Abstract:

The COVID-19 pandemic has necessitated social distancing at every level of society, including universities and research institutes, raising essential questions concerning the continuing importance of physical proximity for scientific and scholarly advance. Using customized author surveys about the intellectual influence of referenced work on scientists' own papers, combined with precise measures of geographic and semantic distances between focal and referenced works, we find that being at the same institution is strongly associated with intellectual influence on scientists' and scholars' published work. However, this influence increases with intellectual distance: the more different the referenced work done by colleagues at one's institution, the more influential it is on one's own. Universities worldwide constitute places where people doing very different work engage in sustained interactions through departments, committees, seminars, and communities. These interactions come to uniquely influence their published research, suggesting the need to replace rather than displace diverse engagements for sustainable advance.

Being Together in Place as a Catalyst for Scientific Advance

Abstract:

The COVID-19 pandemic has necessitated social distancing at every level of society, including universities and research institutes, raising essential questions concerning the continuing importance of physical proximity for scientific and scholarly advance. Using customized author surveys about the intellectual influence of referenced work on scientists' own papers, combined with precise measures of geographic and semantic distances between focal and referenced works, we find that being at the same institution is strongly associated with intellectual influence on scientists' and scholars' published work. However, this influence increases with intellectual distance: the more different the referenced work done by colleagues at one's institution, the more influential it is on one's own. Universities worldwide constitute places where people doing very different work engage in sustained interactions through departments, committees, seminars, and communities. These interactions come to uniquely influence their published research, suggesting the need to replace rather than displace diverse engagements for sustainable advance.

Highlights

- Seminars, committees, and communities facilitate critically diverse encounters.
- Scientists discover influential work through these local connections and experiences.
- Sharing an institution strongly predicts the transmission of intellectual influence.
- Influence grows with intellectual distance: the more different, the more influential.
- For sustained advance, COVID recovery must replace not displace diverse engagement.

The COVID-19 pandemic has necessitated social distancing at every level of society, raising essential questions concerning the importance of place and proximity. Universities have substituted face-to-face instruction, mentorship, faculty meetings, and research seminars with video conferences, not replacing but displacing interactions that otherwise lead to spill-over conversations and unintentional connections, which, in turn, spark innovative scientific and scholarly ideas and collaboration. With university laboratories only partially staffed, seminar rooms empty, workshops closed to outsiders, and conferences made either hybrid or virtual, delayed, or indefinitely rain checked, questions arise regarding the effect that this social distance will have on scientists' knowledge of emerging ideas and findings, and their ability to influence and be influenced by one another on the path to discovery and collective advance. With some parts of the world still under (or reentering) restriction, and others either emerging from or under little or no restriction, unique, natural experiments are currently underway that will add critical insight to these questions.

Researchers have examined the effect of spatial distance on the practice of both science and invention. Ubiquitous digitization, virtual classrooms, workshops, and conferences have led some to declare a "death of distance" not only in the world but also in science (Cairncross 1997; Friedman 2006). Recent experience and employee interest have led many businesses and institutions to announce that they plan to make remote work a more permanent feature of their organizational structure. But does the collapse of distance with advances in transportation and communication technology remove the geographic agglomeration that has always characterized the production and consumption of complex scientific and technical knowledge (Collins 1974)? Recent high-profile commentary argues that there is no support for creative contributions catalyzed by being together in place (Miller 2021) or that findings are mixed (Mors and Waguespack 2021). But new research implies that geography may still matter. Distance has been found to be a significant factor conditioning collaboration (Olechnicka, Ploszaj, and Celińska-Janowicz 2018; Morgan 2004; Olson and Olson 2000; Adams 2013; Fernández, Ferrándiz, and León 2016; Catalini 2018; Criscuolo and Verspagen 2008). In a recent study involving tens of thousands of information workers at a major technology company, remote work during COVID-19 shutdowns resulted in a more siloed, static and asynchronous collaboration network, with fewer bridges between disparate parts of the firm

network to facilitate rapid information flow (Yang et al. 2021). There is some evidence that regional scales affect knowledge spillovers with scholarly citation decreasing with distance (Wichmann Matthiessen, Winkel Schwarz, and Find 2002; Börner et al. 2006), most research on distance has tended to focus on inventive activity where patent citing practices remain distinct from those in science (Criscuolo and Verspagen 2008). All of this work suggests that distance matters for increasing awareness of relevant research, but these studies also suggest that what it means to be “close” can be as far as the same country, region, or within hundreds of miles. Not very close. If this diffuse geographic influence were all to the story, then the dissipation of concrete university settings into clouds would be less cause for concern.

Attempts have been made to “zoom in” on micro, hyper-local scales, with a focus on particular institutions and even buildings. While macro distances seem to play an important role in determining what prior knowledge scientists are more likely to cite, micro distances have been shown to reorient research directions and productivity (Rawlings and McFarland 2011), catalyze the consummation of research relationships (Kabo et al. 2015), facilitate the transfer of skills and tacit knowledge (Collins 1974; Collins and Harrison 1975), and promote the consolidation of distinct and diverse epistemic cultures (Cetina 2009). In a very recent study, researchers found that co-location within an institution has the most substantial distance-related effect on the probability of citation, and that sharing an institution improves the probability that intellectually distant works will be cited (Wuestman, Hoekman, and Frenken 2019). Yet, it remains unclear whether the physically proximate, nearby work we are more likely to cite is vital for our own work, or simply a curious but ornamental allusion. Moreover, while paths of possible collaborators are likely to cross more often in buildings and on campuses, how do the partnerships that emerge from those interactions rank in importance and influence relative to those formed across longer distances? While estimates of the probability of citation tell us something about the ways in which institutions facilitate access to scholarship, they do not tell us enough about the impact of co-location on intellectual influence to shape policy. Institutions are faced with a costly decision for which current literature gives them little guidance. Does the probability of citation under- or overestimate the probability of influence? Depending on the answer to this question, a cost-benefit analysis may recommend continued virtualization or a

wholesale return to physical co-location. As we show in this article, misspecifying the relationship between citation and influence could have substantial effects on innovative capacity moving forward. The limitation of prior work in this area is that it focuses on how distance affects the probability of citation or collaboration but leaves us in the dark about what it means for intellectual influence. After all, not all references denote intellectual impact (Bornmann and Daniel 2008; MacRoberts and MacRoberts 1996; Nicolaisen 2007). With some citations indicating meaningful influence and others denoting obligatory signals of membership within an intellectual community or the flex of intellectual control, attempts to observe the effect of distance on scholarship that rely primarily on the probability of citation cannot disentangle influence from exposure.

