Research Center evaluation.[1]

C_2Cl_2 Enthalpy from Manion evaluation based on calculations involving isodesmic reactions.[4]

CH_2CCl_2 Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of 2.8±1.3 kJ mol^{-1}.[7]

***cis*-CHClCHCl**

Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of 4.6±8.4 kJ mol^{-1}.[7]

***trans*-CHClCHCl**

Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of 5.0±8.4 kJ mol^{-1}.[7]

CH_3CCl_2 Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[9]

CH_3CHCl_2 Enthalpy from Manion evaluation.[4] Entropy from a Thermodynamics Research Center evaluation.[1] Pedley review gives an enthalpy value of -127.7±1.4 kJ mol^{-1}.[7]

$CHCl_2CH_2$ Measured rate constant for the reaction of the radical with HBr, combined with calculated (MP2(fc)/6-31G(d,p)) values for the reverse reaction, leading to thermodynamic values obtained through a second-law analysis.[11]

CH_2ClCH_2Cl

Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of -126.4±2.3 kJ mol^{-1}.[7]

C_2HCl_3 Enthalpy from Manion evaluation.[4] Previous enthalpy from the heat of combustion of trichloroethene, $\Delta_f H^\circ_{298} = -19.1 \pm 3.0$ kJ mol^{-1}.[6] Entropy from review of Frenkel.[2] Pedley review gives an enthalpy value of -9.0±8.8 kJ mol^{-1}.[7]

$CH_2ClCHCl_2$

Enthalpy from Manion evaluation.[4]

CH_2CCl_3 An analysis of the kinetic data from the bromine-catalyzed elimination of HCl from CH_3CCl_3 resulted in a C-H bond strength of 103.8±2 kcal mol^{-1}.[8]

CH_3CCl_3 Enthalpy from Manion evaluation.[4] Entropy from a Thermodynamics Research Center evaluation.[1] Pedley review gives an enthalpy value of -144.4±1.7 kJ mol^{-1}.[7]

C_2Cl_4 Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of -10.9±8.3 kJ mol^{-1}.[7] Entropy from Gurvich et al.[3]

$CHCl_2CHCl_2$

Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of -149.3±8.4 kJ mol^{-1}.[7]

CH_2ClCCl_3

Enthalpy from Manion evaluation.[4]

C_2Cl_5 Derived from both second- and third-law analyses of the equilibrium data for the reaction $Cl + C_2Cl_4 \leftrightarrow C_2Cl_5$, with the enthalpy adjusted for present reference values,[5] $\Delta_f H_0^\circ = 5.2 \pm 1.5$ kcal mol^{-1}.

C_2HCl_5 Enthalpy from Manion evaluation.[4] Pedley review gives an enthalpy value of -142.0±9.0 kJ mol^{-1}.[7]

C_2Cl_6 Enthalpy from Manion evaluation.[4] Entropy from Gurvich et al.[3] Pedley review gives an enthalpy value of −143.6±9.1 kJ mol^{-1}.[7]

$ClCH_2CH_2OH$

The enthalpy of formation of the liquid was determined by using rotating-bomb combustion calorimetry to be $\Delta_f H^\circ_{298}(l) = -315.5\pm0.7$ kJ mol^{-1}. The molar enthalpy of vaporization was then determined by use of Calvert-drop microcalorimetry as $\Delta_{vap}H^\circ_{298} = 48.32\pm0.37$ kJ mol^{-1}.[1]

CH_3CHClO_2

Based on a re-analysis of previous equilibrium data on $R + O_2 \leftrightarrow RO_2$ from the same laboratory.[4]

$CH_3C(O)Cl$, acetyl chloride

Enthalpy from review of Pedley.[6]

$CH_2ClC(O)OH$

Review of the literature.[2] Pedley review gives an enthalpy value of –435.2±9.3 kJ mol^{-1}.[6]

$CH_2ClCOOH$

Geometries and frequencies calculated at the B3LYP/6-31G(d,p) level of theory. Enthalpy calculated from three isodesmic reactions at the CBSQ//B3LYP/6-31(Gd,p) level and corrected for mixing of rotational conformers.[7]

$CH_3CHClOOH$

Geometric parameters calculated at the RHF/6-31G* and MP2/6-31G* levels of theory, and the entropy obtained using the rigid-rotor/harmonic-oscillator approximation. Enthalpy calculated using the isodesmic reaction $CH_3OOH + C_2H_5Cl \leftrightarrow CH_3CHClOOH + CH_4$, adjusted with reference values from the present Table.[5]

CH_3CCl_2OOH

Geometric parameters calculated at the RHF/6-31G* and MP2/6-31G* levels of theory, and the entropy obtained using the rigid-rotor/harmonic-oscillator approximation. Enthalpy calculated using the isodesmic reaction $CH_3OOH + 1,1\text{-}C_2H_4Cl_2 \leftrightarrow CH_3CCl_2OOH + CH_4$, adjusted with reference values from the present Table.[5]

$CH_2ClC(O)OCl$, chloroacetyl chloride

Enthalpy value taken from review of Pedley.[6]

$Cl(O)CC(O)Cl$, ethanedioyl cichloride (oxalyl chloride)

Enthalpy value taken from review of Pedley.[6]

$CHCl_2C(O)Cl$, dichloroacetyl chloride

Enthalpy value taken from review of Pedley.[6]

CCl_3CH_2OOH

Geometries and frequencies calculated at the B3LYP/6-31G(d,p) level of theory. Enthalpy calculated from three isodesmic reactions at the CBSQ//B3LYP/6-31(Gd,p) level and corrected for mixing of rotational conformers.[7]

CCl_3CO Enthalpy is an average of values obtained at the CBS-4//HF/3-21G* and G2(MP2(full)//MP2(full)/6-31G(d) levels of theory, using both atomization energies and formation from molecular species. Entropy at the G2(MP2(full)//MP2(full)/6-31G(d) level treating internal rotations as harmonic oscillators.[8]

$CCl_3C(O)H$

Thermodynamic properties calculated at the G2(MP2(full)//MP2(full)/6-31G(d) level of theory. Enthalpy from atomization energy and entropy calculated treating internal rotations as harmonic oscillators. Similar values obtained at the CBS-4//HF/3021G* level.[8]

$CCl_3C(O)Cl$, trichloroacetyl chloride

Enthalpy from review of Pedley.[6]

$CH_3CCl_2O_2$

Based on the equilibrium study using laser photolysis/PI mass spectrometry,[3] adjusted by using the enthalpy for CH_3CCl_2 cited in this Table.

$CHCl_2CH_2OOH$

Geometries and frequencies calculated at the B3LYP/6-31G(d,p) level of theory. Enthalpy calculated from three isodesmic reactions at the CBSQ//B3LYP/6-31(Gd,p) level and corrected for mixing of rotational conformers.[7]

Back to Table

$CH_3CHClCH_3$

The measured onset energy for *i*-$C_3H_7^+$ from iPEPICO spectroscopy of *i*- C_3H_7Cl was used in conjunction with a new value of the ion enthalpy of formation to obtain the 0 K enthalpy of the chloride.[2]

$CF_2ClC(O)OCH_3$ and $CF_2ClC(O)OCH_3$

Geometry optimization carried out using the hybrid meta-density functional, MPWB1K with the 6-31+G(d,p) basis set. Energies refined using G2(MP2). Enthalpy of formation calculated by using two group-balanced isodesmic reactions.[1]

Note 39: *Inorganic compounds containing Br*

Back to Table

Br	CODATA Key Value.[2]
Br_2(g)	CODATA Key Value.[2] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 33.1±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 47.7±4 kJ mol^{-1}.[5]
HBr	CODATA Key Value.[2] The most recent NIST-JANAF review gives and enthalpy of -36.29±0.16 kJ mol^{-1} and an entropy of 198.699±0.005 J K^{-1} mol^{-1}.[16]
BrO	Enthalpy derived from a photodissociation dynamics study using velocity map ion imaging.[8] Previous enthalpy value of 30.2±0.4 kcal mol^{-1} based on a Birge-Sponer extrapolation.[18] Entropy from the JANAF table for bromine oxides.[1] A CCSD(T) calculation of the dissociation energy, both directly and through a negative ion thermochemical cycle, led to enthalpy values of $\Delta_f H_0^\circ$ = 31.4±0.4 and $\Delta_f H^\circ_{298}$ = 29.6±0.4 kcal mol^{-1}.[15] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 128±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 136±6 kJ mol^{-1}.[5]
OBrO	Enthalpy based on the photoionization appearance energy of BrO^+ from OBrO, recalculated using the Table enthalpy for BrO.[9] A newer computational study gives an enthalpy at 0 K of 163.9±7.1 kJ mol^{-1}.[10] Entropy taken from the JANAF table for bromine oxides.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 169.9±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 179.5±6 kJ mol^{-1}.[5]
BrOO	Enthalpy for the reaction HOOBr + FOO → HOOF + BrOO at the CCSD(T)/CBS(Q5) level of theory, adjusted for the Table value for FOO, leads the cited enthalpy.[5] An estimate based on recombination rate constants for bromine atoms and subsequent calculations of interaction potentials, leads to a bond strength of about 1 kcal mol^{-1} and $\Delta_f H^\circ_{298}$ = 108±40 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 116±10 kJ mol^{-1}.[1] These results have been supported by other computational studies.[14,17] CCSD(T)/AREP calculations predict, however, that BrOO lies below OBrO by about 5 kcal mol^{-1}, which appears to be inconsistent with these results.[14] Entropy value is taken from NIST-JANAF thermochemical tables for bromine oxides.[1]
BrO_3	Estimated values taken from the NIST-JANAF thermochemical tables for bromine oxides.[1]
BrOBr	Enthalpy derived from a photoionization study. This value was accepted by the NIST-JANAF thermochemical tables for bromine oxides, which also discussed three related studies and recommended the entropy value.[1] A CCSD(T)/ANO4 result based on the isodesmic reaction 2HOBr → H_2O + Br_2O, adjusted for the present enthalpy values for the references, gives 26.9±1.6 kcal mol^{-1}.[11] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 108.4±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 124.7±6 kJ mol^{-1}.[5]
BrBrO	The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. Listed value is for the $^1A'$ state. $\Delta_f H^\circ_{298}$ = 236.0±6 kJ mol^{-1} for the $^3A''$ state and $\Delta_f H^\circ_{298}$ = 251.5±6 kJ mol^{-1} for the $^3A'$ state.[5] Entropy from the NIST-JANAF thermochemical tables for bromine oxides, which estimated the enthalpy as 168±20 kJ mol^{-1}.[1]
BrOOBr	The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Calculated enthalpy for the reaction BrO + BrO → BrOOBr, ΔE = −16.93 kcal mol^{-1} by B3LYP/aug-cc-pVTZ method, leads to $\Delta_f H^\circ_{298}$ = 42.1 kcal mol^{-1}.[4] The dominant product observed in the matrix isolation/infrared spectroscopy study was BrOBrO.
BrOBrO	The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Calculated enthalpy for the reaction BrO + BrO → BrOBrO, ΔE = −6.08 kcal

