Abstract

This chapter reviews what is known about how leisure contributes to subjective well-being (SWB). We review evidence documenting the importance of leisure for SWB and point to psychological need fulfillment as the main mechanism through which leisure promotes well-being. We discuss why individuals often do not fully experience the beneficial effects of leisure, focusing on intrapersonal, interpersonal, and structural constraints to leisure participation, and review differences in the degree and type of constraints experienced by different demographic groups. Finally, we review research on the cognitive and behavioral strategies individuals employ to overcome leisure constraints, and highlight the need to understand how societal and institutional policies influence leisure participation and quality. Throughout, we identify important questions for future research.

Keywords: Leisure, Subjective well-being, Leisure constraints

The role leisure plays in facilitating well-being is a timeless topic. For many, leisure has been regarded as essential for a satisfying life. The ancient Greek philosopher Aristotle wrote about the centrality of leisure for a satisfying life, emphasizing that—unlike work—leisure activities are particularly worthwhile because they are done for their own sake (trans. 1980). Echoing these ideas, the 19th to 20th century playwright George Bernard Shaw (1971) commented that "leisure…is not idleness. It is not even a luxury: it is a necessity, and a necessity of first importance." More recently, the German philosopher Josef Pieper—in his critique of the culture of overwork and busyness (1952)—celebrated leisure as an essential element of a happy life and a necessary escape from the busyness of the working world. Yet, for others, leisure is regarded as an aspect of life that must be sacrificed to achieve higher, more useful ends or as a luxury that must be forgone until retirement.

On balance, however, people do value leisure and to consider it important for a satisfying life. In fact, in a recently nationally representative survey of the U.S., 43% of working adults said that leisure is very important to their lives—a number slightly greater than the 38% who considered work very important to their lives (World Values Survey, 2016). Yet, while people value leisure and while leisure is an ideal context for engaging in activities to promote well-being, people often do not use their leisure to engage in the types of activities that are most conducive to promoting well-being. In fact, recent U.S. nationally representative time use data showed that people spend over 50% of their free time watching television—an activity that is likely very limited in its potential for psychological need fulfillment—and very little time pursuing activities that are likely to fulfill a wider range of social needs such as social activities (13% of free time) and sports (6% of free time; Bureau of Labor Statistics, 2017). Together, these features of leisure —that it is commonly highly valued for a satisfying life yet seemingly not commonly utilized to promote well-being—bring it to the forefront as a domain that is potentially very important for promoting individual and societal well-being (Kuykendall, Tay, & Ng, 2015).

With these broader issues in mind, the current chapter reviews the psychological literature on the role leisure plays in promoting well-being. First, we define leisure and important aspects of leisure (i.e., leisure engagement, leisure satisfaction). Then, drawing on bottom-up perspectives on SWB, we explain whether and when leisure satisfaction contributes to SWB and review the available evidence. Next, we introduce psychological need fulfillment as the main mechanism through which leisure influences SWB, focusing on evidence that leisure promotes SWB when leisure activities fulfill a broad range of psychological needs and when leisure is used to compensate for needs and values that are unmet by other life domains. Following the evidence for the role leisure plays in facilitating SWB, we then discuss what is known about the intrapersonal, interpersonal, and structural constraints that prevent people from engaging in and experiencing high-quality leisure, the constraints that are experienced by specific demographic groups, and the processes through which people attempt to overcome those constraints. In each section, we identify important questions for future research.

Defining Leisure

In conceptualizing leisure, researchers distinguish between leisure engagement (also called leisure participation) and leisure satisfaction. Leisure engagement refers to the extent to which people participate in leisure and is measured based on time spent in leisure or the breadth and/or frequency of participation in leisure activities. Within measures of leisure engagement, researchers distinguish between *residual* definitions and *experiential* definitions of leisure (Haworth & Veal, 2004). Residual definitions define leisure as all activities other than paid work or other obligatory activities. In contrast, experiential definitions of leisure define leisure based on characteristic experiential features. The experiential approach is exemplified in Neulinger's (1981) work on pure leisure, which defines pure leisure as activities that are freely chosen and intrinsically motivated. Leisure satisfaction refers to the degree to which individuals derive enjoyment or satisfaction from their leisure activities.

Why Leisure Influences Well-Being

Bottom-up models of well-being have been commonly used to explain how and when leisure influences SWB. Bottom-up models posits that individuals judge their overall life satisfaction based on their satisfaction in specific life domains, with the greatest weight given to the most valued domains. While the bottom-up mechanism is not the only mechanism linking domain satisfaction to SWB, it has been supported by a wide range of empirical findings (see Schimmack, 2008 for a review) and specifically as applied to leisure with meta-analytic findings on the relationship between leisure satisfaction and subjective well-being (Kuykendall et al., 2015). In the bottom-up model, leisure satisfaction (rather than leisure engagement) most proximally influences SWB, with leisure engagement being an important antecedent of leisure satisfaction (Kuykendall et al., 2015; Newman, Tay, & Diener, 2014).

Evidence for bottom-up effects of leisure on SWB. This bottom-up account suggests that improving the satisfaction with leisure is important for improving overall SWB. Supporting this prediction, a recent meta-analysis of experimental studies showed that interventions targeting the quality of leisure experiences improves SWB, providing further support for bottom-up mechanisms as applied to leisure, albeit limited generalizability, as the samples were largely older adults (Kuykendall et al., 2015).

In addition to directly influencing well-being, leisure experiences can also indirectly impact well-being through bottom-up mechanisms by affecting satisfaction with other domains (e.g., job satisfaction, family satisfaction). The few rigorous studies that have examined this mechanism have provided initial support for this mechanism for some types of leisure engagement. For instance, in a short-term (two-week) longitudinal study of Canadian university employees, Hecht & Boies (2009) found that volunteering (but not sports activities or membership in nonwork organizations) was associated with increased job satisfaction, career satisfaction, and life satisfaction. One study has also shown positive effects of volunteering on work-domain well-being. In a two-week daily diary study of working adults, Mojza, Sonnentag, & Bornemann (2011) found that the amount of time spent volunteering was associated with lower levels of negative affect (but not positive affect) during the following workday.

One longitudinal study has also examined how leisure experiences impact marital satisfaction. Crawford, Jackson, & Godbey (1991) used a 13-year longitudinal study to examine whether marital leisure patterns influence marital satisfaction or whether marital satisfaction influences marital leisure patterns and found support for a bi-directional relationship. That is, low-quality leisure patterns (i.e., engaging in leisure activities that the husband enjoyed but the wife did not) both influenced—and were influenced by—marital satisfaction. In sum, this research establishes that participation in leisure activities can influence the quality of one's work and family experiences, though the effects may depend on certain features of leisure activities (e.g., type of activity, enjoyment of activity). Future research should focus on identifying the types of activities that are most conducive to positive effects on the quality of others domains and the mechanisms responsible for these positive effects, taking into account that the most conducive activities may vary depending on features of the job and the person.

Are the effects of leisure moderated by its subjective value? Regarding the question of when leisure most strongly impacts well-being, bottom-up theory—specifically, the values-as-moderator hypothesis—predicts that leisure satisfaction will have a stronger impact on SWB to the extent that it is a valued life domain. While the values-as-moderator hypothesis was supported initially (Oishi, Diener, Suh, & Lucas, 1999), it has recently been suggested that the values-as-moderator effect may operate differently for different life domains. In a recent study examining this issue, some domain satisfactions were important for well-being only if they were valued, whereas others were important regardless of whether they were valued (Tiefenbach & Kohlbacher, 2015).

One implication of this research is that the values-as-moderator hypotheses may need to be assessed for specific domains. Regarding the domain of leisure, very few—if any—studies have examined whether the impact of leisure on well-being is moderated by how strongly leisure is valued. However, in research recently conducted in our lab, we found that leisure role salience—a concept very similar to how strongly

leisure is valued—did not moderate the effects of leisure satisfaction on workers' SWB (Kuykendall et al., 2017). That is, leisure satisfaction was generally important for workers' SWB regardless of how strongly it was valued. While additional research is needed to understand why this pattern emerged, one possibility is that individuals are not fully aware of the benefits of leisure. That is, leisure may provide certain unique benefits (e.g., relaxation, autonomy) that cannot be provided—and are often obstructed—by other, more subjectively valued domains such as work and family, yet individuals may fail to fully recognize or subjectively value these benefits. Thus, satisfying leisure may be important for predicting well-being even if individuals are unaware of its value.