Our research design seeks to directly assess intellectual influence using publication data from Clarivate's *Web of Science* and surveyed author reports as in (Teplitskiy et al. 2020). Here we first summarize the process, then detail each step in the Methods section below. We began by randomly sampling seed articles from 15 diverse fields drawn from the physical sciences, life sciences, social sciences, and humanities. For each field, we randomly selected focal articles that cited these seed papers. We selected two references from each focal paper and surveyed corresponding authors of the focal papers regarding how much each referenced paper influenced the author of the focal paper, how well they knew it, and how and where they first discovered it (e.g., database, colleague, presentation). This yielded measurements of the intellectual influence, familiarity, and provenance of two referenced works for a total of 12,008 works (with some works rated by multiple respondents). To understand how intellectual influence is related to physical proximity, we gathered information on the institutional and geographic location of the home institutions for focal and referenced papers. To understand how intellectual influence is related to intellectual distance, we measured the intellectual (scientific and semantic) distance between referenced and focal papers with semantic precision by encoding a rich trace of the content (e.g. title and abstract) in a geometric embedding space using one of the unsupervised machine learning models that have come to exhibit human-level sensitivity in natural language tasks (Mikolov et al. 2013; Pennington, Socher, and Manning 2014; Peters et al. 2018; Devlin et al. 2018). Our analysis then involved regressing intellectual influence on

institutional and intellectual distance measurements to identify the relationship between institutional proximity and influence.

Methods

We used data from Clarivate's complete *Web of Science* (WoS) database to systematically sample the scholarly literature and survey the scientific community across the following 15 fields indexed by WoS: biochemistry & molecular biology, physical chemistry, economics, endocrinology & metabolism, energy & fuels, electrical & electronic engineering, history & philosophy of science, immunology, linguistics, nanoscience & nanotechnology, oncology, pharmacology & pharmacy, applied physics, psychology, and telecommunications.

For each discipline, we identified all research articles published in 2000, 2005, and 2010 and ranked them according to the number of citations they had accrued through 2015. From each percentile of the distribution, we randomly selected five referenced papers. From the pool of papers that cited those references, we randomly selected five focal papers published in 2015. In 2018, we contacted the corresponding author of each focal paper with a personalized survey and asked them about two of the randomly selected reference papers that they cited in their paper. Our survey focuses on identifying how much a reference paper influenced the citing author (focal paper) and how well they know it. We measured how influential a reference paper was to the focal paper with the question, "How much did this reference influence the research choices in your paper?" Answer choices ranged from 1 (very minor influence: paper would have been very similar without this reference) to 5 (very major influence: motivated the entire project). We measured how well the respondent knew the content of the reference with the question, "How well do you know this paper?" Answer choices ranged from 1 (not well: only familiar with main findings) to 5 (Extremely well: know it as well as my own work). This approach yields a direct measure of the intellectual influence that a particular referenced work had on an author's own work and how well authors know the reference papers they cited in their own work. Specifically, we asked respondents the extent to which the two cited reference papers influenced their own paper. Because survey completion rates varied by field, this yielded 1060 responses from biochemistry & molecular biology, 1361 from physical chemistry, 1078

from economics, 589 from endocrinology & metabolism, 1419 from energy & fuels, 688 from electrical & electronic engineering, 209 from history & philosophy of science, 622 from immunology, 421 from linguistics, 497 from nanoscience & nanotechnology, 701 from oncology, 834 from pharmacology & pharmacy, 864 from applied physics, 1096 from psychology, and 569 from telecommunications. (See Figure B1 and Table B1 in the Appendices).

In order to analyze how intellectual influence relates to physical proximity, we gathered information on how the respondent found the referenced paper and information on the geographic location of the home institutions for focal and referenced papers. We extracted institutional addresses for each paper's corresponding author recorded in the *Web of Science* to accomplish this. Next, we geocoded these addresses using the Google Maps API to resolve their precise latitude and longitude, as well as city, country, and institutional information. Additionally, we extracted the institution and department names from the WoS database and cross-checked the institution with the Maps API. Finally, we calculated the geodesic distance between each focal paper and its corresponding reference paper institutions in kilometers. When evaluating the effect of the continuous distance variable on intellectual influence, we found that effects were prominent when distances between focal papers and reference papers are near zero (see Figures E1 & E2 in Appendix E). To explore this, we discretized geographical distance into five categories: "same academic department," "same institution," "same city," "same country," "same world."

We regressed intellectual influence and knowledge of each paper on the distinct pathways through which an author found that paper using ordinal logistic regressions (and linear mixed models reported in Appendix D) to quantify the relationship source and influence. Coefficients are detailed in Tables 1 and D3, all of which are consistent with the correlations presented below in Figure 1.

In order to analyze how intellectual influence relates to intellectual distance, we measured the intellectual (scientific and semantic) distance between referenced and focal papers with semantic precision. To do this, we elected to encode a rich trace of the content (article title and abstract) in a geometric embedding space with one of the unsupervised machine learning models that have

transformed modern natural language processing (Mikolov et al. 2013; Pennington, Socher, and Manning 2014; Peters et al. 2018; Devlin et al. 2018). These models draw on large-scale text corpora and “discover” semantics from linguistic context and validate the distribution hypothesis that words occurring in the same contexts tend to have similar meanings (Harris 1954) by performing at human-level on analogy tests (Mikolov et al. 2013; Pennington, Socher, and Manning 2014), question answering (Peters et al. 2018; Devlin et al. 2018), and a wide range of language understanding tasks. It has been demonstrated that embedding texts produced by persons in given times and places can replicate surveyed associations among people from those same times and places (Kozlowski, Taddy, and Evans 2019; Caliskan, Bryson, and Narayanan 2017; Lewis and Lupyán 2019; Garg et al. 2018). Here, we use a popular word and document embedding algorithm (Gensim implementation of the Doc2Vec algorithm) (Le and Mikolov 2014), and calculate intellectual distance as the cosine similarity of the angle between fixed-length feature vector representations of each referenced and focal paper. This approach produces estimates of greater semantic similarity than bibliometric approaches for assessing the co-citation of articles or journals (Hamers and Others 1989), while not assuming that the compared works frame themselves with respect to the same prior work (see Appendix C for details on sampling and hyper-parameterization).