mol^{-1} by B3LYP/aug-cc-pVTZ method, leads to $\Delta_f H^\circ_{298}$ = 52.9 kcal mol^{-1}.[4] The dominant product observed in the matrix isolation/infrared spectroscopy study was BrOBrO.

OBrBrO Calculated enthalpy for the reaction BrO + BrO → OBrBrO, ΔE = +13.44 kcal mol^{-1} by B3LYP/aug-cc-pVTZ method.[4] The dominant product observed in the matrix isolation/infrared spectroscopy study was BrOBrO.

$BrBrO_2$ The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5]

HOBr Enthalpy value from an evaluation of the experimental data.[6] An enthalpy value of –15.3±0.6 kcal mol^{-1} has been calculated by coupled-cluster theory with correlation consistent basis sets and corrections for core-valence, relativistic, and anharmonic effects.[3] Entropy value calculated from the experimental structure and vibrational frequencies.[13] A re-evaluation of the photoionization results, along with a newer value for the OH enthalpy, led to a value of $\Delta_f H_0^\circ$ = −47.7±1.8 kJ mol^{-1}.[7]

BrOOH CCSD(T) calculation with spdfg one-particle basis set, using isodesmic reaction and present values of reference enthalpies.[12]

HOBrO and $HBrO_2$

Isomerization energy calculated at CCSD(T)/ANO4 level of theory, corrected for zero-point energy and to 298 K. BrOOH energy from present table.[12]

Note 40: *Inorganic compounds containing Br and F*

Back to Table

BrF Taken from a review of the literature.[1] A calculation of the total atomization energy using a composite electronic structure approach based on CCSD(T) and extrapolated to the complete basis set limit with a two-point extrapolation scheme, Q5 led to a value of $\Delta_f H^\circ_{298} = -58.9$ kJ mol^{-1}. Additional corrections included zero-point energy, core-valence effect, for scalar relativistic effects, and spin-orbit corrections.[2]

BrOF, BrO$_2$F

The total atomization energy was calculated using a composite electronic structure approach based on CCSD(T) and extrapolated to the complete basis set limit with a two-point extrapolation scheme, Q5. Additional corrections included zero-point energy, core-valence effect, for scalar relativistic effects, and spin-orbit corrections.[2]

Back to Table

BrCl Review of the literature.[2] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298} = 15.9 \pm 6$ kJ mol^{-1} and $\Delta_f H_0^\circ = 23.4 \pm 6$ kJ mol^{1}.[1]

ClOBr The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] A CCSD(T)/ANO4 study, based on the isodesmic reaction HOBr + HOCl → H$_2$O +ClOBr, adjusted for the present enthalpy values for the references, led to $\Delta_f H^\circ_{298} = 98 \pm 7$ kJ mol^{-1}.[3]

ClBrO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. $\Delta_f H^\circ_{298} = 145.2 \pm 6$ kJ mol^{-1} for the ^{3}A" state and $\Delta_f H^\circ_{298} = 252.7 \pm 6$ kJ mol^{-1} for the ^{3}A' state.[1]

BrClO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. Listed enthalpy is for the ^{1}A' state. $\Delta_f H^\circ_{298} = 226.4 \pm 6$ kcal mol^{-1} for the ^{3}A' state.[1]

ClOOBr, BlOBrO, BrOClO, ClBrO$_2$, BrClO$_2$

The enthalpy values are from calculations of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1]

Note 42: *Inorganic compounds containing Br, N, and O* Back to Table

BrNO Taken from the NBS thermochemical tables.[6] A CCSD(T)/ANO4 result based on the homodesmic reaction BrNO + $H_2O \rightarrow$ HNO + HOBr, adjusted for the present enthalpy values for the references, gives 22.7±1.9 kcal mol^{-1}.[1]

***cis*-BrONO** Calculated using the isodesmic reaction H_2O + *cis*-BrONO → *cis*-HONO + HOBr at several levels of theory, leading to a reaction enthalpy of 7.6 kcal mol^{-1}.[2]

***trans*-BrONO** Based on a calculated energy difference above $BrNO_3$ of 10.3 kcal mol^{-1} from calculations at several levels of theory.[2]

$BrNO_2$ Based on a calculated energy difference below *cis*-BrONO of 6.4 kcal mol^{-1} from calculations at several levels of theory.[2]

$BrONO_2$ The study of the thermal decomposition of $BrONO_2$ to BrO and NO_2 was used to obtain a reaction enthalpy of 28.2±1.5 kcal mol^{-1} (118±6.3 kJ mol^{-1}).[3] A computational study at the CCSD(T) level with a TZ2P basis set involving several isodesmic reactions[4] led to a value of $\Delta_f H^\circ_{298}$ = 42.3 kJ mol^{-1} whereas a CCSD(T)/cc-pV5Z calculation, extrapolated to the basis set limit, led to a BDE of 125.3 kJ mol^{-1}.[7]

Note 44: *Compounds containing one C and one or more Br*

Back to Table

CBr	Enthalpy from a CCSD(T) calculation extrapolated to the CBS limit.[2] A calculation at the W2DK level of theory gave an enthalpy of 118.51 kcal mol^{-1}.[7] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.
CHBr	Enthalpy from a CCSD(T) calculation extrapolated to the CBS limit.[2] A calculation at the DK-CCSD(T)/Aug-VTZ level, utilizing methyl bromide in an isodesmic reaction, resulted in an enthalpy value of 90.12 kcal mol^{-1}.[7] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations. Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ results in $\Delta_f H^\circ_{298}$ = 380 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[10]
CH_2Br	Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[11] Recalculated from C-H bond strength of 427.2 kJ mol^{-1} and enthalpy for CH_3Br and H from this Table. Statistical thermodynamic methods also utilized. *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide, resulted in an enthalpy value of 166.6±3 kJ mol^{-1}.[6]
CH_3Br	Calculated from the dissociation of energy-selected CH_3Br^+ and its adiabatic ionization energy.[12] Enthalpy from Gurvich et al. review is –36.4±0.5 kJ mol^{-1}.[3] Entropy taken from Ideal Gas Thermodynamic Properties, which gives an enthalpy of –37.7±1.5 kJ mol^{-1}.[4] Pedley review gives an enthalpy of –35.4±1.1 kJ mol^{-1}.[9]
CBr_2	Enthalpy from a CCSD(T) calculation extrapolated to the CBS limit.[2] Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ results in $\Delta_f H^\circ_{298}$ = 339 kJ mol^{-1} at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[10] A calculation at the W2DK level of theory gave an enthalpy of 82.10 kcal mol^{-1}.[7] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.
$CHBr_2$	Enthalpy derived from an analysis of thermochemical and kinetic data on the bromination of CH_2FCl.[13] *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide, resulted in an enthalpy value of 191.7±6 kJ mol^{-1}.[6] A calculation at the DK-CCSD(T)/Aug-VTZ level, again utilizing methyl bromide in an isodesmic reaction, resulted in an enthalpy value of 47.44 kcal mol^{-1}.[7] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.
CH_2Br_2	Enthalpy taken from a dissociative photoionization study of a series of dihalomethanes, normalized using the experimental enthalpy of dichloromethane.[5] The reported value has been adjusted by +0.4 kJ mol^{-1} to agree with the present enthalpy for CH_2Cl_2. Previous value of –11.1 kJ mol^{-1} from Allen bond-energy scheme.[1] Ab initio calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide, resulted in an enthalpy value of 4.3±6 kJ mol^{-1}.[6] Entropy from evaluation of Gurvich et al.[3]
CBr_3	Enthalpy value from ab initio calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide.[6] A calculation at the DK-CCSD(T)/Aug-VTZ level, again utilizing methyl bromide in an isodesmic reaction, resulted in an enthalpy value of 55.50 kcal mol^{-1}.[7] This same study, using a DFT approach for geometry optimization and frequency calculations, reported an entropy value of 80.60 cal K^{-1}. Gurvich et al. review has 235±25 kJ mol^{-1}. Entropy from Gurvich et al.[3]
$CHBr_3$	Enthalpy of formation derived from the heat of combustion of the liquid of 545.1±3.3 kJ mol^{-1} measured by bomb calorimetry.[8] An enthalpy value of 51.6±9 kJ mol^{-1} was obtained from *ab*

initio calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide.[6] A calculation at the DK-CCSD(T)/Aug-VTZ level, again utilizing methyl bromide in an isodesmic reaction, resulted in an enthalpy value of 12.97 kcal mol^{-1}.[7] This same study, using a DFT approach for geometry optimization and frequency calculations, reported an entropy value of 78.93 cal K^{-1}. Previous value of 5.7 kcal mol^{-1} from Allen bond-energy scheme.[1] Entropy from evaluation of Gurvich et al.[3] Pedley gives enthalpy as 23.8±4.5 kJ mol^{-1}.[9]