While very little research has explicitly assessed the values-as-moderator hypothesis for the effects of leisure on well-being, a substantial body of research has indirectly addressed these questions by assessing whether leisure is more strongly associated with SWB in specific populations that are thought to place greater value on leisure (e.g., people in specific life stages). Specifically, developmental life stage theorists posit that well-being hinges on pursuing and achieving progress with respect to one's central life tasks (Sanderson & Cantor, 1999; Super, 1990). In working adulthood, these central life tasks tend to revolve around work and family, with leisure being less important. However, as one ages and has fewer work and family-related central tasks, leisure should become increasingly important. As such, comparing the impact of leisure on well-being for different life stages provides an indirect test of the values-as-moderator hypothesis. A recent meta-analysis comparing the effects in cross-sectional studies did find support for these predictions, revealing that leisure satisfaction is more strongly related to SWB for retired individuals than for workers (Kuykendall et al., 2015). However, it is worth noting that—even though the effect was stronger for retired individuals than for workers—the relationship between leisure satisfaction and life satisfaction did remain significant for workers, suggesting that leisure satisfaction is still important for workers' well-being, albeit less important than it is for retired individuals.

In addition to life stage, another demographic factor thought to the impact the value of leisure is cultural values. Specifically, Schwartz (1999) has suggested that leisure is less important in societies where mastery values and hierarchy values are important, and leisure is more important in societies in which affective autonomy values, egalitarian values, harmony values, and conservatism values are important. These predictions have been supported indirectly by research showing that individuals in European countries (with values corresponding to those that should predict valuing leisure) value work less and work fewer hours (Schwartz, 1999; Organisation for Economic Cooperation and Development, 2009) and—by extension—value leisure more. However, in a recent meta-analysis, the effect of leisure satisfaction on well-being was not significantly different across European and U.S. samples (Kuykendall et al., 2015), though the European sample included more worker studies than the U.S. sample, preventing a precise and more conclusive test of the hypothesis that teased apart the effects of life stage and cultural values.

In sum, while the main prediction of bottom-up theories is strongly supported for leisure—namely, that leisure satisfaction impacts overall SWB—the prediction that the size of the effect varies based on how important leisure is has not yet been fully resolved, with some research showing that leisure satisfaction is important for well-being regardless of whether it is valued and some research showing—albeit indirectly—that it is more important in life stages when it is likely more strongly valued.

If future research replicates the finding that leisure is important for well-being regardless of the extent to which it is valued, it will be important to understand why this is the case. Specifically, research should consider the possibility that leisure provides unique benefits (i.e., autonomy, rest) that are typically not sufficiently afforded by other life domains. Additionally, research could consider the possibility that seeking satisfaction and need fulfillment across numerous life domains is more beneficial than seeking concentrated need fulfillment in one domain (e.g., seeking mastery only at work)—an idea that has been raised recently in the literature on balanced need satisfaction (Milyavskaya et al., 2009). Addressing these questions would help further clarify the types of leisure participation that are most likely to enhance SWB.

What Facilitates High-Quality Leisure?

Given that leisure is generally very malleable compared to other life domains (i.e., individuals can typically choose what to do with their leisure time), that leisure satisfaction predicts well-being across a range of life stages and cultures, and that the effects of leisure satisfaction on well-being have been supported across cross-sectional, longitudinal, and experimental studies, leisure satisfaction is likely an important target for enhancing well-being. Accordingly, it is important to understand the experiential aspects of leisure that are most likely to facilitate satisfaction and enhance SWB. In this section, we highlight psychological need fulfillment as the main mechanism through which leisure influences SWB.

Need-based perspectives. Needs-based perspectives posit that leisure activities are most likely to be satisfying and to facilitate SWB when they fulfill fundamental psychological needs. Integrating needs posited by prominent needs-based theories, Newman et al. (2014) recently proposed the DRAMMA model

to delineate how leisure facilitates SWB through specific needs. Drawing from a number of needs-based theories, their framework includes Detachment-Recovery, Autonomy, Meaning, Mastery, and Affiliation (DRAMMA) as the distinct needs through which leisure engagement can facilitate need fulfillment and subsequently overall SWB. In what follows, we provide an overview of each of these needs, review the evidence linking fulfillment of these needs through leisure to SWB, and discuss any known interventions that help people fulfill each need through leisure.

Detachment-recovery. Detachment occurs when people refrain from job-related activities and thoughts during nonwork time (Sonnentag & Fritz, 2015). Detachment is an important prerequisite for facilitating recovery, which is the "process during which individual functional systems that have been called upon during a stressful experience return to their prestressor levels" (p. 205; Sonnentag & Fritz, 2007). Detachment and recovery are necessary for protecting well-being on a daily basis from the short-term consequences of exposure to demands and stressors and from the long-term consequences of cumulative exposure to stressors without sufficient rest. After periods of exerting effort to address demands and stressors, individuals feel exhausted and desire a break from continued effort (Meijman & Mulder, 1998). This experience has been called the need for recovery (Sonnentag & Zijlstra, 2006). Without restorative breaks that facilitate detachment and recovery, SWB suffers (Fritz, Sonnentag, Spector, & McInroe, 2010; Siltaloppi, Kinnunen, & Feldt, 2009; Sonnentag & Fritz, 2007).

Detachment and recovery are increasingly difficult for working adults, as many workers feel pressure to respond to work-related emails during non-work hours—a phenomenon recently coined "telepressure" (Barber & Santuzzi, 2015). Research has shown that high levels of smartphone usage during nonwork time impair psychological detachment and subsequently harm well-being (Derks, van Mierlo, & Schmitz, 2014). Learning to detach from demands during the evening is difficult, but possible. In the first attempt at a psychological detachment intervention, an intervention designed to facilitate recovery experience during leisure (i.e., detachment, relaxation, mastery, and control) educated participants about the benefits of detachment, presented different strategies for detaching from work (e.g., engaging in absorbing activities, using "transition rituals" to separate work and nonwork time), and asked participants to set personal goals for promoting better detachment (Hahn, Binnewies, Sonnentag, & Mojza, 2011). This intervention resulted in improved psychological detachment compared to the experimental group one week and three weeks after the training and decreased state negative affect three weeks after the training. Other approaches to improve psychological detachment have used mindfulness interventions and have yielded inconsistent results with one study effectively increasing psychological detachment (Michel, Bosch, & Rexroth, 2014) and the other not (Hülsheger, Feinholdt, & Nübold, 2015), highlighting the need for additional research about whether and when mindfulness interventions can help improve detachment.

Given that the types of activities that most effectively facilitate detachment likely depend on the person and his or her job characteristics, interventions like the Hahn et al. (2011) intervention that educate people about how different activities might facilitate detachment and encourage individuals to reflect on and set goals for activities that would be most conducive will likely be more effective than encouraging specific types of leisure activities. To support the design and refinement of such interventions, future research is needed to determine the personal and contextual factors that impact the effectiveness of different types of activities for facilitating detachment. For instance, people with ruminative tendencies may benefit more from effortful and absorbing activities than from more relaxing activities that don't necessarily demand one's full attention. Additionally, in line with the recent emphasis on well-being interventions addressing both the person and organization (Hammer & Sauter, 2013), interventions should be expanded to include what organizations, not just individuals, can do to facilitate detachment, as work-related variables such as time pressure and long work hours are associated with poor detachment (see review in Sonnentag & Fritz, 2015).

Autonomy. Autonomy refers to the sense that one's actions are freely chosen and reflect what one wants to do. Autonomy and similar concepts (e.g., control, perceived freedom, autonomous motivation) are highlighted as essential psychological needs in numerous theoretical models of well-being (e.g., Ryan & Deci, 2000; Ryff & Keyes, 1995; Su, Tay, & Diener, 2014). Because leisure is a domain that is typically characterized by greater freedom of choice than other life domains (e.g., work and household activities; Graef, Csikszentmihalyi, & Gianinno, 1983), it is an ideal context for promoting autonomy and thereby contributing to well-being. Accordingly, autonomy (or control) plays a central role in several leisure frameworks that explain the importance of leisure for well-being (e.g., the leisure and well-being model; Carruthers & Hood, 2007; the recovery experiences framework; Sonnentag & Fritz, 2007). In fact, several researchers consider autonomy (or related concepts) to be a defining feature of leisure (Iso-Ahola, 1999; Kelly, 1972; Neulinger, 1981). While different theories provide different reasons for why autonomy is important for subjective well-being, most explanations emphasize that people have desire to feel that their lives are predictable and within their control and that their actions are a reflection of their values and

desires rather than controlled or coerced by external influences. When this sense is threatened, well-being is diminished. Although autonomy is generally higher in leisure than in other life domains (Graef et al., 1983), individuals do differ in the extent to which their leisure activities fulfill their needs for autonomy, and those who experience greater autonomy have higher levels of well-being (Derous & Ryan, 2008; Sonnentag & Fritz, 2007).

Given the importance of leisure autonomy for well-being and the unique opportunity leisure affords for promoting well-being, interventions designed to facilitate leisure autonomy are likely very important for facilitating well-being, particularly when experiences in other life domains (e.g., work and family) are less malleable. In the previously discussed Hahn et al. (2011) intervention, one module focused on leisure control and involved educating participants about its importance for well-being, facilitating a reflection to help participants identify the activities during which they experience control, deciding on changes to make to their leisure, and providing goal-setting, implementation intention, and time management strategies for accomplishing changes. This intervention resulted in improved control during leisure when comparing the experimental group to the control group one week and three weeks after the training and decreased state negative affect three weeks after the training. Future interventions should continue to build upon and refine this model.