We regressed intellectual influence on institutional and intellectual distance measurements using ordinal logistic regressions reported in Table 2 below, but also linear mixed models (Table E3 in Appendix E) and to quantify the relationship between a focal paper’s distances (geographic and intellectual) from its references and its influence on the corresponding author’s knowledge of it and the degree to which it shaped research choices, results and implications. Author-fixed effects enable us to control for all (stable) differences between authors, including their fields. This approach accounts for the possibility that the composition of authors varies significantly across the citation distribution of references. For example, authors may have different standards for “influence.” Additional details are described in Appendices A through E.

Results

In summary, we find that for all fields the most intellectually distant papers influence scientists and scholars most and that they are significantly more likely to find those papers at their home institutions. What is the mode of exposure to these papers? Sustained human interaction. As revealed in the correlations reported in Figure 1, being at the same institution, influence, and knowledge of the paper are each most positively correlated with knowing the author personally, having the author as a colleague and learning of the paper through a presentation or seminar. By contrast, being at the same institution, influence and knowledge of the paper are most negatively correlated with finding the paper through a scholarly database, another paper, or not remembering how the paper was found.

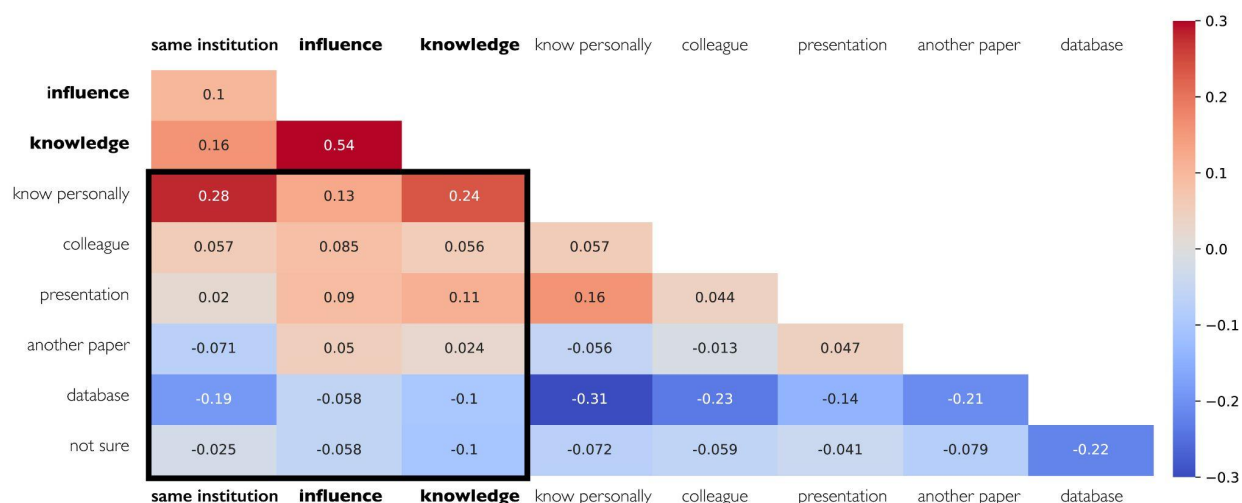

Figure 1: Correlation table between authors sharing the *same institution*, the *influence* cited papers had on the papers that cited them, the *knowledge* that citers have of the focal article, and the various channels (*know personally*; *colleague*; *presentation*; *another paper*; *database search*; *not sure*) through which authors came to find and cite focal papers.

In order to take these sources into account simultaneously and respect the discrete, Likert-scale outcome, we use ordinal logistic regression models to quantify the relationship between a referenced paper's influence and an author's knowledge of it and their source, finding the same pattern of relationship (see Table 1, but also Table E1 for the results of an equivalent linear models). We note that we were unable to analyze article provenance with a fixed-author-effects model because not enough respondents answered the question about provenance for both papers. Nevertheless, our random effects models suggest that across the distribution of respondents, influence and knowledge

were most strongly associated with knowing the author personally, learning of the paper through a presentation and receiving it from a colleague, respectively. If we convert the coefficients into odds ratios through exponentiation, we see that knowing the author is associated with an increase in the odds of an additional unit of influence (on the 1-5 Likert scale) by 1.8 times and a unit of familiarity by more than three times. Influence and knowledge of the paper were unsurprisingly most negatively predicted by not knowing how they discovered the paper and through database search.

Table 1: Ordinal logistic regression demonstrating the effect that various channels through which authors found the focal papers have on influence and knowledge.

We also allowed respondents to provide free text information on “other” ways they found cited papers. In analyzing these self-described “other” channels, we sorted responses by the amount of influence the referenced paper had on the focal paper. Reading through responses for those that imparted a high degree of influence, we found that a much higher proportion describe personal relationships. Consider the following responses: “[M]y supervisor was the co-author [of the

referenced paper]”; the author of the referenced paper is the “[f]ormer Ph.D. advisor of my co-author”; “[t]he first author [of the referenced paper] has collaborated on other projects with me.” In contrast, text responses describing other ways of finding referenced papers that confer little influence tend to evince confusion: many respondents state plainly, “I don’t remember” or “I would assume that my coauthor learned about this paper via normal database search”; “searched for relevant papers, and [the referenced article] was one that came up”; or the referenced article was “suggested by a referee”, signifying no influence at all.

Geographically, we find that when scientists share an institution, the chances they will report having been influenced by other scholars is maximized. When distance between authors increases from within an institution to within a city, and to within a country, influence falls precipitously (see Figure 2). This suggests that institutions matter not only for access to ideas but for facilitating the transfer and influential absorption of those ideas. While it is significantly more likely that authors will cite works from other institutions, the works they encounter at their home institutions are the ones that influence them most. Notably, however, when authors of citing and cited papers share a department within the same institution, the influence they confer upon one another falls. This is likely because colleagues within a department likely share enough background (Chu and Evans 2021) that their work cannot surprise and so is less likely to substantially influence.