CBr$_4$ Enthalpy from rotation-bomb calorimetry.[1] *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide, resulted in an enthalpy value of 110.6±12 kJ mol^{-1}.[6] A calculation at the DK-CCSD(T)/Aug-VTZ level, again utilizing methyl bromide in an isodesmic reaction, resulted in an enthalpy value of 28.49 kcal mol^{-1}.[7] This same study, using a DFT approach for geometry optimization and frequency calculations, reported an entropy value of 85.61 cal K^{-1}. Entropy from Gurvich et al.[3]

CFBr Enthalpy obtained using the computed enthalpy of a reaction of the type: CH$_2$(^{1}A$_1$) + CH$_2$F$_2$ + 2CH$_3$Y → CFY(^{1}A$_1$) + 3CH$_4$ at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[4]

CH_2FBr Taken from review of Kudchadker and Kudchadker. Enthalpy estimated.[1]

CHF_2Br Enthalpy from review of Pedley.[2] Entropy from review of Kudchadker and Kudchadker, who also estimate an enthalpy of –102.66 kcal mol^{-1}.[1]

CF_3Br Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[3] Entropy from review of Kudchadker and Kudchadker.[1]

CF_2Br_2 Taken from review of Kudchadker and Kudchadker. All parameters estimated.[1]

$CFBr_3$ Taken from review of Kudchadker and Kudchadker. Enthalpy estimated.[1]

CClBr Enthalpy obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[4]

CHClBr Measured rate constant for the reaction of the radical with HBr, combined with previous measurements on the reverse reaction, with thermodynamic values obtained through a second-law analysis.[6]

CH_2ClBr Enthalpy taken from a dissociative photoionization study of a series of dihalomethanes, normalized using the experimental enthalpy of dichloromethane.[2] The reported value has been adjusted by +0.4 kJ mol^{-1} to agree with the present enthalpy for CH_2Cl_2.

CCl_2Br Measured rate constant for the reaction of the radical with HBr, combined with calculated (MP2(fc)/6-31G(d,p)) values for the reverse reaction, leading to thermodynamic values obtained through a second-law analysis.[5]

$CHCl_2Br$ Taken from review of Kudchadker and Kudchadker. All parameters estimated.[1]

CCl_3Br Enthalpy from review of Pedley.[3] Entropy and enthalpy difference from review of Kudchadker and Kudchadker.[1]

CCl_2Br Measured rate constant for the reaction of the radical with HBr, combined with calculated (MP2(fc)/6-31G(d,p)) values for the reverse reaction, leading to thermodynamic values obtained through a second-law analysis.[5]

Note 48: *Compounds containing one C, one or more O, and Br*

Back to Table

CBr_2O, carbonyl bromide

Enthalpy from review of Pedley.[4]

CBr_3O Derived from a G2 calculation of the total energy of formation from the gas-phase elements.[1]

CBr_3OX (X=H,F,Cl,Br)

Derived from a G2 calculation of the total energy of formation from the gas-phase elements.[2]

CCl_3OBr Derived from a G2 calculation of the total energy of formation from the gas-phase elements.[2]

CH_2BrOOH, CHFBrOOH, CHClBeOOH

Geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level. The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate the enthalpy of formation at 298 K.[3] This was adjusted to the radical values from the present Table.

Note 49: *Compounds containing two C and Br*

Back to Table

C_2Br An *ab initio* calculation at the W2DK level of theory.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

C_2HBr, bromoacetylene

Enthalpy from measurements of the photodissociation of bromoacetylene, leading to dissociation energy of 91.0±1.2 kcal mol^{-1}.[8] $\Delta_f H_0^o$ = 71.3±1.5 kcal mol^{-1}. A calculation at the W2DK level of theory gave an enthalpy of 67.50 kcal mol^{-1}.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

C_2CHBr Enthalpy from review of Pedley.[10] An enthalpy of 74.1±3.1 kJ mol^{-1} has been derived from a dissociative photoionization study of $CH_2BrCHBr_2$ with a computed vinyl cation enthalpy.[5]

CH_2CH_2Br

An experimental study of the reaction Br + C_2H_4 ↔ C_2H_4Br led to an enthalpy of reaction of 6.8±1.6 kcal mol^{-1}.[1]

CH_3CHBr A photobromination study leads to D(CH_3CHBr-H) = 97.2±1 kcal mol^{-1}.[6]

CH_3CH_2Br

Enthalpy obtained from a TPEPICO determination of the onset energy of the ethyl cation from the photodissociation of ethyl bromide, taking $\Delta_f H_0^o(C_2H_5^+)$ = 915.5±1.3 kJ mol^{-1}.[2] Previous enthalpy value, –61.5±1.0 kJ mol^{-1}, was taken from review of the literature.[3] Entropy calculated by Kudchadker and Kudchadker.[4]

C_2Br_2 An *ab initio* calculation at the W2DK level of theory.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

***trans*-CHBrCBr, *trans*-dibromovinyl radical**

A calculation at the DK-CCSD(T)/Aug-VTZ level, utilizing methyl bromide in an isodesmic reaction.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

CH_3CBr_2 A photobromination study leads to D($CClF_2$-H) = 94.9±1.2 kcal mol^{-1}.[7]

CH_3CBr_2H Taken from a review of the literature.[3]

$CHBrCBr_2$, tribromoethene

A calculation at the DK-CCSD(T)/Aug-VTZ level, utilizing methyl bromide in an isodesmic reaction.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

CH_2BrCH_2Br

Enthalpy from review of Pedley.[10]

C_2Br_3 A calculation at the DK-CCSD(T)/Aug-VTZ level, utilizing methyl bromide in an isodesmic reaction.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

$CH_2BrCHBr_2$

Enthalpy derived from a dissociative photoionization study of $CH_2BrCHBr_2$ and a computed vinyl cation enthalpy.[5]

CH_3CBr_3 Taken from a Thermodynamics Research Center review. Enthalpy estimated.[4]

C_2Br_4, $CHBr_2CBr_2$, CBr_3CHBr, C_2Br_5, C_2Br_6

A calculation at the DK-CCSD(T)/Aug-VTZ level, utilizing methyl bromide in an isodesmic reaction.[9] Entropy obtained from the same study, using a DFT approach (B97-1/Aug-cc-pVTZ) for geometry optimization and frequency calculations.

$CH_3C(O)Br$, acetyl bromide

Enthalpy from review of Pedley.[3]

$CH_2BrCOOH$

Review of the literature by Dorofeeva et al.[2]

$BrCH_2CH_2OH$

The enthalpy of formation of the liquid was determined by using rotating-bomb combustion calorimetry to be $\Delta_f H^\circ_{298}(l) = -275.8 \pm 0.6$ kJ mol^{-1}. The molar enthalpy of vaporization was then determined by use of Calvert-drop microcalorimetry as $\Delta_{vap} H^\circ_{298} = 54.08 \pm 0.40$ kJ mol^{-1}.[1]

Note 54: *Compounds containing I and O* Back to Table

IO The photodissociation dynamics of expansion-cooled IO was investigated, using velocity map ion imaging. This led to D_0 = 54.9 (+0.2 -0.4) kcal mol^{-1} and to the recommended enthalpy values.[3] Previous recommendation of the enthalpy, $\Delta_f H_0^\circ$ = 127.2±2.5 kJ mol^{-1}, $\Delta_f H^\circ_{298}$= 125.1±2.5 kJ mol^{-1}, was from a CCSD(T) calculation of the dissociation energy, both directly and through a negative ion thermochemical cycle.[10] The NIST-JANAF thermochemical tables for iodine oxides recommends $\Delta_f H^\circ_{298}$ = 126±18 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 128±18 kJ mol^{-1}, based on molecular beam studies.[2] The earlier spectroscopic studies are also discussed here. An equilibrium constant derived from the forward and reverse rate constants for IO + ClO ↔ I + OClO leads to an enthalpy at 298 K of about 28.6 kcal mol^{-1} (using reference values from this table) and 27.5 kcal mol^{-1} from the equilibrium Cl + IO ↔ I + ClO.[1] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for I + O → IO, using Table reference values, leads to $\Delta_f H^\circ_{298}$ = 117.3 kJ mol^{-1}.[7] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 128.0±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 130.1±6 kJ mol^{-1}.[5] Entropy based on extensive calculations.[6]

OIO The enthalpy value was from a determination of the threshold for the appearance of IO upon pulsed photolysis of OIO, indicating a bond strength of D_0(O-IO) = 248.8±1 kJ mol^{-1}.[4] The previous values of $\Delta_f H^\circ_{298}$ = 117.7±6 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 123.4±6 kJ mol^{-1} were from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory provided the entropy and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 75 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9] A more recent computational study gives an enthalpy at 0 K of 113.9±10.3 kJ mol^{-1}.[8] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for 2IO → OIO + I leads to a 298 K enthalpy of 110.1 kJ mol^{-1}.[7]

IOO Enthalpy for the reaction HOOI + FOO → HOOF + IOO at the CCSD(T)/CBS(DTQ) level of theory, adjusted for the Table value for FOO, leads the cited enthalpy.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 96 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9]

IO_3 Enthalpy at 298 K of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for OIO + IO_3 → I_2O_5.[7] Entropy and enthalpy difference from NIST-JANAF thermochemical tables for iodine oxides.[2] Previous enthalpy value of 242 kJ mol^{-1} was estimated.