Mastery. Needs for mastery are fulfilled when individuals have opportunities to utilize or increase their skills or learn something new. Mastery and similar concepts such as accomplishment and competence are needs emphasized in numerous theories of well-being (i.e., Csikszentmihalyi, 1990; Diener, 1984; Ryan & Deci, 2000; Ryff & Keyes, 1995; Seligman, 2011) and also in leisure-specific well-being frameworks (i.e., Sonnentag & Fritz, 2007). Mastery plays a central role in the literature on serious leisure (Stebbins, 1992; 1997)—a particular type of leisure defined as "the systematic pursuit of an amateur, hobbyist, or volunteer activity sufficiently substantial and interesting for participants to find a career there in the acquisition and expression of a combination of its special skills, knowledge, and experience" (p. 3, Stebbins, 1992). Stebbins suggests that serious leisure promotes life satisfaction and attributes its effects on well-being largely to sense of skill development and accomplishment that can be derived from serious leisure pursuits.

Empirical research supports these predictions, as experience-sampling studies have shown that engaging in leisure activities that facilitate mastery is associated with well-being (Sonnentag & Fritz, 2007), and daily mastery experiences in leisure predict high levels of momentary well-being (Sonnentag, Binnewies, & Mojza, 2008). Further, the pursuit of serious leisure, which has a large mastery component, is generally positively associated with leisure satisfaction and life satisfaction—a finding that has been replicated across a number of specific populations (e.g., older adult volunteers in Taiwan: Chen, 2014; older adult competitive athletes in the United States: Heo, Lee, McCormick, & Pedersen, 2010; Heo, Stebbins, Kim, & Lee, 2013; participants in arts groups in a Chinese university: Liu, 2014; recreational event volunteers in Taiwan: Pi, Lin, Chen, Chiu, & Chen, 2014). However, future research is needed on the potential negative well-being consequences of sustained serious leisure, given that it may give rise to role conflicts (Stebbins, 1997).

In the Hahn et al. (2011) intervention, the module focused on leisure mastery educated participants about the importance of mastery for well-being, facilitated a reflection to help participants identify the types of challenging leisure activity that could provide mastery, provided a short exercise to boost self-efficacy for engaging in challenging activities, and asked participants to identify changes to make to improve their leisure. This intervention resulted in improved leisure mastery one week but not three weeks after the training and decreased state negative affect three weeks after the training. Future interventions should continue to build upon and refine this model to determine ways to facilitate longer lasting changes in leisure mastery.

Meaning. Another need that is frequently emphasized in theories of well-being is meaning, which is also sometimes referred to as purpose in life. Meaning has been emphasized as an important psychological need for fulfilling well-being in general well-being theories (Diener et al., 2009; Ryff & Keyes, 1995; Seligman, 2011) as well as leisure-specific perspectives (Carruthers & Hood, 2007; Iwasaki, 2008), and is an important antecedent of life satisfaction, especially when affect is non-optimal (Diener, Fujita, Tay, & Biswas-Diener, 2012). Specifically, Iwasaki (2008) has focused on leisure as a key domain of life for meaning-making and has begun to investigate the common ways that meaning in life can be facilitated through leisure activities (see Iwasaki, 2016 for a review). Iwasaki's research has suggested that a variety of leisure activities can be used for meaning-making, and has identified several specific ways that people engage in meaning-making through leisure, including cultivating a positive group or individual identity, engaging in creative expression, cultivating connectedness with others or nature, experiencing harmony/balance that is not necessarily available through other demanding domains, and experiencing growth/transformation. Similarly, Petrou, Bakker, & van den Heuvel (2017) found that weekly leisure

crafting, defined as "the proactive pursuit of leisure activities targeted at goal setting, human connection, learning, and personal development" (p. 129), was associated with meaning-making in a sample of Dutch employees.

Affiliation. The need for social connection—often called affiliation or relatedness—is emphasized in nearly all theoretical models of well-being (Diener et al., 2009; Ryff & Keyes, 1995; Seligman, 2011). Because many leisure activities are social, leisure is an important context for fulfilling the need for affiliation and subsequently enhancing well-being. As expected, social leisure activities are positively associated with well-being (Kelly, Steinkamp, & Kelly, 1987; Reyes-Garcia et al., 2009), including in an experience-sampling studies of working adults (Sonnentag, 2001; Sonnentag et al., 2008; Sonnentag & Ziljstra, 2006) and a short-term longitudinal study of working adults (Fritz & Sonnentag, 2005).

Compensatory benefits of fulfilling needs through leisure. While much research focuses on the ways that leisure directly promotes SWB, other research focuses on how leisure activities can protect well-being when used to compensate for the lack of need fulfillment in other life domains. Because people tend to have high levels of freedom to choose their leisure activities, leisure can be used as an opportunity to fulfill needs and desires that are not met in other domains such as work. Such compensatory use of leisure should protect well-being in general and possibly also in the domain for which need fulfillment is obstructed by substituting for need fulfillment in that domain (Heine, Proulx, & Vohs, 2006; Petrou & Bakker, 2016; Petrou et al., 2017; Vogel, Rodell, & Lynch, 2016; Vallerand, 2000).

Studies have shown that leisure activities are important for protecting well-being when those interests or values are not congruent with one's job. For instance, in a study of working professionals, Melamed, Meir, and Samson (1995) found that engaging in leisure activities was beneficial to a wide range of well-being indicators, particularly for workers whose jobs were not congruent with their interests. More recently, in a sample of working adults from a variety of industries, Vogel et al. (2016) found that involvement in leisure activities lessens the negative effects of working in an organization that has values incongruent with the subjective quality of one's work experiences. Similarly, Petrou and Bakker (2016) found that weekly leisure crafting (i.e., "the proactive pursuit and enactment of leisure activities target at goal setting, human connection, learning, and personal development" p. 1) is most strongly related to weekly well-being when opportunities for job crafting are low. Along the same lines, within counseling psychology, leisure-based interventions have been suggested for increasing the life satisfaction of individuals who are situationally constrained from leaving dissatisfying jobs (Hansen, Dik, & Zhou, 2008) and also for increasing the well-being of other special populations such as unemployed adults (Liptak, 1991), college students (Lengfelder, 1987), older adults (Munson & Munson, 1986), and individuals coping with mental health issues (Juniper, 2005).

While several theoretical models assume that people will adaptively seek need fulfillment in leisure for needs that are not met in other domains (Guest, 2002), inconsistent support for these compensatory models—as well as the prevalence of passive forms of leisure—raises doubts about how commonly people engage in these adaptive compensatory processes and highlights the need to understand the motivational processes that drive leisure decisions and to identify the processes and situational factors that would facilitate participation in activities that would compensate for needs that are insufficiently fulfilled by other domains (Petrou & Bakker, 2016; Petrou et al., 2017).

One question that emerges when considering the compensatory benefits of leisure is whether leisure activities that fulfill one's needs and values are important for well-being even if those needs and values are met by other domains. Research relevant to this issue has yielded mixed findings, with at least one study (Melamed et al., 1995) finding that engaging in leisure congruent with one's personality was associated with higher levels of well-being, even for workers with congruent jobs, and other studies have failed to find effects of leisure congruence on well-being for workers with congruent jobs (e.g., Kabanoff, 1980; Loscocco & Roschelle, 1991; Spreitzer & Snyder, 1987; Staines, 1980; Surber, 1983). Given these mixed results, future research is needed to resolve the issue of whether leisure need fulfillment benefits well-being even when needs are met in other important domains. On the one hand, for specific populations (e.g., "happy workaholics" who invest intensely in highly need-fulfilling jobs), engaging in activities that fulfill only a small subset of needs such as detachment and recovery, which are not fulfilled by work, may be the main benefit of leisure for well-being. Alternatively, balanced need satisfaction perspectives would suggest that seeking satisfaction and need fulfillment across numerous life domains is more beneficial than seeking concentrated need fulfillment in one domain (Milyavskaya et al., 2009). Given the mixed findings and divergent theoretical perspectives on this issue, future research is needed to untangle whether and when broad need fulfillment in leisure is important for well-being. That is, is broad need fulfillment in leisure important only when work does not fulfill a wide range of psychological needs, or would individuals benefit from broadly need-fulfilling leisure even when work fulfills a wide range of psychological needs?