Figure 2: Influence of papers at nested categorical distances from the focal paper. The first point is the intellectual influence of work cited from an author's own department(s); second the influence of work cited from an author's institution(s) but not same department; third the influence of work cited from an author's same city but not same institution; fourth the influence of work cited from an author's same country but not same city; and finally the influence of work cited from outside the author's country. The greatest influence is from the author's institution, but not from their department or field. Being at the same institution as cited work is blue, and being at other institutions is red.

When we examine the relationship between intellectual distance and influence, we find that in every field more intellectually distant papers—those with a smaller cosine similarity between the document vectors of focal and reference papers—are rated as more influential. Moreover, in every field, when citing and cited papers share an institution, they are, on average, more intellectually distant from one another and represent a higher transfer of influence (see Figure 3). This result explains the observed increase in influence within institutions when moving from pairs of papers that share a department to pairs that do not (Figure 2). In general, intellectual distance is otherwise uncorrelated with geographic distance, suggesting that institutions facilitate influentially distant and often chance

intellectual encounters—such as showing up at an unexpected presentation on campus—underlying a disproportionate share of scientific and scholarly advance.

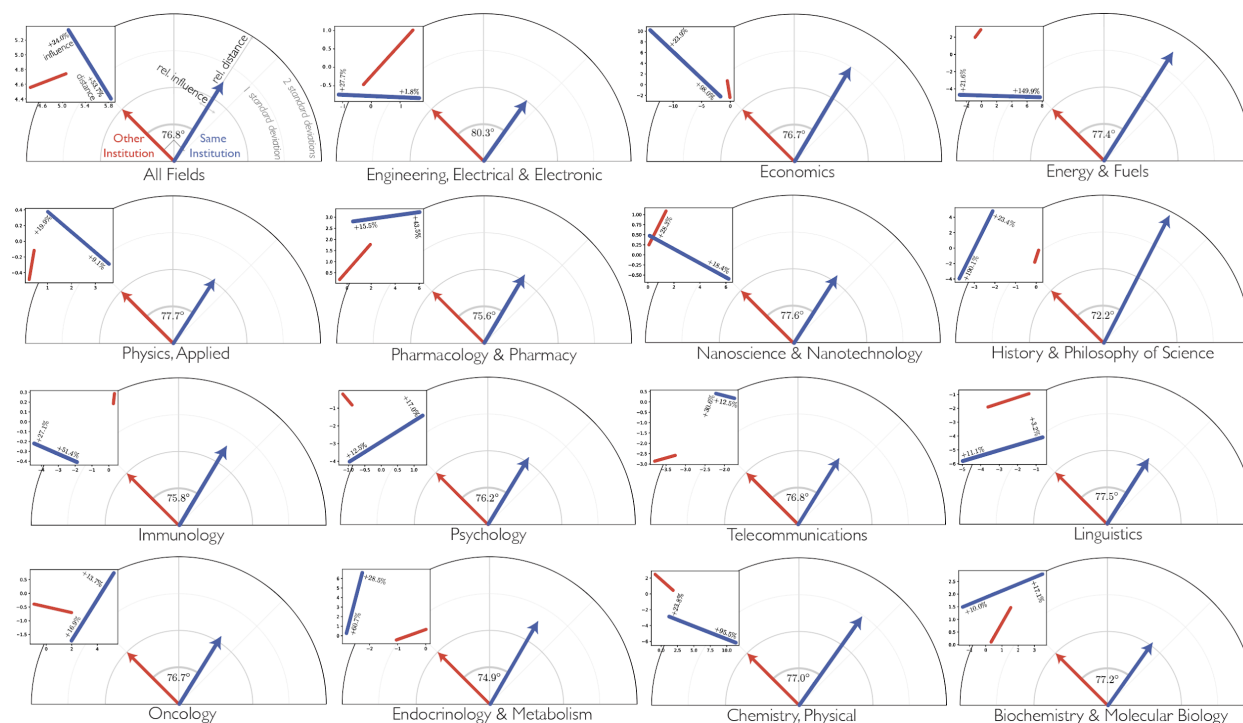

Figure 3: Influence and Intellectual Distance of Papers from same versus other institutions. The red hand of each “clock” is fixed and represents the intellectual influence (thickness) and intellectual distance (length) of papers cited from other institutions relative to the focal paper at center. The blue hand represents the intellectual influence and distance of papers from the same institution, and the angle between red and blue is the intellectual distance between cited papers from the same and other institutions (90° indicates no semantic relation). For every field studied, articles cited from the same institutions are more distant and more influential. The inset is a 2-dimensional UMAP projection of the position of focal papers relative to the papers they cite from other institutions (ends of the red line) and relative to those from the same institution (ends of the blue line.) Numbers orthogonal to each blue line are percentage increases in the intellectual influence of papers from the same relative to other institutions, and numbers along the blue line are percentage increases in the intellectual distance of papers from the same relative to other institutions in the uncompressed 300-dimensional semantic space in which they were embedded.

We regressed intellectual influence on institutional and intellectual distance measurements to identify the relationship between institutional proximity and influence. As detailed in Methods above and Appendix E below, we perform ordinal logistic regressions to quantify the relationship between a focal paper’s distances (geographic and intellectual) from its references and its influence on the

corresponding author's knowledge of it and its influence on research choices, incorporating author fixed effects. We use author fixed effects for both the dependent variables of Influence and Knowledge with coefficients represented in Table 2 (see Appendix E for equivalent linear mixed models). Both within and across individual scientists, being at the same institution with the author of research that is maximally different from your own is associated with a marked, statistically significant increase in its likelihood of influence. The effect of sharing an institution on influence is similarly strong.

<i>Independent Variables</i>	<i>Dependent Variable:</i>	
	influence	knowledge
	(1)	(2)

Note: + $p < .1$, * $p < .05$, ** $p < .01$, *** $p < .001$

Table 2: Effect and interaction effect of sharing an institution and increasing document similarity on influence and knowledge.