IOI The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 92.5±17 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9]

IIO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. Listed value is for the ^{1}A' state. $\Delta_f H^\circ_{298}$ = 234.3±6 kJ mol^{-1} for the $^3A_2$ state.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 134±17 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9]

IOOI The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 157 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for IO + IO → IOOI leads to a 298 K enthalpy of 179.9 kJ mol^{-1}.[7]

IIO_2 The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 103 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for IO + IO → IIO_2, using Table reference values, leads to a 298 K enthalpy of 157.9 kJ mol^{-1}.[7]

IOIO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Entropy from molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory and, with this information, an enthalpy of $\Delta_f H^\circ_{298}$ = 124 kJ mol^{-1} was derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions.[9] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for IO + IO → IOIO leads to a 298 K enthalpy of 141.3 kJ mol^{-1}.[7]

OIIO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[5] Molecular properties calculated at the MP2/6-31G(d) and MP2/6-311+G(3df) levels of theory. Enthalpy derived using approximate QCISD(T)/6-311+G93df) energies coupled with isodesmic reactions gives $\Delta_f H^\circ_{298}$ = 224 kJ mol^{-1}.[9]

I_2O_3 Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for IO + OIO → I_2O_3.[7]

I_2O_4 Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for 2OIO → I_2O.[7]

I_2O_5 Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for $I_2O_4 + O_3 \rightarrow I_2O_5 + O$.[7]

HOI Reaction enthalpies for a set of isogyric reactions were calculated using CR-CCSD(T) with single and double excitation and with second-order spin-free Douglas-Kroll-Hess Hamiltonian applied to account for the scalar relativistic effects. The listed values are from a recalculation using the present Table values, which are particularly different for IO and OH. The authors report: $\Delta_f H^\circ_{298} = -69.0\pm3.7$ kJ mol^{-1}.[7] A computational study of the OH + CH_2BrI → HOI + CH_2Br reaction at the DK-CCSD(T)/ANO-RCC-L(1)//MP2/ccpVTZ level of theory led to $\Delta_f H^\circ_{298} = -62.9$ kJ mol^{-1}.[6] The previous values of $\Delta_f H^\circ_{298} = -69.6\pm5.4$ kJ mol^{-1} and $\Delta_f H_0^\circ = -64.9\pm5.4$ kJ mol^{-1} was based on the measured activation energy of the reaction OH + CF_3I → CF_3 + HOI and G2(MP2) calculation indicating a negligible barrier for the reverse reaction.[2] Entropy based on extensive calculations.[3] Enthalpy values have also been calculated using the isogyric reaction HOOH + IO → HOO + HOI with density functional theory (GP96PW91 level), leading to –58.6 kJ mol^{-1} and –63.3 kJ mol^{-1} at 0 and 298 K, employing reference enthalpies from this Table.[1] A calculation involving a pair of isodesmic reactions at the CCSD(T) level of theory in conjunction with the aug-cc-pVTZ-PP and aug-cc-pVQZ-PP basis sets led to $\Delta_f H^\circ_{298}$ = −59.2±3.9 kJ mol^{-1} and $\Delta_f H_0^\circ$ = −54.5±3.9 kJ mol^{-1}.[5]

HIO Enthalpy difference calculated HOI → HIO with density functional theory (GP96PW91 level).[1]

HOIO Enthalpy differences were calculated for IO + OH → HIO_2, I + HO_2 → HIO_2, HIO_2 + HI → H_2O2 + I_2 at the CCSD(T) level for B3LYP geometries.[4] Previous enthalpy value $\Delta_f H^\circ_{298}$ = −17.4 kJ mol^{-1} calculated from the difference for HOOI → HOIO with density functional theory (GP96PW91 level), $\Delta_f H_0^\circ$ = −11.0 kJ mol^{-1}.[1]

HOOI Enthalpy differences were calculated for IO + OH → HIO_2, I + HO_2 → HIO_2, HIO_2 + HI → H_2O2 + I_2 at the CCSD(T) level for B3LYP geometries.[4] Previous enthalpy value $\Delta_f H^\circ_{298}$ = 36.9 kJ mol^{-1} calculated using the isogyric reaction HOOH + IO → HO + HOOI with density functional theory (GP96PW91 level), employing reference enthalpies from this Table.[1]

ClOI The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Enthalpy derived using molecular properties calculated at the MP2/6-311+G(3df) level of theory, with Gaussian-2 energies coupled with isodesmic reactions, resulted in $\Delta_f H^\circ_{298}$ = 76.1 kJ mol^{-1}. [2]

ClIO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. This value is for the ^{1}A' state. $\Delta_f H^\circ_{298}$ = 164.0±6 kJ mol^{-1} for the ^{3}A" state.[1] Enthalpy derived using molecular properties calculated at the MP2/6-311+G(3df) level of theory, with Gaussian-2 energies coupled with isodesmic reactions, resulted in $\Delta_f H^\circ_{298}$ = 68.2 kJ mol^{-1}.[2]

IClO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 166 kJ mol^{-1}.[2]

$ClIO_2$ The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 10.9 kJ mol^{-1}.[2]

ClOIO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 107 kJ mol^{-1}.[2]

ClOOI The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 126 kJ mol^{-1}.[2]

IOClO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 154 kJ mol^{-1}.[2]

$IClO_2$ The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[1] Calculations using molecular properties at the MP2/6-311+G(3df) level of theory and Gaussian-2 energies, coupled with isodesmic reactions and reference enthalpies changed to correspond to values in this Table, resulted in $\Delta_f H^\circ_{298}$ = 188 kJ mol^{-1}.[2]

INO Thermodynamic parameters from a third-law analysis of the equilibrium reaction I + NO (+He) ↔ INO (+He).[4] Enthalpy of reaction obtained using CCSD(T) calculations at B3LYP geometries, with corrections for spin-orbit coupling, for I + NO → INO, using Table reference values, leads to a 298 K enthalpy of 134.2 kJ mol^{-1}.[1]

INO_2 Thermodynamic parameters from a third-law analysis of the equilibrium reaction I + NO_2 (+He) ↔ INO_2 (+He).[4]

IOONO Derived from CCSD(T) single-point calculations at B3LYP geometries for the interconversion of the two isomers.[3] The dissociation energy for $IONO_2$ was also calculated to be 131.4 kJ mol^{-1}, leading to an enthalpy at 298K for that isomer of 24.8 kJ mol^{-1}, whereas a value of 37.5 kJ mol^{-1} has been selected for this Table.

$IONO_2$ The enthalpy values were derived from the average of the IO – NO_2 bond dissociation energies calculated by Kaltsoyannis and Plane[1] and by Marshall.[2] See Table 3-1, note 32 for more details. The selected entropy value is also discussed in that note.

Back to Table

CI Enthalpy computed from atomization energies at the CBS limit using valence correlated (R/U)CCSD(T) with au-cc-pVxZ (x=T,Q,5) basis sets, with relativistic and spin-orbit corrections. Geometries and vibrational frequencies obtained at the CCSD level with the cc-pVTZ basis set.[1]

CHI Enthalpy computed from atomization and dissociation energies at the CBS limit using valence correlated (R/U)CCSD(T) with aug-cc-pVxZ (x=T,Q,5) basis sets, with relativistic and spin-orbit corrections.[1] Geometries and vibrational frequencies obtained at the CCSD level with the cc-pVTZ basis set. Previous value of $\Delta_f H^\circ_{298}$ = 425 kJ mol^{-1} was obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y = CXY(^1A_1) + 2CH_4$ at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[10]

CH_2I Enthalpy value from *ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide.[9] A computational study of the $OH + CH_3I \rightarrow H_2O + CH_2I$ reaction at the DK-CCSD(T)/ANO-RCC-L(1)//MP2/ccpVTZ level of theory led to $\Delta_f H^\circ_{298}$ = 215.9 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 220.2 kJ mol^{-1}.[8] These values provided the enthalpy difference utilized. A subsequent study on the reaction $OH + CH_2IBr \rightarrow HOBr + CH_2I$ led to $\Delta_f H^\circ_{298}$ = 218.4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 223.3 kJ mol^{-1}.[14] Previous enthalpy value of 228.0±2.8 kJ mol^{-1} from *ab initio* calculations used to determine the entropies of the reactants and the transition state for $Br + CH_3I \rightarrow HBr + CH_2I$. Arrhenius parameters were then calculated by transition state theory. The kinetics of the reverse reactions were measured in a flow system. The enthalpy value was obtained from a second-law analysis.[11]

CH_3I Enthalpy values from an imaging PEPICO study of the dissociative photoionization of methyl iodide, using both room temperature and supersonically cooled gas.[3] The previously recommended value, $\Delta_f H^\circ_{298}$= 13.22±0.5 kJ mol^{-1}, was calculated from the dissociation of energy-selected CH_3I^+ and its adiabatic ionization energy.[12] Enthalpy from rotating combustion calorimetry is 14.4±1.4 kJ mol^{-1}.[4] A review of the literature gave $\Delta_f H^\circ_{298}$= 13.8±1.2 kJ mol^{-1} and the enthalpy difference; the entropy is from ideal gas thermodynamic properties.[5]