Summary of need-based perspectives. In sum, research has shown that people have higher well-being when they engage in leisure activities that fulfill the needs for detachment-recovery, autonomy, meaning, mastery, and affiliation. While much research in this area has been cross-sectional, the longitudinal, experience-sampling, and experimental work conducted has also been largely supportive of the effects of need-fulfilling leisure on well-being. While fewer studies have focused on whether and how each of these needs uniquely relates to well-being, research in the general well-being literature has shown that needs tend to have an additive effect on well-being—that is, fulfillment of each need contributes beyond the fulfillment of other needs (Tay & Diener, 2011). Accordingly, the best way to optimize leisure with respect to promoting well-being may be to prioritize activities that fulfill multiple needs, particularly those needs that are not fulfilled through other domains. Unfortunately, however, this does not appear to be how people make leisure choices. Recent U.S. nationally representative time use data showed that people spend over 50% of their free time watching television—an activity that is likely very limited in its potential for need fulfillment—and spend very little time pursuing activities that are likely to fulfill a wider range of needs such as social activities (13% of free time) and sports (6% of free time; Bureau of Labor Statistics, 2017). These trends have been documented not only in the United States but also in all eighteen countries surveyed by the Organisation for Economic Cooperation and Development (2009). As such, increasing the amount of time people spend in leisure activities that are more broadly need-fulfilling and that fulfill needs that are obstructed by other domains may be an important target for enhancing societal well-being across the world. Future experimental research is needed to assess whether and for whom such approaches would be effective for enhancing well-being.

Future research should also examine whether leisure provides the opportunity for fulfillment of some needs that typically are not emphasized in general models of well-being. For instance, play is a psychological state that has been recently highlighted as essential for well-being but is not included in typical need-based models of well-being (Brown, 2009).

Barriers to Leisure Engagement and Satisfaction

Given the documented importance of leisure for well-being, a substantial body of research has focused on understanding the barriers to leisure engagement and satisfaction. In what follows, we review the most prominent model of leisure barriers—the hierarchical leisure constraints model. We review several contributions of this model, including its emphasis on the important types of leisure constraints, the ways people negotiation or overcome leisure constraints, and demographic differences in leisure constraints. We also briefly mention the literature on leisure affordances—factors that facilitate interest in leisure. Finally, we review research on barriers to leisure time physical activity—a specific type of leisure activity that received substantial attention due to its importance for health and well-being

Types of leisure constraints. Given the documented importance of leisure for well-being, a substantial body of research has focused on understanding the barriers to leisure engagement and satisfaction. Within this stream of research, the most prominent organizing framework has been the hierarchical leisure constraints model (Crawford et al., 1991; Crawford & Godbey, 1987; Godbey, Crawford, & Shen, 2010), which has focused on specifying the most common types of leisure constraints (i.e., factors that limited the desired level or quality of leisure participation) and understanding the process through which people negotiate or fail to negotiate these constraints. Their model specifies three types of leisure constraints. Intrapersonal constraints are internal states such as feelings of guilt or beliefs about one's capabilities that act as barriers to developing leisure interests. Interpersonal constraints are social factors such as a lack of activity partners or a spouse's leisure preferences that influence one's own preferences and the level of participation in one's preferred leisure activities. Structural constraints are contextual or environmental factors such as a lack of local recreational opportunities, lack of financial resources, or inflexible/highly demanding work schedules that interfere with participation in a preferred activity.

The hierarchical leisure constraints model posits that, of the three types of constraints, intrapersonal factors most strongly and proximally influence leisure interests and preferences, whereas structural constraints primarily influence the relationship between preferences and participation and interpersonal constraints influence both preferences and acting on preferences (Crawford et al., 1991). The model further specifies that encountering and negotiating leisure constraints should occur in a sequential fashion (Jackson, Crawford, & Godbey, 1992), with people first encountering intrapersonal constraints (and possibly also interpersonal constraints) and then experiencing structural constraints as salient primarily after intrapersonal barriers have been addressed and leisure preference have been formed. While the model has not been completely and consistently supported, the supportive evidence that does exist (e.g., Raymore, Godbey, & Crawford, 1994; Raymore, Godbey, Crawford, & von Eye, 1993) has sustained its prominence as the leading model of leisure constraint negotiation. Importantly, the hierarchical leisure constrains model has been influential in suggesting that a focus on structural constraints is likely to be effective only insofar

as preferences are formed, and such formation requires first overcoming intrapersonal (and often interpersonal) constraints.

Overcoming leisure constraints. More recently, researchers have also sought to understand the specific strategies individuals employ to negotiate or overcome leisure constraints. In some cases, when leisure constraints are sufficiently severe, people abandon the pursuit of a leisure activity or settle for low levels or quality of participation. Jackson et al. (1992) have suggested that abandonment of leisure interests is often a result of cognitive dissonance processes in which people devalue an activity when participating in it seems unfeasible. These processes can have positive or negative impacts on well-being. On the one hand, abandoning the activity and devaluing unattainable activities can help people to be more satisfied with the activities they can pursue (Wrosch, Scheier, Miller, Schulz, & Carver, 2003). However, in abandoning the activity, they may be prematurely foregoing other strategies that would allow them to retain the activity and thereby missing out on the benefits of the activity (Kleiber, Walker, & Mannell, 2011). For instance, abandoning one's interest in physically active leisure would likely come at a cost to health and well-being.

However, in other cases, even sometimes in cases where constraints are severe, people can overcome interpersonal or structural constraints that are preventing them from pursuing a preferred leisure activity (Kleiber et al., 2011). Both behavioral and cognitive negotiation strategies have proven useful for overcoming leisure constraints in ways that allow people to sustain participation in desired leisure activities. Behavioral strategies include actions individuals engage in to overcome leisure constraints. These actions can be directed toward the leisure activity or toward other aspects of life. Examples of leisure-directed behavioral strategies include choosing alternative sites for participating in leisure that are more affordable in order to overcome financial constraints or changing the timing of participation to overcome work-related or family-related barriers to participation. Examples of nonleisure-directed behavioral strategies include rearranging one's work schedule to better accommodate leisure participation or reducing other expenses to overcome financial leisure constraints (Lyu & Oh, 2015). Cognitive strategies include changes in the way one thinks about barriers to leisure participation. For instance, intrapersonal barriers related to competence may be overcome by persuading oneself that high levels of skills are not necessary for leisure participation or quality. Similarly, barriers related to guilt may be overcome by persuading oneself that leisure participation will help a person be a better employee or family member. Several studies have shown that people tend to use both strategies jointly (Jun & Kyle, 2011; Jackson & Rucks, 1995), though behavioral strategies are often used as the first option. Understanding when decisions to abandon leisure activities are adaptive or harmful to well-being and what factors drive these decisions is an important area for future research.

Demographic differences in leisure constraints. Another important contribution of the hierarchical leisure constraints model is the emphasis on demographic differences in leisure constraints, which has proven useful for guiding research on leisure constraints experienced by specific subpopulations. The model posits that social privilege influences the experience of leisure constraints and subsequently leisure participation and quality. Crawford et al. (1991) argued that individuals with lower income and education would experience more severe leisure constraints, and similar arguments have also been expanded to include women as a less privileged group. Supporting these predictions, studies have shown that leisure is more constrained (Jackson & Henderson, 1995) for women than for men, and has documented leisure constraints that are unique to women, particularly working mothers, such as intrapersonal constraints related to caring behaviors and a lack of sense of entitlement to leisure and structural constraints such as time scarcity and fewer opportunities to participate in sports (Shaw & Henderson, 2005). Research has also shown that individuals with lower levels of income and education experience overall higher levels of leisure constraints than do affluent and highly educated individuals (McCarville & Smale, 1993; Alexandris & Carroll, 1997; Raymore et al., 1994). Research in this framework has also considered leisure constraints for racial minorities (Shinew & Floyd, 2005) and immigrants (Stodolska & Yi-Kook, 2005).

While not necessarily under the scope of social privilege, research has also examined how leisure constraints differ across the life span (Jackson, 2000), highlighting that the leisure experiences of young people tend to be constrained by a lack of money, opportunities for participation, and participation partners. In contrast, in middle adulthood, the barriers that are typically present for young people decrease and time commitments become a salient barrier to leisure. For older adults, time commitments are typically no longer a barrier, but skills and isolation more commonly constrain leisure.

Moving forward, research on demographic differences in leisure constraints would likely benefit from understanding how national and local policies influence demographic differences in leisure constraints, seeking to identify any policies that alleviate leisure constraints—and enhance leisure participation and satisfaction—for disadvantaged or vulnerable populations.

Leisure affordances. While research on the causes of leisure engagement has focused primarily on

factors that impede participation, researchers have recently emphasized the need to focus on leisure affordances, defined as "the environmental conditions that elicit motivation (e.g., interest, enthusiasm, approach) in conjunction with felt needs" (p. 239, Kleiber, Wade, & Loucks-Atkinson, 2005). Emphasizing how positive motivational forces (e.g., enjoyment) work in conjunction with constraints and negotiation strategies to influence participation, Hubbard and Mannell (2001) tested multiple conceptual models and found that positive motivational components increase engagement in negotiation strategies and in leisure participation, and contribute uniquely to participation beyond the effects of constraints. These findings motivated subsequent research, which is still in very early stages, examining how structural and environmental conditions can elicit these positive motivational forces. Along these lines, future research should focus on understanding how communities and institutions can better design environments to elicit interest in beneficial leisure activities.