If we convert the coefficients into odds ratios through exponentiation, we see that being at the same institution is associated with an increase in the odds of an additional unit of influence (on the 1-5

Likert scale) by 8.63 times and a unit of knowledge by 20.11 times. The effect of document similarity (in isolation) on influence varies between the ordinal and linear models (slightly increasing influence by 1.39 times in the ordinal model; and slightly decreasing it in the linear model), which does not affect the claims of this paper. Being at the same institution and having document similarity strongly decreases the likelihood of influence to .32 times, suggesting that the sure path to influence involves being at the same institution and sharing less document similarity. When the dependent variable is “knowledge”, only the effect of sharing an institution reached statistical significance.

Discussion

Our study has natural limitations. For one, we use self-reports of intellectual influence and familiarity. Nevertheless, the design of the sampling and solicitation process reduces self-selection and reporting biases: we explicitly compare randomly sampled citations from the same paper, the respondent was not free to select the paper(s) or citations they report on, and we confirm that they cited and remembered cited papers, adding a layer of explicit verification atop self-reported citations. This improves upon the established survey approach of asking respondents to identify an instance of a phenomenon in question (e.g., a case of discrimination, influence, etc.) and then answer questions relevant to that case, which leads to a focus on extreme or subjectively salient instances. By contrast, we randomly sample from the space of acknowledged influences, validate their recognition of that cited influence, and ask details about it relative to another sampled, cited influence from the same source. An obvious limitation of this sampling strategy is that it cannot select papers respondents read but did not cite. Another limitation is that the degree to which each researcher is susceptible to influence and how they interpret the survey questions may be different. Yet, we control for this by asking respondents about two referenced papers and perform regressions with respondent fixed-effects where possible. These “within-author” models ensure that observed differences are not confounded by endogenous citing tendencies or idiosyncratic definitions of “influence.”

Our investigation demonstrates that sharing an institution is a critically important mesoscale for intellectual exposure and influence between the micro-scale of sharing an office, hallway, or department and the macro-scale of sharing a city, state, or country. This level matters more than any

other for facilitating the transfer of influence in science by promoting occasions for interaction between diverse intellectual viewpoints through committees, seminars, gyms, and dining halls—the work of the university and the often insular communities that serve them. At the micro-scale of the office next door and the macro-scale of the international scientific congress, researchers interact with others more intellectually similar to themselves. The value of critical mesoscales has been observed in online communities like Wikipedia, where the institutional constraint of a single article for a single topic—the work of producing an encyclopedia—necessitates interaction between diverse viewpoints, which is in turn associated with higher quality encyclopedia articles (Shi et al. 2019). At the micro and macroscales of the internet as a whole, we see the opposite, with ideological echo chambers serving as the paradigm of what can happen when proper institutional constraints for the promotion of sustained, diverse interactions are not in place (Bishop 2009; Sunstein 2001; Bail et al. 2018). Our work suggests that the social proximity associated with the modern university is a core ingredient in producing sustainable innovation by exposing scientists to intellectually distant ideas. The importance of this ingredient can easily be missed with more blunt instruments such as citation counts but becomes clear when we focus directly on what such instruments try to capture—influence.

These findings fly in the face of recent commentary, as at the *New York Times*, where a recent investigative piece asked the question “Do Chance Meetings at the Office Boost Innovation?” and answered, “There’s No Evidence of It.” The piece quoted, at length, a scholar of workplace interaction and transparency from Harvard Business School who stated, “there’s credibility behind the argument that if you put people in spaces where they are likely to collide with one another, they are likely to have a conversation, but is that conversation likely to be helpful for innovation, creativity, useful at all for what an organization hopes people would talk about? There, there is almost no data whatsoever. All of this suggests to me that the idea of random serendipity being productive is more fairy tale than reality” (Miller 2021). In contrast, our findings provide data that demonstrate the innovative power of in-place serendipitous encounters for science.

Being physically proximate to others that do very different—apparently unrelated—research at one’s own university dramatically increases the degree to which their work influences and potentially drives one’s published discoveries. In recent years, the importance of place has been enshrined within built infrastructure for interdisciplinary engagement (Mäkinen, Evans, and McFarland 2020), but comparable investments have been made in inter-institutional research networks and distributed “centers” of excellence around the world. Our findings here document the value of fostering sustained diversity in place. In this age of continuing COVID-19 care, if we hope to continue to fuel the engine of innovation, we will need to replace, and not simply displace, this essential but underappreciated mechanism of influence operating within our physical universities. We will need to find new ways of coming into sustained contact with seemingly unrelated but potentially critical influences that drive our newest insights about the natural and social world.

Appendix A. Survey materials

The following text and figures illustrate the survey flow. Figure A1 displays the (anonymized) recruitment email.