CI_2 Enthalpy computed from atomization and dissociation energies at the CBS limit using valence correlated (R/U)CCSD(T) with aug-cc-pVxZ (x=T,Q,5) basis sets, with relativistic and spin-orbit corrections.[1] Geometries and vibrational frequencies obtained at the CCSD level with the cc-pVTZ basis set. Previous value of $\Delta_f H^\circ_{298}$ = 450 kJ mol^{-1} was obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_3X + CH_3Y \rightarrow CXY(^1A_1) + 2CH_4$ at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory. Calculations also done at the G2 level.[10]

CHI_2 Enthalpy value from *ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide.[9] A computational study of the $OH + CH_3I \rightarrow HOI + CHI_2$ reaction at the CCSD(T)/ANO-RCC-Large//MP2/ccpVTZ level of theory led to $\Delta_f H^\circ_{298}$ = 309.2 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 298.9 kJ mol^{-1}.[13] These values provided the enthalpy difference utilized. A computational study of the $OH + CH_2I_2 \rightarrow H_2O + CHI_2$ reaction at the DK-CCSD(T)/ANO-RCC-L(1)//MP2/ccpVTZ level of theory led to $\Delta_f H^\circ_{298}$ = 298.7 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 303.5 kJ mol^{-1}.[8] Previous enthalpy value of 314.4±3.3 kJ mol^{-1} from *ab initio* calculations used to determine the entropies of the reactants and the transition state for $Br + CH_2I_2 \rightarrow HBr + CHI_2$. Arrhenius parameters were then calculated by transition state theory. The kinetics of the reverse reactions were estimated. The enthalpy value was obtained from a second-law analysis.[11]

CH_2I_2 Enthalpy taken from a dissociative photoionization study of a series of dihalomethanes, normalized using the experimental enthalpy of dichloromethane.[7] The reported value has been adjusted by +0.4 kJ mol^{-1} to agree with the present enthalpy for CH_2Cl_2. Previous value of 119.5±2.2 kJ mol^{-1} from rotating combustion calorimetry.[4] *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl iodide, resulted in an enthalpy value of 108.1±6 kJ mol^{-1}.[9] A review of the literature gave $\Delta_f H^\circ_{298}$= 117.6±4.2 kJ mol^{-1} and the enthalpy difference; the entropy is from ideal gas thermodynamic properties.[6] In a more recent study, involving a TPEPICO determination of the heat of formation of 1,2-$C_2H_4I_2$, an analysis of the *ab initio* isodesmic reactions energies of four reactions led to a recommendation that the enthalpy values be reduced to $\Delta_f H_0^\circ$ = 123.1±2.0 kJ mol^{-1} and $\Delta_f H^\circ_{298}$ = 113.5±2.0 kJ mol^{-1}.[2]

CHI_3 *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl iodide.[9] Previous enthalpy value of 251.1±1.4 kJ mol^{-1} from rotating combustion calorimetry.[4] A review of the literature gave $\Delta_f H^\circ_{298}$= 210.9±4.2 kJ mol^{-1} and the enthalpy difference; the entropy is from ideal gas thermodynamic properties.[5]

CI_3 Enthalpy value from *ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl bromide.[9] A computational study of the $OH + CH_3I \rightarrow H_2O + CI_3$ reaction at the CCSD(T)/ANO-RCC-Large//MP2/ccpVTZ level of theory led to $\Delta_f H^\circ_{298}$ = 387.4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 384.4 kJ mol^{-1}.[13] These values provided the enthalpy difference utilized. Previous enthalpy value of 424.9±2.8 kJ mol^{-1} from *ab initio* calculations used to determine the entropies of the reactants and the transition state for $Br + CH_2I_2 \rightarrow HBr + CHI_2$. Arrhenius parameters were then calculated by transition state theory. The kinetics of the reverse reactions were estimated. The enthalpy value was obtained from a second-law analysis.[11] The uncertainty in the *ab initio* was suggested to be ±9 kJ mol^{-1}. We have expanded that considerably due to these obvious disagreements.

CI_4 *Ab initio* calculations at the QCISD(T)/6-311+G(3df,2p) level of theory, utilizing an isodesmic reaction with methyl iodide.[9] Previous enthalpy value of 474±13 kJ mol^{-1} from rotating combustion calorimetry.[4] A review of the literature estimated $\Delta_f H^\circ_{298}$= 268±4.2 kJ mol^{-1} and the enthalpy difference; the entropy is from ideal gas thermodynamic properties.[6] The uncertainty in the *ab initio* was suggested to be ±12 kJ mol^{-1}. We have expanded that considerably due to these obvious disagreements.

CH_2IOOH, CHI_2OOH

Geometry optimization and frequency calculations were performed at the MP2/6-31G(d) and the B3LYP/6-311++G(d,p) levels of theory, with a single-point energy calculation at the CCSD(T)/6-311++G(d,p//B3LYP/6-311++G(d,p) level. The dissociation energy into HO_2 and the alkyl radical was then evaluated and used, after thermal correction, to calculate the enthalpy of formation at 298 K.[1] This was adjusted to the radical values from the present Table.

CFI Enthalpy values calculated from atomization energies by using the (R/U)CCSD(T) level of theory.[1] Basis sets from cc-pVTZ to aug-cc-pV5Z and cc-pwCVQZ were employed. Small-core relativistic pseudopotentials were used as needed. Geometric parameters and frequencies were computed using the CCSD method. A singlet-triplet spacing of 114.2 kJ mol^{-1} was also obtained. The previously listed enthalpy value of $\Delta_f H^\circ_{298}$= 154 kJ mol^{-1} was obtained using the computed enthalpy of a reaction of the type: $CH_2(^1A_1) + CH_2F_2 + 2CH_3Y \rightarrow CFY(^1A_1) + 3CH_4$ at the QCISD(T)/6-311+G(3df,2p)//QCISD/6-311G(d,p) level of theory, with calculations also done at the G2 level.[5]

CF_3I Enthalpy from a simultaneous solution of a thermochemical network for the CF_3X species, where X = nil, H, Cl, Br, I, CF_3, CN.[4] Entropy from recommendation of Gurvich et al.[2]

CF_2I_2 Taken from review of Kudchadker and Kudchadker. All parameters estimated.[3]

Enthalpy value taken from review of Pedley.[2]

ICH_2CH_2OH

The enthalpy of formation of the liquid was determined by using rotating-bomb combustion calorimetry to be $\Delta_f H^\circ_{298}(l) = -207.3\pm0.7$ kJ mol^{-1}. The molar enthalpy of vaporization was then determined by use of Calvert-drop microcalorimetry to be $\Delta_{vap}H^\circ_{298} = 57.03\pm0.20$ kJ mol^{-1}.[1]

S CODATA Key Value.[2] The JANAF Tables give $\Delta_f H_0^\circ = 274.735$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = 276.98$ kJ mol^{-1}, and $S^\circ = 167.828$ J mol^{-1}.[1]

S_2 CODATA Key Value.[2] The JANAF Tables give $\Delta_f H_0^\circ = 128.3$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = 128.6$ kJ mol^{-1}, and $S^\circ = 228.165$ J mol^{-1}.[1]

HS Updated and corrected NIST-JANAF thermochemical tables.[7] Enthalpy calculated at the CCSD(T)/CBS level of theory is 34.4 kcal mol^{-1}.[9] Thermodynamic parameters calculated at the CCSDT(Q)/cc-pV(T+d)Z level of theory give $\Delta_f H_0^\circ = 142.6$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = 143.4$ kJ mol^{-1}, and $S^\circ = 195.4$ J mol^{-1}.[8] A computational study of S-centered radicals, with geometry and conformational optimization at the M06-2X/6-31G(d) level of theory and energies determined using the G3(MP2)-RAD composite method, obtained $\Delta_f H_{298}^\circ = 140.89$ kJ mol^{-1}, taking H_2S and H enthalpy values from the present Table.[3]

H_2S CODATA Key Value.[2] The JANAF Tables give $\Delta_f H_0^\circ = -17.58$ kJ mol^{-1}, $\Delta_f H_{298}^\circ = -20.50$ kJ mol^{-1}, and $S^\circ = 205.757$ J mol^{-1}.[1]

HSS A UCCSD(T)/cc-pV(n+d)Z(n=D,T,Q,5) calculation with correlation-consistent basis sets results in 3.63±1.0 kcal mol^{-1}.[4] Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level gives $\Delta_f H^\circ_{298} = 24.3\pm1$ kcal mol^{-1} and $\Delta_f H_0^\circ = -25.0\pm1$ kcal mol^{-1}.[6] A computational study of S-centered radicals, with geometry and conformational optimization at the M06-2X/6-31G(d) level of theory and energies determined using the G3(MP2)-RAD composite method, obtained $\Delta_\mathrm{f}H_{298}^\circ$ = 106.3 kJ mol^{-1}, taking H_2S_2 and H enthalpy values from the present Table.[3]

HSSH Thermodynamics Center recommendation.[5] A UCCSD(T) calculation with correlation-consistent basis sets results in 3.63±1.0 kcal mol^{-1}.[4] The atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level, gives $\Delta_\mathrm{f}H^\circ_{298}$ = 3.4±1 kcal mol^{-1} and $\Delta_\mathrm{f}H_0^\circ$ = 4.8±1 kcal mol^{-1}.[6] Lowest energy configuration is the *syn* isomer. Values for the *trans* isomer are $\Delta_\mathrm{f}H^\circ_{298}$ = 7.8±1 kcal mol^{-1} and $\Delta_\mathrm{f}H_0^\circ$ = 9.3±1 kcal mol^{-1} and for the *cis* isomer $\Delta_\mathrm{f}H^\circ_{298}$ = 10.0±1 kcal mol^{-1} and $\Delta_\mathrm{f}H_0^\circ$ = 11.5±1 kcal mol^{-1}.