Barriers to leisure time physical activity. Within the literature on antecedents to leisure participation, one particular leisure activity that has received substantial attention is leisure time physical activity (LTPA)—a leisure activity that has been of particular interest because of its importance for health and well-being (Sofi, Capalbo, Cesari, Abbate, & Gensini, 2008; Wiese, Kuykendall, & Tay, 2017) and because the increasing prevalence of sedentary work makes leisure the most prominent context for pursuing physical activity (Church et al., 2011). Because physical activity is at lower than ideal levels for much of the U.S. population (National Center for Health Statistics, 2017), increasing LTPA is a major societal concern. Though much of the research on barriers to LTPA has been guided by the Theory of Planned Behavior (Ajzen, 1991)—an influential social psychological theory commonly used to explain health-promoting behaviors—rather than the hierarchical leisure constraints model, the findings can still be summarized based on intrapersonal, interpersonal, and structural factors.

In a recent systematic review of determinants of adults' physically active leisure, Wendel-Vos, Droomers, Kremers, Brug, & Van Lenthe (2007) found that the most important interpersonal predictors were having social support for leisure and having a companion for physical activity. Structural factors were also important, as availability of physical activity equipment was associated with vigorous physical activity/sports, and connectivity of trails was associated with active commuting. Yet, this systematic review was limited in that it focused exclusively on cross-sectional studies.

More recently, reviews have focused on barriers to physically active leisure using more rigorous studies, albeit in narrower populations. A more recent meta-analysis (Prince et al., 2016) that focused specifically on the determinants of physically active leisure of adult women based on prospective cohort studies—a much stronger design than cross-sectional designs—found evidence for both intrapersonal, interpersonal, and structural determinants. Intrapersonal factors that were most commonly and consistently associated with physically active leisure were intentions, perceived behavioral control, self-efficacy, self-rated health, and quality of life. The interpersonal factor most commonly negatively associated with physically active leisure was having children.

In a recent systematic review assessing the determinants of physical activity and exercise in healthy older adults, similar findings emerged. Specifically, change in exercise self-efficacy was associated with exercise (Koeneman, Verheijden, Chinapaw, & Hopman-Rock, 2011). The most important interpersonal determinants were social capital and spousal physical activity, and the most important environmental factor was the season of the year. As many of the factors shown to be associated with leisure time physical activity across these studies are modifiable, they serve as promising targets for enhancing physically active leisure.

In the literature on physically active leisure, the emphasis has been primarily on intrapersonal and interpersonal determinants, with less emphasis on environmental determinants. Specifically, one of the most salient needs for future research is papers that examine how policies (e.g., workplace policies such as subsidies for gym memberships, enforced breaks or governmental policies such as active commuting incentives) influence physically active leisure (Prince et al., 2016), as very few—if any—studies have examined how national or workplaces policies influence physically active leisure.

Conclusion

To summarize, while much research is needed to more fully understand the role leisure plays in promoting SWB, the current literature does suggest that leisure is important for well-being across a wide range of cultures and life stages and that leisure oriented toward fulfilling psychological needs and compensating for needs or values that are not fulfilled in other domains is particularly important for SWB. While a variety of intrapersonal, interpersonal, and structural constraints prevent people from being interested in and engaged in the types of leisure activities that would enhance their well-being, specific behavioral and cognitive strategies can be employed to help facilitate leisure engagement and leisure quality. Research has not yet identified the types of societal and institutional policies that can help promote high-quality leisure, and understanding these factors—and how to design interventions that remove both

personal and contextual barriers to high-quality leisure—should be an important priority moving forward.

Abstract

For decades, researchers and practitioners have theorized psychological disorder and health as opposite ends of a single continuum. We offer a more nuanced, data driven examination into the various ways that people with psychological disorders experience well-being. We review research on the positive emotions, meaning and purpose in life, and social relationships of people diagnosed with major depressive disorder, bipolar disorder, social anxiety disorder, schizophrenia, and trauma-related disorders. We also discuss when and how friends, family members, and caregivers of these people are adversely impacted in terms of their well-being. Throughout, we highlight important, often overlooked findings that not all people with mental illness are devoid of well-being. This review is meant to be illustrative as opposed to comprehensive, synthesizing existing knowledge and inspiring explorations of unclear or undiscovered territory.

Keywords: Well-being; positive emotions; meaning; purpose; social relationships

Well-being is associated with a broad range of positive outcomes, including strong work engagement, performance, creativity, strong social connections, effective coping and problem solving strategies, physical health, and life longevity (e.g., Diener, Pressman, Hunter, & Delgadillo-Chase, 2017; Lyubomirsky, King, & Diener 2005). By definition, people with mental disorders experience significant distress and/or impairment in everyday life (Widiger & Clark, 2000). The grammatical conjunction "and/or" is of paramount importance in defining a psychological disorder, as this indicates that a person can experience frequent, intense, enduring distress with the potential of minimal functional impairment (McKnight & Kashdan, 2009a; McKnight, Monfort, Kashdan, Blalock, & Calton, 2016).

Researchers and practitioners often assume a linear association between the number of mental illness symptoms present and a person's overall functioning. Meta-analyses suggest these correlations are modest to weak and vary across disorders (Cacioppo & Bernston, 1999; Clark, Watson, & Mineka, 1994). Further, the presence of negative emotions in psychological disorders does not negate the possibility of positive emotions. Research suggests that positive and negative emotions are not on opposite ends of the same continuum, but rather, operate relatively independent of one another (e.g., Bradburn, 1969; Carver, 2001; Tellegen, Watson, & Clark, 1999; Watson & Tellegen, 1985). Other research suggests that positive and negative emotions are bipolar ends of the same spectrum (e.g., Russell & Carroll, 1999), but people perceive that they co-occur when their emotional state is close to the middle of this spectrum (Tay & Kuykendall, 2017). What is clear is that negative and positive emotions are not mutually exclusive even in psychopathology. For example, individuals with eating disorders and bipolar disorder may experience an escalation in negative emotions while positive emotions remain, similar to healthy adults (e.g., Gruber, Dutra, Eidelman, Johnson, & Harvey, 2011; Overton, Selway, Strongman, & Houston, 2005).

Research on mental illness has historically focused on the presence of aversive experiences. Diagnostic categorizations of psychological disorders contain a near exclusive focus on negative emotions and thoughts, and the avoidance of these unwanted experiences. Treatment of mental disorders extended this approach with a focus on symptom reduction (e.g., Hollon & Beck, 1993). More recently, treatments have emerged to promote the experience and savoring of positive emotions, instill strategies to satisfy psychological needs for belonging, competence, and autonomy, and assist toward the clarification of values and construction and pursuit of goals aligned with them (e.g., Fava, Rafanelli, Cazzaro, Conti, & Grandi, 1998; Ryan & Deci, 2008; Seligman, 2002; Seligman, Rashid, Parks, 2006).

In these interventions, people with psychological disorders acquire skills to move beyond "normative" functioning in the pursuit of life success and fulfillment. Since initial trials to treat emotional disorders (e.g., Fava et al., 1998; Seligman et al., 2006), quality of life interventions have been tailored for a variety of community (e.g., Abbott, Kline, Hamilton, & Rosenthal, 2009; Feldman & Dreher, 2012;

Lyubomirsky, Dickerhoof, Boehm, & Sheldon, 2011) and clinical populations (Fava et al., 2005; Gander, Proyer, Ruch, & Wyss, 2012; Grant, Curtayne, & Burton, 2009; Ryan, Patrick, Deci, & Williams, 2008). If practitioners wish to successfully enhance well-being among people suffering from psychological distress, it is important to understand both the disorder-specific pathways that compromise well-being and the areas of well-being that remain intact and even enhanced in the presence of disorder. Below, we review research on the presence and absence of three key domains of well-being (positive emotions, meaning and purpose in life, and social relationships) in various psychological disorders (depression, bipolar disorder, social anxiety disorder, schizophrenia, and trauma-related disorders). This chapter is not an exhaustive review, and due to space constraints, not every disorder is reviewed in every section. This chapter *is* intended to highlight and synthesize key findings across disparate literatures to illustrate the ways in which psychopathology interferes with well-being, and in other cases, co-exists with elements of a happy, meaningful, and socially connected life.