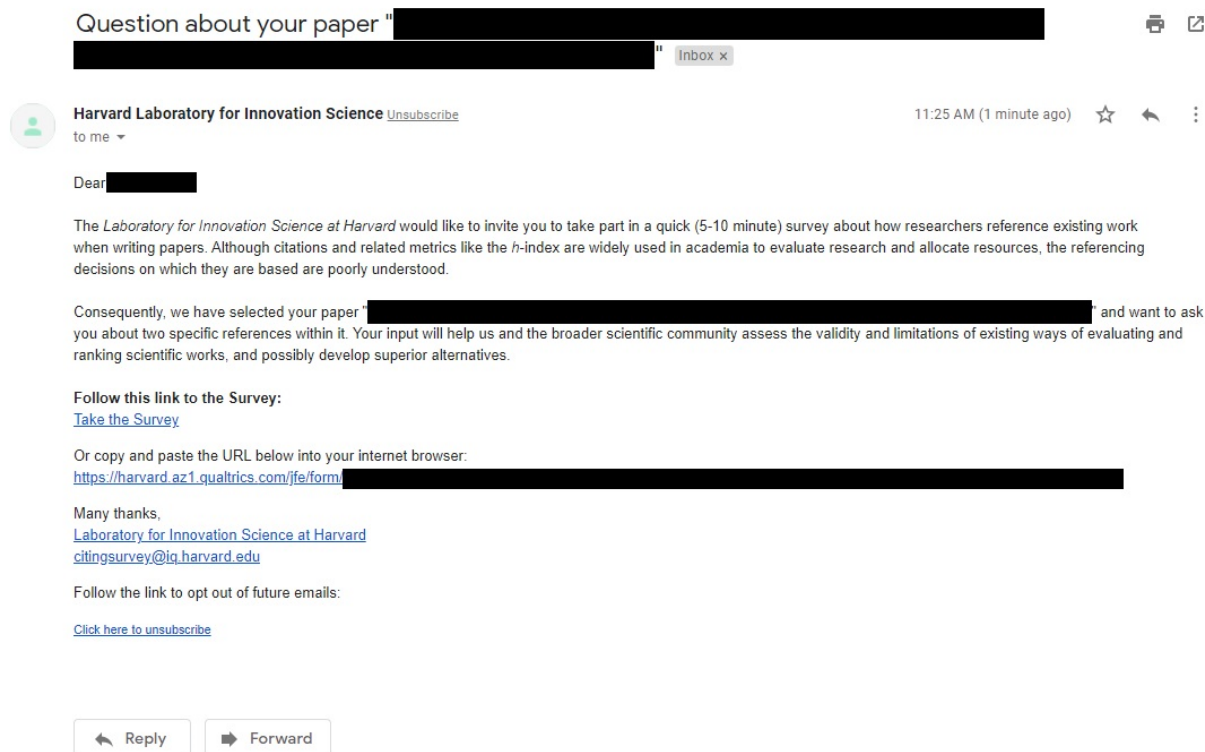

Figure A1: Sample recruitment email.

After clicking on the link, respondents proceeded to confirm that the paper was indeed theirs and read IRB information. Next, they proceeded to a randomized page, the two versions of which are displayed in Figure A2. The control (panel A) and treatment (panel B) versions are identical except that treatment includes the reference's citation information.

A	B

Figure A2: Two forms used for the reach signal experiment. 85% of randomly assigned respondents saw the control form (Panel A), which does not show any citation information, and 15% saw the treatment form (Panel B), which displays the true citation count and percentile.

Next, respondents answered questions about their knowledge of the reference, how much it influenced them, which aspects of their work were influenced (Figure A3). To account for ordering effects in answer choices, respondents were randomized into two forms with identical questions but reversed answer choice order. Form A's answer choices ranged from smallest/least to biggest/most, while form B had the opposite ordering. Next, respondents rated the reference on various dimensions of quality (Figure A4), described their expertise in the reference and how/when they first discovered it (Figure A5). Lastly, respondents provided some demographic information.

reference string

How well do you know this paper?

- Extremely well (know it as well as my own work)
- Very well (familiar with all findings, data & methods, all limitations and critiques)
- Well (familiar with all findings, data & methods, some limitations)
- Slightly well (familiar with all findings, data & methods)
- Not well (only familiar with main findings)

How much did this reference influence the research choices in your paper?

- Very major influence (motivated the entire project)
- Major influence (influenced a core part of paper, e.g. choice of theory or method)
- Moderate influence (influenced an important part of the paper, e.g. additional analysis)
- Minor influence (influenced a small part of paper, e.g. added sentence(s) to Discussion)
- Very minor influence (paper would've been very similar without this reference)
- Not sure

Which aspects of your paper did this reference influence? (Mark all that apply)

- Only minor influence
- Topic
- Theory or conceptualization
- Data
- Methods
- Other. Please explain

Figure A3: Screenshot illustrating questions about the author's knowledge of the reference and its impact on the author. Randomly assigned half of the respondents saw this ordering of answer choices, while another half saw the reverse ordering.

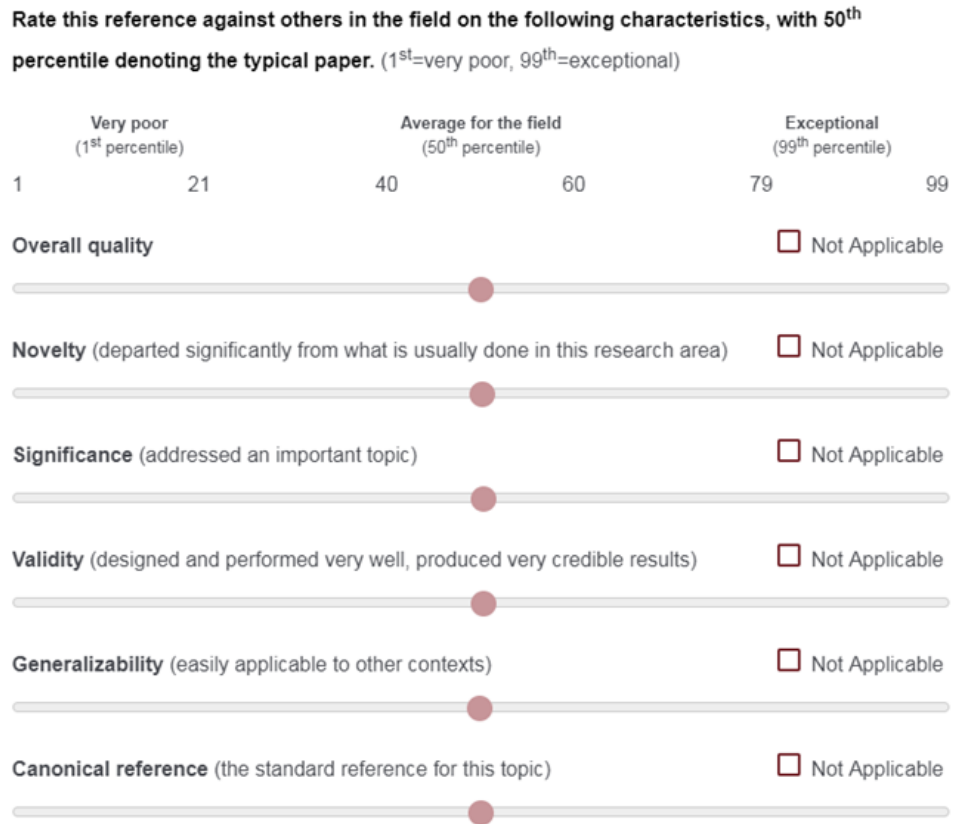

Figure A4: Panel of questions about perceived quality of the reference. The attribute in the last position was randomized to be “Canonical” or “Prominent.” Data from this last position is not included in the present analyses due to its indirect relationship with quality, but is available from the authors upon request.

How much expertise do you have in the topic(s) of this reference?

- Very high expertise (inside my core research area)
 - High expertise
 - Moderate expertise (at the boundary of my research area)
 - Some expertise
 - Very little expertise (outside my research area)
 - Not sure
-

How did you (or the co-author who added this reference) first learn about this reference?