HSSS Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level.[6] Lowest energy configuration is the *syn* isomer. Values for the *cis* isomer are $\Delta_\mathrm{f}H^\circ_{298}$ = 27.0±1 kcal mol^{-1} and $\Delta_\mathrm{f}H_0^\circ$ = 28.1±1 kcal mol^{-1} and for the *trans* isomer $\Delta_\mathrm{f}H^\circ_{298}$ = 27.0±1 kcal mol^{-1} and $\Delta_\mathrm{f}H_0^\circ$ = 27.7±1 kcal mol^{-1}.

HSSSH Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[6] Lowest energy configuration is the *syn* isomer.

SO Enthalpy value based on the dissociation energy of SO.[4]

SOO Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level, $\Delta_\mathrm{f}H_0^\circ$ = 49.5±1 kcal mol^{-1}.[3]

SO_2 CODATA Key Value.[2] The JANAF Tables give $\Delta_\mathrm{f}H_0^\circ$ = –294.3 kJ mol^{-1}, $\Delta_\mathrm{f}H_{298}^\circ$ = –296.8 kJ mol^{-1}, and S° = 248.212 J mol^{-1}.[1]

SO_3 Taken from a review of the literature.[4] The JANAF Tables give $\Delta_\mathrm{f}H_0^\circ$ = –390.0 kJ mol^{-1}, $\Delta_\mathrm{f}H_{298}^\circ$ = –395.8 kJ mol^{-1}, and S° = 256.769 J mol^{-1}.[1]

SSO Updated and corrected NIST-JANAF thermochemical tables.[5] Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the

CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level gives $\Delta_f H^\circ_{298}$ = -13.1 ± 1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = -13.1 ± 1 kcal mol^{-1}.[3]

Back to Table

HSO An enthalpy at 0 K determined to be -0.9 ± 0.7 kcal mol^{-1} (-3.8 ± 2.9 kJ mol^{-1}) from crossed beam reactive scattering of O + H_2S.[2] This was the value recommended in the previous Table. In a more recent study, the authors suggested that the lower bound to the uncertainty could be as much as -3 kcal mol^{-1}, but confirmed the upper bound as 0.7 kcal mol^{-1}.[3] A number of computational studies have converged on the significantly lower value presently recommended, which is taken from a study where the atomization energy was calculated by CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level.[7] This value was chosen for consistency with the other HxOySz species from the same work included in the table. In a more recent study, at the CCSDT(Q)/cc-pV(T+d)Z level, led to a value of $\Delta_f H_{298}^\circ$ = -22.6 ± 2.3 kJ mol^{-1}, in close agreement, and to the entropy value cited.[8]

HOS Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level.[7] In a more recent study, at the CCSDT(Q)/cc-pV(T+d)Z level, led to a value of $\Delta_f H_{298}^\circ$ = -5.3 ± 2.3 kJ mol^{-1}, in close agreement, and to the entropy value cited.[8]

HSO_2 Enthalpy obtained with DFT calculations on dissociation, atomization, and isodesmic reactions.[5] Value supported by a calculation of the H + SO_2 dissociation asymptote.[1] The latter study shows that HOSO is the more stable configuration, with HSO(O) as a local minimum.

HOSO Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level.[7] Lowest energy configuration is the *cis* isomer. Values for the *trans* isomer are $\Delta_f H^\circ_{298}$ = -56.2 ± 1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = -55.1 ± 1 kcal mol^{-1}. Another CCSD(T) calculation to the CBS limit, with additional corrections, including correlation through the CBSDT(Q) level, resulted in values for these isomers (identified as the *syn* and *anti* isomers) of $\Delta_f H_0^\circ$ = -58.0 kcal mol^{-1} and $\Delta_f H_0^\circ$ = -55.7 kcal mol^{-1}, respectively.[9]

HSOO Enthalpy for the reaction HOOSH + FOO → HOOF + HSOO at the CCSD(T)/CBS(Q,5) level of theory is 18.00 kcal mol^{-1}. Adjusted for the Table reference values, this gives the cited enthalpy of formation.[7] Lowest energy configuration is the *syn* isomer. Values for the *cis* isomer are $\Delta_f H^\circ_{298}$ = 29.9 ± 1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 31.3 ± 1 kcal mol^{-1} and for the *trans* isomer $\Delta_f H^\circ_{298}$ = 29.8 ± 1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 31.2 ± 1 kcal mol^{-1}.

HOSH Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(n+d)Z (n = D,T,Q,5) level. $\Delta_f H_0^\circ$ = -26.5 ± 1 kcal mol^{-1}.[7] Lowest energy configuration is the *syn* isomer. Values for the *trans* isomer are $\Delta_f H^\circ_{298}$ = -24.3 ± 1 kcal

	mol^{-1} and $\Delta_f H_0^\circ$ = −22.7±1 kcal mol^{-1} and for the *cis* isomer $\Delta_f H^\circ_{298}$ = −22.6±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = −21.0±1 kcal mol^{-1}.
HOOS	Enthalpy for the reaction HOOSH + FOO → HOOF + HOOS at the CCSD(T)/CBS(Q,5) level of theory is 5.14 kcal mol^{-1}. Adjusted for the Table reference values, this gives the cited enthalpy of formation, $\Delta_f H_0^\circ$ = 15.3±1.5 kcal mol^{-1}.[7]
HOOSH	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *syn* isomer.
HOSOH	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *syn* isomer.
$HOSO_2$	Thermodynamic parameters calculated at the CCSDT(Q)/cc-pV(T+d)Z level of theory.[8] A third-law analysis of equilibrium data for the reaction OH + SO_2 ↔ $HOSO_2$ (extrapolated from data over the temperature range 523 to 603 K) led to $\Delta_f H_{298}^\circ$ = 373±6 kJ mol^{-1}, in good agreement with the computed value.[4]
H_2SO_4	Taken from review of Dorofeeva et al.[6]
HOSS	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *cis* isomer. Values for the *trans* isomer are $\Delta_f H^\circ_{298}$ = −13.6±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = −12.7±1 kcal mol^{-1}.
HSSO	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *syn* isomer. Values for the *cis* isomer are $\Delta_f H^\circ_{298}$ = −9.1±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = −7.8±1 kcal mol^{-1} and for the *trans* isomer $\Delta_f H^\circ_{298}$ = −8.7±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = −7.8±1 kcal mol^{-1}.
HSOS	Enthalpy for the reaction HSOSH + FOO → HOOF + HSOS at the CCSD(T)/CBS(Q,5) level of theory is 8.81 kcal mol^{-1}. Adjusted for the Table reference values, this gives the cited enthalpy of formation.[7] Lowest energy configuration is the *syn* isomer. Values for the *cis* isomer are $\Delta_f H^\circ_{298}$ = 27.5±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 28.9±1 kcal mol^{-1} and for the *trans* isomer $\Delta_f H^\circ_{298}$ = 28.1±1 kcal mol^{-1} and $\Delta_f H_0^\circ$ = 28.9±1 kcal mol^{-1}.
HOSSH	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *syn* isomer.
HSOSH	Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit, with geometry optimized at the CCSD(T)/aV(T+d)Z level.[7] Lowest energy configuration is the *syn* isomer.

CS	Taken from review of Gurvich et al.[6] The JANAF tables give $\Delta_f H_0^o$ = 277.1 kJ mol^{-1}, $\Delta_f H_{298}^o$ = 280.3 kJ mol^{-1}, and S^o = 210.554 J mol^{-1}.[2]
CS$_2$	Taken from review of Gurvich et al.[6] The JANAF tables give $\Delta_f H_0^o$ = 116.1 kJ mol^{-1}, $\Delta_f H_{298}^o$ = 116.9 kJ mol^{-1}, and S^o = 237.977 J mol^{-1}.[2]
HCS	Enthalpy $\Delta_f H_0^o$ = 71.7±2.0 kcal mol^{-1} obtained from a photoionization study of CH_2S and CHS, obtained by sequential abstraction from CH_3SH.[11] 298 K value from Berkowitz et al.[1]
CH$_2$S	Enthalpy $\Delta_f H_0^o$ = 28.3±2.0 kcal mol^{-1} obtained from a photoionization study of CH_2S and CHS, obtained by sequential abstraction from CH_3SH.[11] Integrated heat capacity from Berkowitz et al.[1]
CH$_3$S	Second- and third-law analysis were utilized to obtain an enthalpy of reaction of –0.14±0.28 kcal mol^{-1} for the reaction Br + CH_3SH ↔ HBr + CH_3S.[8] Enthalpy calculated at the CCSD(T)/CBS level of theory is 29.7 kcal mol^{-1}.[10] DFT calculations support an enthalpy value of 29.78±0.44 kcal mol^{-1}.[4] A computational study of S-centered radicals, with geometry and conformational optimization at the M06-2X/6-31G(d) level of theory and energies determined using the G3(MP2)-RAD composite method, obtained $\Delta_f H_{298}^o$ = 120.6 kJ mol^{-1}, taking CH_3SH and H enthalpy values from the present Table.[3]
CH$_2$SH	A photoionization study[11] leads to a recommended value for H-CH_2SH of 93.9±2.0 kcal mol^{-1}.[1] The enthalpy is from this and the present values for H and CH_3SH. Enthalpy values calculated at the CCSDT(Q)/cc-pV(T+d)Z level of theory give $\Delta_f H_0^o$ = 142.6 kJ mol^{-1} and $\Delta_f H_{298}^o$ = 143.4 kJ mol^{-1}.[7] The entropy value is also from this reference.
CH$_3$SH	Enthalpy from Pedley[9] entropy from Frenkel et al.[5] Enthalpy calculated at the CCSD(T)/CBS level of theory is –5.31 kcal mol^{-1}.[10]