Positive Emotions

Besides being subjectively pleasurable, even mild positive emotions serve an everyday purpose. A growing body of research suggests that the experience of positive emotions fosters helpful and generous behavior toward other people, increases open-mindedness and reduces defensiveness in social situations, and broadens considerations when making decisions (Fredrickson, 1998; Isen, 1987). Of most relevance to psychological disorder, positive emotions enhance people's ability to choose targeted, effective coping strategies to deal with stressful events (Fredrickson & Branigan, 2005; Fredrickson, Mancuso, Branigan & Tugade, 2000; Tugade & Fredrickson, 2004). When people experience positive emotions, their attentional resources broaden such that efforts are devoted toward aspirational life aims (instead of merely safety and security) (Fredrickson, 2001). Of course, it is important not to overgeneralize these benefits, as discrete types of positive emotions inspire variable behaviors and goal pursuits: love, interest, joy, amusement, contentment, compassion, gratitude, awe, pride, admiration, hope, and relief (Roseman, 2011). Minimal attention is given to discrete positive emotions and their relation to psychopathology because the small body of research available tends to rely on the larger category of positive versus negative emotions.

Extreme positive emotional experiences are poorly understood. At one extreme, the relative absence of positive emotions is associated with apathetic reactions to potentially rewarding events, behavioral inhibition, and disengagement (Pizzagalli, 2014). At the other extreme, a hyperactive pleasure system stuck in an appetitive phase is often an indicator of uncontrollable, manic episodes (Johnson, 2005). We first review evidence for the former extreme (positive emotion deficits) among individuals with major depressive disorder and social anxiety disorder. We then explore the latter extreme (positive emotion excess) among individuals with bipolar disorder.

Major Depressive Disorder

Recent research challenges the assumption that being depressed leads to greater negativity in response to stressful events and less reward responsiveness to positive events. Based on evolutionary theory and strong methodological studies, it appears that when a person crosses the threshold from feeling depressed to being diagnosed with major depressive disorder, two things occur (Bylsma, Morris, & Rottenberg, 2008; Rottenberg & Gotlib, 2004). First, people are less emotionally reactive to negative events. This appears counter-intuitive to everything written in biographies, scientific journal articles, and popular media. But in fact, depressed individuals respond to negative events with less distress than healthy adults. Second, depressed individuals are less emotionally reactive to positive events. They are insensitive to environmental changes, regardless of whether events are positively or negatively valenced. They shut down. Across contexts, people with depression show emotional inertia or a resistance to change.

People with depression tend to have a diminished capacity to experience positive emotions or pleasure (i.e., anhedonia). When they encounter pleasant events or experiences, depressed people often respond by dampening or suppressing positive emotions (Feldman, Joormann, & Johnson, 2008). They might tell themselves that their streak of good luck will end soon or that pleasurable emotions will be short-lived. They are less likely to mentally elaborate on positive mood states, such as savoring an experience by replaying the highlights or identifying moments they are grateful for (Eisner, Johnson, & Carver, 2009). This means that people who are depressed are reacting to positively appraised real-life events by downplaying and resisting them.

Laboratory studies have showcased how adults with depression respond to a variety of rewarding stimuli with blunted reactions (for review see Bylsma, Morris, & Rottenberg, 2008). For example, after watching an amusing film clip, participants with depression felt less amusement than healthy controls (Rottenberg, Kasch, Gross, & Gotlib, 2002). In another study, after viewing a series of pleasant pictures, participants with depression reported diminished emotional responses and displayed less frequent and intense positive facial expressions than healthy controls (Sloan, Strauss, & Wisner, 2001). In an

autobiographical interview, adults with and without depression were videotaped talking about their happiest memory. Participants with depression took longer to retrieve their happy moments and recalled fewer specific details compared with healthy adults (Rottenberg, Hildner, & Gotlib, 2006).

Results from experience sampling studies offer a more mixed picture of emotional insensitivity. One study found that people with greater depressive symptoms experienced less intense positive emotions in response to daily positive events compared to people with fewer depressive symptoms (Carl, Fairholme, Gallagher, Thompson-Hollands, & Barlow, 2014). They also tried to suppress or dampen their positive emotions more frequently. While this pattern of results indicates emotion insensitivity, other studies have found that depression is associated with *increased* reactivity. In one study, people with elevated depression experienced greater emotional reactivity in response to both negative and positive events (Nezlek & Gable, 2001). A similar pattern of results were found in a study of social interactions; following both positive and negative social interactions, depressed people reported greater emotional reactivity than less depressed peers (Steger & Kashdan, 2009). The authors interpreted these results within evolutionary theory, suggesting that social contexts might evoke a different response than reflecting on prior events, observing movies and pictures, and other intrapersonal events. Depressive symptoms help people determine whether their social value is declining, putting them at risk of being insecurely attached to a tribe, isolated, and deprived of the psychological, physical, and social resources derived from group membership (Allen & Badcock, 2003; Watson & Andrews, 2002). Because social acceptance is central to the basic tenets of evolutionary survival and reproduction, it makes sense that depressed adults reported fewer occurrences of positive social interactions but experienced greater well-being benefits when they occurred; these events are cause for relief, as they are indicators that they are valued, cared for, and part of the tribe. It also makes sense that depressed adults, chronically concerned about their precarious social standing, react to negative social events with particularly strong emotions and experience diminished well-being due to the fear of being ostracized and banished.

Research is needed to determine the extent to which disparate findings are a function of methodology or phenomenology. In terms of methodology, it is possible that highly controlled laboratory environments do not accurately reflect everyday experiences. Simulated threats and aversive stimuli may be less stressful in laboratories, where a person can dampen their response by reminding themselves they are not in real danger, compared with real-world, real-time threats. In terms of phenomenology, it is possible that laboratory studies capture a limited subset of stimuli in which people with depression display emotional insensitivity. Laboratory studies have primarily used emotion-eliciting images with little consideration of more complex, naturally occurring situations (e.g., stressful social interactions, romantic relationship break-ups, academic failures).

The emotional complexity of people with depression goes beyond the intensity of emotions experienced. Depressed people are characterized by emotional inertia, in which prior emotions are strongly predictive of future emotions to the point of being rigid or frozen in time, irrespective of what is occurring around them (Kuppens et al., 2012). Another way to study emotional complexity is by examining the density of emotion networks. Rather than focusing on a single emotion (e.g., sadness), density analyses allow a group of emotions to be examined at once (e.g., sadness, anger, guilt). In one such study, depression was associated with a greater density of negative emotions, but not positive emotions (Pe et al., 2015). A density-distribution approach to emotions suggests that the positive emotions experienced when depressed are fewer in type and less predictable. Still, it is unclear which positive emotions fail to arise in particular situations. Moral emotions that are closely aligned to social activity such as gratitude, compassion, and love might be deficient during depressed states, serving as potent targets for interventions designed to enhance well-being.

These findings support a conceptualization that deficits in key areas of positivity such as positive affect and behavioral activation confer risk for depression in addition to negative risk factors such as pessimistic attributional styles, which have received more attention. Future research is needed to disentangle the strength and temporal sequence of attenuated positivity and depression. Does depression lead to a lack of motivation and sensitivity to potential positive rewards in a person's environment, or does diminished reward responsiveness increase risk for depression? A recent meta-analysis of longitudinal studies offers support for a bidirectional effect (Khazanov & Ruscio, 2016). Self-report measures of positive emotionality (positive affect, extraversion, and behavioral activation) prospectively predicted increases in depression, and depression predicted subsequent decreases in positive emotionality. Fine-grained analyses that target discrete positive emotions will offer insight into the behaviors and goals that depressed children, adolescents, and adults are being pulled toward and away from. By identifying which positive emotions possess the strongest ties to depression, interventions can be developed that target specific positive emotions such as gratitude, compassion, amusement, and love (e.g., Gander, Proyer, Ruch, & Wyss, 2013; Hofmann, Grossman, & Hinton, 2011; Stellar et al., 2017).

Bipolar Disorder

Positive emotional experiences are a defining feature of bipolar disorder. The consequences of the intense euphoria, impulsivity, and grandiosity during manic episodes often lead to significant personal damage including financial disarray after spending sprees, relationship problems after infidelities, physical damage after excessive drug use, and risky sexual behavior. But in some cases, individuals with bipolar disorder have the unique capacity to experience pronounced positive emotions in a broader range of circumstances relative to healthy individuals. Past research has focused on positive emotions and experiences during manic episodes. When manic, people with bipolar disorder are more reactive to positive compared with negative stimuli (e.g., Johnson, 2005). They recall three times the amount of positive memories as negative memories, whereas healthy controls tend to remember about 10% more positive than negative memories during a typical good mood (Eich, Micaulay, & Lam, 1997). They are also more likely to remember positive descriptive words about themselves compared to psychologically healthy adults (Van der Gucht, Morriss, Lancaster, Kinderman, & Bentall, 2009).