(Mark all that apply)

- Self-citation
- Know the author personally
- Recommended by a colleague
- Database search (e.g. Google Scholar)
- Saw in a list of references of another paper
- Saw in a conference, presentation, or class
- Not sure
- Other. Please explain

When did you (or the co-author who added this reference) first learn about this reference?

- Before the project started
- During the project's *early* stages (e.g. design, data collection)
- During the project's *middle* stages (e.g. analysis)
- During the project's *late* stages (e.g. drafting the manuscript)
- During review/publication process
- Not sure

Figure A5: Questions about respondent's expertise in the topic(s) of the reference, and how and when the respondent first learned about the reference.

Appendix B. Response Analysis

Disciplines

Response rates were measured by clicks on the personalized survey link. Rates varied substantially across disciplines. The lowest response rate came from oncology (12.9%) and the highest (34.1%)

from history and philosophy of science. The number of completed responses and response rates by discipline are displayed in Figure B1.

Figure B1: Response counts and response rates by discipline. Each response, if filled out completely, provides data on two references. The dotted line shows the mean response rate.

Discipline	Responses on Influence & Knowledge
Economics	1078
Psychology	1096
Biochemistry & Molecular Biology	1060
Applied Physics	864
Physical Chemistry	1361
Pharmacology & Pharmacy	834
Energy & Fuels	1419
Engineering, Electrical & Electronic	688
Immunology	622
Linguistics	421
Endocrinology & Metabolism	589
Oncology	701
Nanoscience & Nanotechnology	497
Telecommunications	569
History and Philosophy of Science	209

Table B1: Responses that included data on ‘Influence’ and ‘Knowledge’. Degree of survey completion varied with some respondents failing to answer certain questions. Responses to questions concerned with Influence and Knowledge represented in this table are included in the results reported in the paper.

Appendix C. Document Embedding

Sample: We used the Gensim implementation of the Doc2Vec algorithm to generate document vector representations of source and target papers in our sample. All papers in our evaluation sample are papers our respondents cited. In order to render the semantic space in such a way as to capture the search space of respondents when selecting papers to read and cite, we gathered a 10% sample of all papers published in each of the years between 2010 and 2015. From this pool, we drew a 10% random sample with replacement of papers. As a result, our embedding space contains 543,936 documents. Each vector in the space represents a document’s ‘title + abstract’.

Hyper-parameterization:

min_count = 10, dm = 0, dbow_words = 0, window = 10, workers = number_of_workers, sample = 0.00001, negative = 5, vector_size = 300

Similarity Metric:

We use cosine similarity between document vectors as a measure of the semantic similarity between documents. Cosine similarity is calculated in the following way:

$$\text{similarity}(A, B) = \frac{A \cdot B}{\|A\| \|B\|} = \frac{\sum_{i=1}^n A_i \times B_i}{\sqrt{\sum_{i=1}^n A_i^2} \times \sqrt{\sum_{i=1}^n B_i^2}}$$

Where vectors A and B are source and target document vectors and values closer to 1 represent more similar documents.

Similarity between documents in our corpus are right skewed (Figure C1), meaning that most citations are very similar to the papers in which they are cited (which we would expect). While we find that more intellectually distant works confer greater influence, we observe the obvious: one cannot cite random papers. As a result, seemingly small movements in the direction of similarity or dissimilarity result in meaningfully large deviations from the mean.

Figure C1: Density plot of cosine similarities in our sample.

As an added validation of our embedding, we hand evaluated the 20 most similar and 20 least similar document pairs to see that the comparisons were reasonable.

Appendix D. Influence, Knowledge & Source

Respondents were asked how they found the papers that they surveyed them about. The options are represented in Figure D1, below.

How did you (or the co-author who added this reference) first learn about this reference?
(Mark all that apply)

- Self-citation
- Know the author personally
- Recommended by a colleague
- Database search (e.g. Google Scholar)
- Saw in a list of references of another paper
- Saw in a conference, presentation, or class
- Not sure
- Other. Please explain

Figure D1: Survey question recording responses on how respondents first learned of the references.

	Know personally	Database search	Another paper	colleague	presentatio n	Not sure	other
count	12149	12149	12149	12149	12149	12149	12149
mean	0.14	0.64	0.25	0.10	0.05	0.04	0.07
std	0.35	0.48	0.43	0.30	0.23	0.20	0.25
min	0	0	0	0	0	0	0
0.25	0	0	0	0	0	0	0
0.5	0	1	0	0	0	0	0
0.75	0	1	0	0	0	0	0
max	1	1	1	1	1	1	1

Table D1: Summary statistics for how respondents found the papers they cited

We then regressed intellectual influence and knowledge of each paper on the distinct pathways through which an author found that paper using both linear mixed models and ordinal logistic regressions to quantify the relationship source and influence. Coefficients are detailed in Tables D2 and D3 and are consistent with the correlations presented in Figure 1. The structure of the linear model is:

$$\mathbf{influence}_{ij} = \alpha_i + \beta \mathbf{source} + \epsilon_{ij}$$

We were unable to analyze these with a fixed author effects model because not enough respondents answered the question about provenance for both papers. Nevertheless, our random effects models suggest that across the distribution of respondents, influence and knowledge were most strongly associated with knowing the author personally, learning of the paper through a presentation and receiving it from a colleague, respectively.

	<i>Dependent variable:</i>	
	influence (1)	knowledge (2)
know_personally	0.351*** (0.030)	0.672*** (0.030)
colleague	0.281*** (0.033)	0.142*** (0.034)
presentation	0.317*** (0.043)	0.367*** (0.043)
another_paper	0.141*** (0.023)	0.086*** (0.024)
database	0.038 (0.025)	-0.009 (0.025)
not_sure	-0.176*** (0.052)	-0.441*** (0.052)
other	0.109*** (0.041)	0.331*** (0.041)
Constant	2.322*** (0.026)	2.778*** (0.026)
Observations	12,149	12,128
R ²	0.031	0.077
Adjusted R ²	0.031	0.076
Residual Std. Error	1.035 (df = 12141)	1.044 (df = 12120)
F Statistic	56.255*** (df = 7; 12141)	143.627*** (df = 7; 12120)
<i>Note:</i>	* p<0.1; ** p<0.05; *** p<0.01	

Table D3: Linear regression demonstrating the effect that various channels through which authors found the focal papers have on influence and knowledge.