Back to Table

CS_2OH The temperature dependence of the equilibrium constant for the reaction $OH + CS_2 \leftrightarrow CS_2OH$ resulted in a heat of reaction of –10.9 ± 1.0 kcal mol^{-1} and an entropy change of –24.0 ± 4.4 cal K^{-1} mol^{-1}.[6]

CH_2SO Thermodynamic parameters calculated at the CCSDT(Q)/cc-pV(T+d)Z level of theory.[7] An enthalpy value of $\Delta_f H_{298}{}^{o}$ = –30 kJ mol^{-1} was derived from CBS-QB3 calculations on 10 reactions (one isodesmic).[9]

$CH_2S(O)O$ Enthalpy derived from B3PW91 and OBS-QB3 calculations on 3 reactions (one isodesmic).[11]

CH_3SO Derived from an reaction enthalpy of –22.88 kcal mol^{-1} for the isodesmic reaction $CH_3S + SO_3 \rightarrow CH_3SO + SO_2$ calculated at the CCSD(T) level extrapolated to the CBS limit.[8]

$CH_3S(O)O$ Enthalpies of formation determined using five isodesmic reactions, with structures, vibrational frequencies, and rotational energies calculated at the B3LYP/6-311G(2p,d) level of theory, while the enthalpies were calculated at the CBS-QB3 level.[4] Heat of atomization, dissociation, and three isodesmic reactions calculated at the G2(MP2) level of theory gave $\Delta_f H^{o}_{298}$ = –211 kJ mol^{-1}, used in the previous Table.[3] Enthalpy calculated at the CCSD(T)/CBS level of theory is –52.2 kcal mol^{-1}.[8] A DFT estimate gives –56.3 kcal mol^{-1}.[2]

CH_3OSO Heat of atomization, dissociation, and two isodesmic reactions calculated at the G2(MP2) level of theory to yield the enthalpy of formation.[3]

CH_3SOO The equilibrium constant for the reaction $CH_3S + O_2 \leftrightarrow CH_3SOO$ was measured between 216 to 258 K and resulted in a bond strength of 11.7±0.9 kcal mol^{-1}.[10]

CH_3SO_3 Computations leading to the equilibrium constant for the reaction $CH_3 + SO_3 \rightarrow CH_3SO_3$ are discussed in Table 3.1 of Section 3 of this report. The selected enthalpy value was obtained from the calculated value of $\Delta_r H_0$ = 78 kJ mol^{-1} obtained by Zhu, et al.[12] by using the CBS-QB3 composite method. This group also obtained a value of $\Delta_r H_0$ = 59.5 kJ mol^{-1} using CCST(T)/6-311++G(3df,2p). The entropy value is taken from Table 3 of Section X, as is the estimated uncertainty in the enthalpy value. Other theoretical calculations leading to the enthalpy of CH_3SO_3 are also discussed in that Table.

$CH_2S(O)OH$ and $CH_3S(O)OH$

Enthalpies of formation determined using five isodesmic reactions, with structures, vibrational frequencies, and rotational energies calculated at the B3LYP/6-311G(2p,d) level of theory, while the enthalpies were calculated at the CBS-QB3 level.[4]

OCS Taken from review of Gurvich et al.[5] The JANAF Tables give $\Delta_f H_0{}^{o}$ = –138.5 kJ mol^{-1}, $\Delta_f H_{298}{}^{o}$ = –138.4 kJ mol^{-1}, and S^{o} = 231.581 J mol^{-1}.[1]

Note 81: *Compounds containing Li*

Back to Table

Li CODATA Key Value.[2] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 159.4±0.4 kJ mol^{-1} and S^o = 138.69 J mol^{-1}.[4]

Li_2 Enthalpy and entropy values from the JANAF tables, adopting the $\Delta_f H^\circ_{298}$ value from the NBS table.[1] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 214.9±1.2 kJ mol^{-1} and S^o = 96.89 J mol^{-1}.[4]

LiH Enthalpy and entropy values from the JANAF tables. A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 138.9±4 kJ mol^{-1} and $\Delta_f H_0{}^o$ = 139.3±4 kJ mol^{-1}.[6]

LiF Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –340.6±4 kJ mol^{-1} and $\Delta_f H_0{}^o$ = –340.6±4 kJ mol^{-1}.[6]

LiCl Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –192.9±4 kJ mol^{-1} and $\Delta_f H_0{}^o$ = –192.9±1 kJ mol^{-1}.[6]

LiBr Enthalpy and entropy values from the JANAF tables.[1]

LiOH From an extensive evaluation from the Thermocenter of the RAS.[3] The JANAF Tables give $\Delta_f H_0{}^o$ = –234±6 kJ mol^{-1} , $\Delta_f H_{298}{}^o$ = –234±4 kJ mol^{-1}, and S^o = 210.66±2.1 J mol^{-1}.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –239.7±4 kJ mol^{-1} and $\Delta_f H_0{}^o$ = –237.7±1 kJ mol^{-1}.[6]

LiO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit. Cited values are for the $^2\Pi$ state. Enthalpy at both 0 K and 298 K for the $^2\Sigma^+$ state is 89.5±4 kJ mol^{-1}.[6] The JANAF values are $\Delta_f H^\circ_{298}$ = 84±21 kJ mol^{-1} and $\Delta_f H_0{}^o$ = 84±21 kJ mol^{-1}, and the cited entropy.[1] The Pedley and Marshall review gives $\Delta_f H^\circ_{298}$ = 75±8 kJ mol^{-1}.[5] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 69.0±4.2 kJ mol^{-1} and S^o = 211.11 J mol^{-1}.[4]

LiO_2 and LiO_3

Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit.[6]

Li_2O The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[6] The JANAF values, calculated from the enthalpy of the crystal and the enthalpy of sublimation, are $\Delta_f H^\circ_{298}$ = −167±10 kJ mol^{-1} and $\Delta_f H_0{}^o$ = −166±10 kJ mol^{-1}, and the cited entropy.[1] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = −172.8±3.7 kJ mol^{-1} and S^o = 229.15 J mol^{-1}.[4]

Note 82: *Compounds containing Na*

Back to Table

Na CODATA Key Value.[2] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 107.1±0.4 kJ mol^{-1} and S^o = 153.57 J mol^{-1}.[4]

Na_2 Enthalpy and entropy values from the JANAF tables.[1]

NaH Enthalpy and entropy values from the JANAF tables.[1]

NaF Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –291.6±4 kJ mol^{-1} and $\Delta_f H_0^o$ = –290.0±4 kJ mol^{-1}.[6]

NaCl Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –180.3±4 kJ mol^{-1} and $\Delta_f H_0^o$ = –178.7±4 kJ mol^{-1}.[6]

NaBr Enthalpy and entropy values from the JANAF tables.[1]

NaOH From an extensive evaluation from the Thermocenter of the RAS.[3] The JANAF Tables give $\Delta_f H^\circ_{298}$ = –198±12 J mol^{-1} and $\Delta_f H_0^o$ = –194±12 J mol^{-1}, and S^o = 228.44 1 J mol^{-1}.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –187.0±4 kJ mol^{-1} and $\Delta_f H_0^o$ = –184.1±4 kJ mol^{-1}.[6]

NaO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[6] Cited values are for the $^2\Pi$ state. For the $^2\Sigma^+$ state $\Delta_f H^\circ_{298}$ = 113.8±4 kJ mol^{-1} and $\Delta_f H_0^o$ = 115.5±4 kJ mol^{-1}. The JANAF values are $\Delta_f H^\circ_{298}$ = 84±40 kJ mol^{-1} and $\Delta_f H_0^o$ = 85±40 kJ mol^{-1}, and the cited entropy.[1] The Pedley and Marshall review gives $\Delta_f H^\circ_{298}$ = 100±17 kJ mol^{-1}.[5] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 104.6±4.2 kJ mol^{-1} and S^o = 228.48 J mol^{-1}.[4]

NaO_2 and NaO_3
Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit.[6]

Na_2O Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit.[6] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = −31.8±3.7 kJ mol^{-1} and the cited entropy.[4]

Note 83: *Compounds containing K*

Back to Table

K CODATA Key Value.[2] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 89.2±0.2 kJ mol^{-1} and the cited entropy.[4]

KH Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = 132.2±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 134.7±4 kJ mol^{-1}.[6]

KF Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –326.8±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –324.7±4 kJ mol^{-1}.[6]

KCl Enthalpy and entropy values from the JANAF tables.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –215.5±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –213.4±4 kJ mol^{-1}.[6]

KBr Enthalpy and entropy values from the JANAF tables.[1]

KOH From an extensive evaluation from the Thermocenter of the RAS.[3] The JANAF Tables give $\Delta_f H^\circ_{298}$ = –233±12 J mol^{-1} and $\Delta_f H_0^\circ$ = –228±12 J mol^{-1}, and S° = 236.379±1.31 J mol^{-1}.[1] A calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit, leads to $\Delta_f H^\circ_{298}$ = –221.8±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = –218.0±4 kJ mol^{-1}.[6]