Enhanced positivity is not confined to manic episodes, however. Research suggests that people diagnosed with and at risk for bipolar disorder tend to display persistent positive emotion across contexts (Johnson, Gruber, & Eisner, 2007). People with bipolar disorder exhibit a greater degree of positive emotions in response to, in anticipation of, and following rewarding stimuli, even when in remission (Gruber, 2011). Self-reports of positive emotions have been substantiated by physiological data showing cardiac and respiratory states indicative of positive emotionality (Gruber, Harvey, & Johnson, 2009; Gruber, Johnson, Oveis & Keltner, 2008). Neurological data converge on a similar conclusion that people with bipolar display elevated reactivity to multiple types of rewards (Dutra, Cunningham, Kober, & Gruber, 2015). While this positive emotionality may not seem problematic, research suggests that people with bipolar disorder show high levels of positive emotions (with self-report and physiological data) in situations that not only lack reward potential but are objectively neutral or aversive (from sad and disgusting film clips to hostile physical gestures by strangers; Gruber, et al., 2008; Piff, Purcell, Gruber, Hertenstein, & Keltner, 2012). This positive emotion persistence extends to self-regulatory difficulties when working toward meaningful life goals. Whereas healthy adults show a reduction in effort expenditure after making goal progress, people with bipolar disorder continue to persist (as if achievement is irrelevant) with sustained, high levels of positive emotions related to goal pursuit (joy, pride) (e.g., Fulford, Johnson, Llabre, & Carver, 2010).

When considering theory and research on positive emotions in bipolar disorder, it makes sense that these individuals are suspected to be more creative than the average population (Johnson et al., 2012). Research suggests that people in highly positive mood states (e.g., those that activate approach behavior, as seen in bipolar disorder) access more unusual and diverse information and in turn, show evidence of greater flexibility and creativity in their ideas and decision-making compared to behavior in other mood states (Baas, De Dreu, & Nijstad, 2008; Isen, 1999). Indeed, historical analyses of highly creative musicians, writers, poets, and politicians identify a meaningful number who likely experienced bipolar disorder at some point in their lives: Ernest Hemingway, Ludwig von Beethoven, Sylvia Plath, Georgia O'Keeffe, Vincent Van Gogh, Robert Schumann, and Winston Churchill, among others (Jamison, 1989; Weisberg, 1994).

Early writings on the association between mania and creativity spawned interest in testing this theory empirically. One early study found that people with bipolar disorder showed levels of creativity similar to creative writers when sorting objects into different categories (Andreasen & Powers, 1975). Another study found that lithium treatment for people with bipolar disorder dampens expansive, creative thinking (Shaw, Mann, Stokes, & Manevitz, 1986); offering a reason why medical compliance is difficult. A number of studies have examined the prevalence of bipolar spectrum disorders in creative professions. One study used structured diagnostic interviews to assess bipolar symptomatology among students at the prestigious University of Iowa Writer's Workshop (Andreasen, 1987). Results showed that 43% of students met criteria for bipolar spectrum disorders compared to 10% of a non-creative control group. Other studies suggest that bipolar disorder is more common among individuals in creative professions such as writers (Ludwig, 1992) and artists (Akiskal, Savino, & Akiskal, 2005). Beyond creative professions, bipolar traits may be more common among those with more daily creative hobbies (Batey, 2007). While potential links between creativity and bipolar disorder are compelling, it is unclear whether, and under what circumstances, bipolar symptomatology actually fosters creativity. With an excessive focus on creative professions, studies have neglected to measure creative activity with validated self-report and behavioral measures. More research is needed to clarify the directionality of findings and uncover ways of harnessing creativity to improve the quality of life for people with bipolar disorder.

Despite upticks in creativity and expansive thinking, positive emotions pose a dilemma for people with bipolar disorder because they can signal the onset of a manic episode. They are forced to balance

natural desires for pleasure and achievement with staving off manic-induced impairment. As they learn from their prior experiences, mania is more likely to occur after achieving important goals (Johnson et al., 2000). As a form of self-intervention, people with bipolar disorder intentionally try to dampen positive experiences. In one study, nearly 80% of people diagnosed with bipolar I disorder reported engaging in at least one strategy to avoid something rewarding in order to prevent mania, such as avoiding hobbies, limiting creative pursuits, and choosing not to have children (Edge et al., 2013). When people with bipolar disorder experience positive emotions, they are more likely to respond to positive experiences with thoughts that curb emotion intensity (e.g., "I do not deserve to feel this good") compared with healthy adults. Unfortunately, emotion dampening is associated with lower self-reported quality of life. This means that in an effort to prevent the onset of mania, people with bipolar sometimes avoid some of life's most rewarding, pleasurable experiences. Emotion regulation strategies such as mindfulness that keep people rooted in the present without any attempt at altering ongoing experiences may be a more adaptive alternative (e.g., Gilbert & Gruber, 2014). Future research can examine iterative decision-making processes among people with bipolar disorder to discover strategies that minimize chances of mania while maximizing the ability to fully engage with personally meaningful pursuits.

Social Anxiety Disorder

People with social anxiety disorder believe their personal characteristics are deficient, flawed, or contrary to perceived social norms. Upon having their personal flaws exposed to others, they worry about being evaluated unfavorably and ultimately rejected (Clark & Wells, 1995; Heimberg, Brozovich, & Rapee, 2010; Moscovitch, 2009). In hopes of preventing rejection, people with social anxiety disorder avoid social situations or endure them with considerable distress. As a result of their distorted beliefs and avoidant strategies, they are less likely to enjoy and pursue potentially pleasurable activities.

Unlike other anxiety disorders, social anxiety disorder is characterized by persistent low positive affect and curiosity (for a meta-analysis, see Kashdan, 2007). Specific positivity deficits in social anxiety disorder include the tendency to disqualify or reject positive feedback, difficulty recalling positive memories, lack of approach-oriented behavior when in neutral, non-threatening situations (Cacioppo & Berntson, 1999), and an impoverished quality of life (e.g., Eng, Coles, Heimberg, & Safren, 2005; Moscovitch, Gavric, Merrifield, Bielak, & Moscovitch, 2011; Weeks, Menatti, & Howell, 2015). One study examined how people with social anxiety disorder anticipate positive events by reading descriptions of situations such as receiving a love letter from a longtime crush or receiving much needed help from a coworker (Gilboa-Schechtman, Franklin, & Foa, 2000). Compared with non-anxious peers, people with social anxiety disorder rated positive social events as less likely to occur in their lives. If positive social events were to occur, they anticipated experiencing stronger negative reactions. These findings suggest that two biases exist, the first being a belief that positive events are unlikely to occur and the second being that if they do, rewards will be ignored and some level of pain/punishment will be recognized and ruminated on.

Positivity deficits appear to be driven in part by frequent and intense self-regulatory efforts (Kashdan, Weeks, Savostyanova, 2011). As an act of self-protection, people with social anxiety disorder try to conceal perceived deficiencies and refrain from expressing intense emotions that might draw unwanted attention (Heimberg et al., 2010; Moscovitch & Huyder, 2011). When people direct their limited attention to reducing their anxiety, appearing less anxious, and making a positive impression, they exhaust the energy necessary to extract rewards from their ongoing environment (Goodman, Larrazabal, West, & Kashdan, in press; Hayes, Luoma, Bond, Masuda, & Lillis, 2006).

When analyzing face-to-face social interactions in everyday life over the course of two weeks, the two characteristics that best distinguished people with social anxiety disorder from healthy controls were the infrequency of positive emotions and reliance on avoiding anxious thoughts and feelings (Kashdan et al., 2013). Notably, people with social anxiety disorder could not be distinguished from healthy controls based on their experience of anxiety or negative emotions during social interactions. The implication is that to understand social anxiety disorder, the action is not with anxiety in social situations, but rather the relative absence of positive social experiences and the sheer amount of effort exerted to feel something other than anxiety.

Experience sampling studies offer insights into how and when individuals with social anxiety disorder experience diminished positivity. Socially anxious people tend to experience the fewest positive events on days when they feel more socially anxious and devote considerable effort to suppress these emotions (Kashdan & Steger, 2006). Irrespective of how anxious a person tends to be across situations (trait social anxiety), participants in this study reported the most intense positive emotions on days when they felt minimal social anxiety and comfortable expressing their emotions openly. Interestingly, people with higher levels of social anxiety experience low doses of positivity regardless of whether they are

socializing with other people or spending time alone (Kashdan & Collins, 2010).

An interesting paradox for people with social anxiety disorder is that in addition to a fear of being evaluated negatively, they fear being evaluated *positively* (Weeks & Howell, 2012). People with social anxiety disorder tend to interpret positive social interactions as a signal of future anxiety-provoking social interactions (Alden, Mellings, & Laposa, 2004). Even if they receive positive feedback, they believe future social interactions will be negative because they will fall short of rising expectations. With higher performance standards, there is a higher probability of failure. They also worry that overly favorable impressions might in some way be construed as threatening to other group members. For instance, they might worry that if their senior director publically compliments their work on a project, their manager will perceive them as threatening. When someone with social anxiety disorder ends up in a rare positive social interaction, they tend to dismiss good news or accomplishments (Weeks, 2010). For example, they might attribute a pleasant conversation to the other person being interesting rather than their social competence in asking good questions. If someone acts friendly towards them, they might assume the other person feels bad or is simply trying to be nice. By being hyper-focused on minimizing and concealing anxiety, people with social anxiety disorder ignore potentially rewarding social cues, such as someone self-disclosing an intimate detail about themselves (Kashdan et al., 2014).