Appendix E. Influence, Knowledge & Distance

Finally, we evaluate the effect of geographic distance on influence and on knowledge. We began by geo-coding all publication data. The Clarivate Analytics *Web of Science* database contains departmental street address strings for publication authors. We extracted these addresses for the corresponding author of source (our survey respondent) and target papers. We fed these addresses into the Google Maps API to retrieve latitude and longitude markers for each. We calculated the geographic distance between source and target paper using the python Geopy geodesic distance function. This yields a distance delta between source and target paper measured in km.

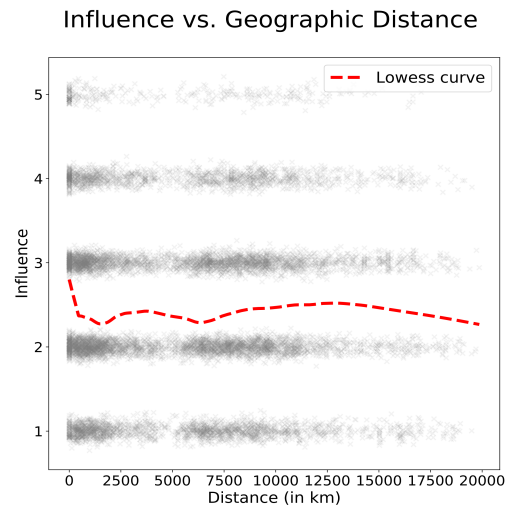

Figure E1: Lowess regression of the effect of geographic distance on influence.

Figure E2: Lowess regression of the effect of geographic distance on knowledge

The immediate and severe drop-off in influence and knowledge around 0 km in Figures E1 and E2 led us to segment distance differently. We extracted the following variables from the geocoded addresses:

same_author_dept_new: indicator variable for whether the corresponding authors share a department.

same_author_institution: indicator variable for whether the corresponding authors share an institution.

same_city_new: indicator variable for whether the corresponding authors share a city.

same_country_new: indicator variable for whether the corresponding authors share a country.

We used the following variable to encode the cosine similarity between source and target papers:

document_similarity: absolute value of the cosine similarity between source and target.

We use linear mixed models to quantify the relationship between a reference's distances (geographic and intellectual) from its target and its influence on the corresponding author's knowledge of it and its influence on research choices. Author-fixed effects enable us control for all (stable) differences between authors, including their fields. This approach accounts for the possibility that the composition of authors varies significantly across the citation distribution of references. For example, authors may have different standards for "influence." We use the following specification for influence and similarly for knowledge:

$$\text{influence}_{ij} = \alpha_i + \beta_0 \text{distance} + \epsilon_{ij}$$

Indices i and j , enumerate authors and references, respectively. The author fixed effects α_i denote author-specific intercepts. Estimates from regressions of this form are shown in the following tables.

	<i>Dependent variable:</i>	
	influence (1)	knowledge (2)
same_author_institution	0.682*** (0.079)	0.919*** (0.077)
Observations	12,309	12,285
R ²	0.015	0.029
Adjusted R ²	-1.466	-1.435
F Statistic	74.545*** (df = 1; 4916)	144.122*** (df = 1; 4900)
<i>Note:</i>	+ p<0.1; * p<0.05; ** p<0.01; *** p<0.001	

Table E1: Model of influence and knowledge as a function of source and target papers sharing an institution with author fixed-effects.

Table E1 shows the effect of sharing an institution on how much an author is influenced by the paper they cite and how well they know the content of that paper. Sharing and institution increases influence by 13.6% and increases knowledge by 18.4% (p<0.001).

	<i>Dependent variable:</i>	
	influence (1)	knowledge (2)
document_similarity	-0.578*** (0.152)	-0.420** (0.148)
Observations	12,309	12,285
R ²	0.003	0.002
Adjusted R ²	-1.496	-1.503
F Statistic	14.398*** (df = 1; 4916)	8.070** (df = 1; 4900)
<i>Note:</i>	+ p<0.1; * p<0.05; ** p<0.01; *** p<0.001	

Table E2: Model of influence and knowledge as a function of cosine similarity between source and target papers.

Table E2 shows the effect on influence and knowledge as papers become more similar. Both influence and knowledge are negatively affected by document similarity moving from maximally dissimilar to maximally similar by 11.6% ($p < 0.001$) and 8.4% ($p < 0.01$) respectively.

Putting these two regressions together, we model the effect and interaction of sharing an institution and increasing document similarity on influence and knowledge:

$$\text{influence}_{ij} = \alpha_i + \beta_0 \text{ same author institution} + \beta_1 \text{ document similarity} + \beta_3 (\text{same author institution} * \text{document similarity}) + \epsilon_{ij}$$

$$\text{knowledge}_{ij} = \alpha_i + \beta_0 \text{ same author institution} + \beta_1 \text{ document similarity} + \beta_3 (\text{same author institution} * \text{document similarity}) + \epsilon_{ij}$$

We observe that both within and across individual scientists, being at the same institution with the author of research that is maximally different from your own is associated with an increase in its likelihood of influence by more than 50% —26% linked to being at the same institution, 8% linked to being dissimilar in content, and nearly 18% linked to both being at the same institution *and* having dissimilar content. Moreover, being at the same institution and doing apparently unrelated research is associated with an increase in the likelihood that you have intimate familiarity with the work by 24%

	<i>Dependent variable:</i>	
	influence (1)	knowledge (2)
same_author_institution	1.344 ^{***} (0.266)	0.878 ^{***} (0.262)
document_similarity	-0.411 ^{**} (0.155)	-0.314 [*] (0.149)
same_author_institution:document_similarity	-0.884 ^{**} (0.330)	0.039 (0.325)
Observations	12,309	12,285
R ²	0.019	0.029
Adjusted R ²	-1.458	-1.434
F Statistic	30.916 ^{***} (df = 3; 4914)	49.571 ^{***} (df = 3; 4898)
<i>Note:</i>	+ p<0.1; * p<0.05; ** p<0.01; *** p<0.001	

Table E3: Effect and interaction effect of sharing an institution and increasing document similarity on influence and knowledge.