KO The enthalpy is from a calculation of the atomization energy at the CCSD(T) level, extrapolated to the CBS limit.[6] Cited values are for the $^2\Pi$ state. For the $^2\Sigma^+$ state $\Delta_f H^\circ_{298}$ = 59.8±4 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 61.9±4 kJ mol^{-1}. The JANAF values are $\Delta_f H^\circ_{298}$ = 71±40 kJ mol^{-1} and $\Delta_f H_0^\circ$ = 73±40 kJ mol^{-1}, and the cited entropy.[1] The Pedley and Marshall review gives $\Delta_f H^\circ_{298}$ = 61±21 kJ mol^{-1}.[5] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = 59.9±4.2 kJ mol^{-1} and S° = 237.88 J mol^{-1}.[4]

KO_2 and KO_3
Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit.[6]

K_2O Atomization energy calculated by the CCSD(T) extrapolated to the CBS limit.[6] The Lamoreaux and Hildenbrand review gives $\Delta_f H^\circ_{298}$ = -58.61±2.2 kJ mol^{-1} and the cited entropy.[4]

K_2SO_4 Enthalpy and entropy values from the JANAF tables.[1]

Back to Table

Hg⁰ CODATA key values,[2] with the 0 K value calculated in JANAF.[1] The NBS Tables give Δ_fH^0(298 K) = 61.32 kJ mol^{-1} and S^0 = 179.03 J mol^{-1} K^{-1}.[11] The review of Hepler and Olofsson accept the NBS value, but also discuss some more recent vapor pressure measurements.[6]

HgH Chosen values from the JANAF Table,[1] based on results reported by Herzberg.[7] Also selected by Hepler and Olofsson.[6] The NBS Tables give Δ_fH^0(298 K) = 239.32 kJ mol^{-1} and S^0 = 219.49 J mol^{-1}K^{-1}.[11] A calculation using NESC/CCSD(T) in combination with triple-zeta basis sets, gave BDE = 38.5 kJ mol^{-1}, which leads to Δ_fH^0(0 K) = 238.76 kJ mol^{-1}.[3]

HgH_2 The cited enthalpy values are an average of those calculated for the atomization energy and for the bond-dissociation reaction, $HgH_2 \rightarrow HgH + H$, both done at the NESC/B3LYP level of theory.[3]

HgO The selected enthalpy of formation is derived from computational determinations of the bond dissociation energy. Dissociation from both the $^1\Sigma^+$ (to Hg^{1}S and O^{1}D) and $^3\Pi$ (to Hg^{1}S and O^{3}P) states of HgO have been reported, with some disagreement about which is the ground state. From a relativistically-corrected MP4/CCSD(T) calculation, D_0 = 9.2 kJ mol^{-1} from a triplet ground state by Filatov and Cremer.[4] A subsequent study from the same group, adding the normalized elimination of the small component technique to improve the treatment of scalar relativistic effects, found the $^3\Pi$ state 5.4 kJ mol^{-1} lower than the $^1\Sigma^+$ state, and also calculated BDEs of 16.1 kJ mol^{-1} along the triplet surface and 202.9 kJ mol^{-1} along the singlet surface, both adjusted to 298 K.[3] At 0 K, the calculated triplet BDE was 14.6 kJ mol^{-1}. In contrast, a MRCI + Q/CBS level calculation by Peterson et al.[8] found a singlet ground state and computed a BDE of 203.3 kJ mol^{-1} at 0 K. This result is in agreement with earlier calculations from the same laboratory which resulted in a BDE to ground-state atoms of 17 and 19.1 kJ mol^{-1}.[9,10]

There has been an experimental determination of the dissociation energy of HgO by using high-temperature mass spectrometry.[5] In strong disagreement with the computational studies, a value of 222±33 kJ mol^{-1} was determined. Filatov and Cremer[4] have made a compelling case that the species detected in the mass spectrometer being a dimer, either or both HgO_2Hg and OHg_2O. There is clearly a great need for additional experimental work on HgO, but at this point, we accept the theoretical argument.

Back to Table

HgF, HgCl, HgBr, HgI, HgF_2, $HgCl_2$, $HgBr_2$, HgI_2

At this time, we accept the JANAF values.[3] More recent experimental and computational results scatter around these values, with no clear pattern. These are discussed below.

HgF The JANAF enthalpy value has a stated uncertainty of ±50 kJ mol^{-1}. We have reduced this to ±20 kJ mol^{-1} in light of the additional results discussed below. The JANAF enthalpy value leads to a BDE of 134±20 kJ mol^{-1} at 0 K. A MP4/CCSD(T) calculation, including a normalized elimination of the small component (NESC) technique to improve the treatment of scalar relativistic effects, resulted in a BDE of 129 kJ mol^{-1},[4] while another CCSD(T) study led to values of 137 and 115 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6]

HgCl The JANAF enthalpy value leads to a BDE of 102±10 kJ mol^{-1} at 0 K. A reanalysis of the spectral data suggested a value of ~106 kJ mol^{-1}.[9] A more recent spectral study led to an upper limit on the BDE of 98 kJ mol^{-1},[8] although an analysis of these data by using empirical potential energy functions led to BDE = 107 kJ mol^{-1}.[2] Computational results tend to be lower: A CCSD(T)/CBS with relativistic pseudopotentials, corrected for spin-orbit coupling, gave a BDE of 96 kJ mol^{-1},[7] whereas a MP4/CCSD(T) calculation, including a normalized elimination of the small component (NESC) technique to improve the treatment of scalar relativistic effects, resulted in a BDE of 89.5 kJ mol^{-1}.[4] Another CCSD(T) study led to values of 94 and 78 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6]

HgBr The JANAF enthalpy value has a stated uncertainty of ±38 kJ mol^{-1}. We have reduced this to ±10 kJ mol^{-1} in light of the additional results discussed below. The JANAF enthalpy value leads to a BDE of 67±10 kJ mol^{-1} at 0 K. A reanalysis of the spectral data suggested a value of ~72 kJ mol^{-1}.[9] A more recent spectral study led to a BDE of 66.1 kJ mol^{-1},[8] although an analysis of these data by using empirical potential energy functions led to BDE = 61.75 kJ mol^{-1}.[2] A CCSD(T)/CBS with relativistic pseudopotentials, corrected for spin-orbit coupling, gave a BDE of 68 kJ mol^{-1},[7] whereas a MP4/CCSD(T) calculation, including a normalized elimination of the small component (NESC) technique to improve the treatment of scalar relativistic effects, resulted in a BDE of 60 kJ mol^{-1}.[4] Another CCSD(T) study led to values of 21 and 59 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6] A slightly different BDE of 66.3 kJ mol^{-1} was used in the analysis of the equilibrium constant data in Table 3-1, Note 33.

HgI The JANAF enthalpy value leads to a BDE of 32.9±5 kJ mol^{-1} at 0 K. A reanalysis of the spectral data suggested a value of 37.3 kJ mol^{-1}.[9] A more recent spectral study led to a BDE of 33.5 kJ mol^{-1},[8] although an analysis of these data by using empirical potential energy functions led to BDE = 37.3 kJ mol^{-1}.[2] A CCSD(T)/CBS calculation with relativistic pseudopotentials, corrected for spin-orbit coupling,[7] gave a BDE of 36 kJ mol^{-1} whereas a MP4/CCSD(T) calculation, including the normalized elimination of the small component (NESC) technique to improve the treatment of scalar relativistic effects, resulted in a BDE of 46 kJ mol^{-1}.[4] Another CCSD(T) study led to values of 15 and 38.5 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6]

HgF_2 In this case, the values listed in the JANAF Table are estimated. Enthalpy values have been calculated for the atomization energy and for the bond-dissociation reaction, $HgF_2 \rightarrow HgF + F$ at the NESC/B3LYP level of theory, leading to average values of $\Delta_fH^0(298\ K) = -288$ kJ mol^{-1} and $\Delta_fH^0(0\ K) = -296$ kJ mol^{-1}.[4] A CCSD(T) study led to $\Delta_fH^0(0\ K) = -302$ and -285 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6]

$HgCl_2$ The values listed in the JANAF Table are based on a third-law analysis. A CCSD(T) calculation utilizing small-core relativistic effective core potentials for the reaction $Hg + Cl_2 \rightarrow HgCl_2$ led to $\Delta_fH^0(0\ K) = -139$ kJ mol^{-1}.[1] Another CCSD(T) study led to $\Delta_fH^0(0\ K) = -134$ and -122 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6] A third CCSD(T) study, with the ECP60MDF relativistic core potential and B3LYP/aVTZ structures gave -135 kJ mol^{-1}.[5]

$HgBr_2$ The values listed in the JANAF Table are based on a third-law analysis. A CCSD(T) calculation utilizing small-core relativistic effective core potentials for the reaction $Hg + Br_2 \rightarrow HgBr_2$ led to $\Delta_fH^0(0\ K) = -67$ kJ mol^{-1}.[1] Another CCSD(T) study led to $\Delta_fH^0(0\ K) = -42$ and -34 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6] A third CCSD(T) study, with the ECP60MDF relativistic core potential and B3LYP/aVTZ structures gave $\Delta_fH^0(0\ K) = -81$ kJ mol^{-1}.[5]

HgI_2 The values listed in the JANAF Table are based on a third-law analysis. A calculated enthalpy for the reaction $HgI_2 \rightarrow Hg + I_2$ at the CCSD(T)/CBS limit with corrections for core-valence correlation, spin-orbit coupling, Lamb shift, and scalar relativity leads to the value $\Delta_fH^0(0\ K) = -16$ kJ mol^{-1}.[7] Another CCSD(T) study led to $\Delta_fH^0(0\ K) = 9.6$ and 20 kJ mol^{-1} with the CRENBL and AVTZ-PP relativistic effective core potentials, respectively.[6]