These concurrent fears of positive and negative evaluation work in concert to contribute to positive and negative emotional suppression (Turk, Heimberg, Luterek, Mennin, & Fresco, 2005). Suppressing positive emotions helps a person with social anxiety disorder minimize attention directed towards them. On days when people high in social anxiety tended to suppress the expression of positive emotions, fewer positive social events and less positive emotions occurred the next day (Farmer & Kashdan, 2012). People generally want to get rid of or downregulate negative emotions and savor or upregulate positive emotions. For people with social anxiety disorder, the choice of which emotions to regulate spans the emotion spectrum. There has yet to be systematic longitudinal studies on how the avoidance and suppression of anxiety and positive emotions influences the development of friendships, romances, interests/passions, and work-related prospects, engagement, performance, and innovation. It will be important for future research to clarify the downstream consequences of decisions to avoid instead of approach over the course of months and years.

To understand the problems inherent to social anxiety disorder, you need to simultaneously consider personality, emotional experiences, how people react to these emotions, and beliefs about emotion display rules. Ignore any of these elements and you will be misled about how they operate together. For instance, there is a subgroup of people with social anxiety disorder (as high as one out of five diagnosed with the condition; Kashdan, McKnight, Richey, & Hofmann, 2009) who instead of trying to escape anxious situations and experiences, tend to be novelty seeking, impulsive, and risk-prone (Kashdan & McKnight, 2010). These people might take over a conversation to demonstrate social dominance or engage in risky sexual behavior to control, instead of being controlled by, their anxiety. Do people in this subgroup have similar positivity deficits, tendencies to conceal the expression of positive emotions, and fears of being positively evaluated as people in the more timid, prototypical group? As for interventions, how can individuals with social anxiety disorder organize their lives in ways that influence the probability of positive experiences? How can they reverse their tendency to ruminate on blunders instead of savor the moments of connection in the aftermath of social encounters? As a condition that affects approximately 7-12% of the population (Fehm, Beesdo, Jacobi, & Fiedler, 2008; Kessler et al., 2005), sufficient basic research exists to begin exploring translational interventions that address the positivity deficits. With the tradeoff made such that people with social anxiety disorder meet their short-term goals of alleviating anxiety and avoiding rejection, at the expense of building positive experiences, much needs to be learned about the ways that well-being interventions require refinement to improve life outcomes beyond symptom reduction.

Meaning and Purpose In Life

Purpose in life has been defined as a central, self-organizing, life aim. Those who acknowledge and live in accordance with their purpose derive a deep sense of meaning in life via the pursuit and attainment of valued goals (Kashdan & McKnight, 2009). A strong sense of purpose is associated with greater meaning in life along with greater happiness and self-esteem, viewing goal pursuits as challenges instead of threats, greater resilience when confronted with emotional difficulties and traumatic events, and longevity (Bonebright, Clay, & Ankenmann, 2000; Boyle, Barnes, Buchman, & Bennett, 2009; McKnight & Kashdan, 2009b; Ryff, 1989). On the other extreme, people who lack a sense of purpose are at greater risk for mental health difficulties (Kashdan & McKnight, 2009; Ryff & Singer, 1996). Emotional distress obstructs awareness of one's purpose and inhibits the mobilization of effort toward one's purpose (e.g., Berenbaum, Raghavan, Le, Vernon, & Gomez, 2003). With less research on the interface of meaning and purpose and psychopathology compared to positive emotions and social relationships, the available review

is streamlined.

Depression

Depression is characterized by a poverty of meaning and purpose (Beck, 1967). Beck's early writings on the subject describe people who are depressed as "having no goals," "having nothing to look forward to," and "seeing no point in living" (Beck, 1967; see Westgate, 1996). In addition to hallmark symptoms found in the DSM, some measures include items about meaninglessness as a specific symptom of depression (e.g., Lovibond & Lovibond, 1995). Meaninglessness may stem from an unfulfilling social support network (Stillman et al., 2009). Given that loneliness and depression frequently co-occur (e.g., Weeks, Michela, Peplau, & Bragg, 1980), it is unsurprising that a lack of meaning may indicate depression. Factor analyses have also suggested that hope about the future is an important component of meaning (Feldman & Snyder, 2005). Since hopelessness is one of the core features of major depression (Abramson, Metalsky, & Alloy, 1989), a lack of hope may underlie deficiencies in meaning and purpose among individuals with depression.

While a lack meaning in life is intertwined with the core features of depression, a strong sense of meaning can play a protective role in the onset and maintenance of depression. In one study, nearly 800 people from 43 countries completed self-report measures of meaning in life and depression five times throughout the year (Disabato, Kashdan, Short, & Jarden, 2017). People with higher meaning in life at the start of the study experienced a decrease in depression three months later. This relationship was partially mediated by positive life events people experienced over the three-month period, such as earning more money or doing something exciting with a friend. These findings suggest that meaning in life can decrease depressive symptoms by generating positive life events. Such findings coincide with the theoretical rationales of interventions that target well-being indicators as outcomes (rather than symptom reduction), which posit that deficient meaning in life is not merely a consequence or correlate of depression but rather, meaning plays a causal role in the development and maintenance of the disorder. As such, enhancing meaning, purpose, and related phenomena should be effective in preventing and treating depression. Treatments such as Acceptance and Commitment Therapy (ACT) help people with depression clarify personal values, and work toward goals that offer the greatest potential for meaning and purpose in life (Hayes, Strosahl, & Wilson, 1999; Zettle, 2007). This is achieved not by eliminating depressive symptoms, per se, but by disengaging from unproductive internal dialogue, acknowledging and accepting uncomfortable emotional experiences while not acting on their behalf, staying in touch with the present moment, and increasing goal-directed behavior irrespective of the presence of distress (Zettle, 2007).

Bipolar Disorder

While mood disorders generally obscure one's sense of meaning and purpose, some people are able to derive meaning from altered emotional states. This is especially evident in bipolar disorder. One qualitative study examined ways in which people with bipolar disorder derive a sense of meaning from their illness (Rusner, Carlsson, Brunt, & Nystrom, 2009). Participants described bipolar disorder as "an illness that is intertwined with one's whole being." They reported an overall intensity of experience that can at times be rich and profound. Participants alluded to a "daily battle" to understand themselves and uncover what is helpful in life, and the distinction between reality and internal fiction. Results suggest that while bipolar disorder creates a challenging existence for those affected, finding meaning within this complexity is achievable.

While some individuals with bipolar disorder struggle to make sense of their often chaotic emotional lives, others are able to derive a coherent sense of meaning with the help of spirituality and/or religion. One study found that 78% of adults with bipolar disorder surveyed held strong spiritual or religious beliefs (Mitchell & Romans, 2003). Theory and research suggest that people with strong religious beliefs and practices are better able to control, monitor, and regulate the self and thus, are more skilled at organizing, prioritizing, and achieving goals (McCullough & Willoughby, 2009). Religious and spiritual beliefs may be particularly beneficial for people with bipolar disorder who have difficulty regulating their emotions in the context of disorganized goal pursuit (Johnson, 2005). Spirituality may also boost well-being among people with bipolar disorder, as research suggests that feeling connected with a higher power is associated with greater well-being at the trait (Pargament & Mahoney, 2009) and daily level (Kashdan & Nezlek, 2012). Many people with bipolar disorder endorse a direct link between religious beliefs and a willingness to manage their illness (e.g., Galvez, Thommi, & Ghaemi, 2011; Mitchell & Romans, 2003), suggesting that meaning derived from spiritual and religious systems may improve the course of bipolar disorder. Some evidence suggests that people with psychological disorders can exhibit excessive religious and spiritual engagement, but this is not the norm (Koenig, 2009). Spirituality and religion should be further explored as a potentially useful paradigm to initiate coping and meaning making among people with bipolar disorder; with the caveat that more attention is needed to the types of beliefs and behavioral

practices that are helpful and unhelpful.

Social Anxiety Disorder

Compared to other anxiety disorders, people with social anxiety disorder are more apt to make decisions that involve avoiding errors, mistakes, and failures than approaching rewards (Kashdan et al., 2011; Rodebaugh & Heimberg, 2008), interfering with the ability to behaviorally commit to goals aligned with a purpose in life. Theory substantiates this notion, as social anxiety is thought to be part of a biologically based avoidance system designed to alert and protect against potential social exclusion (Leary, 2001). Research points to the hypothesis that a coherent sense of purpose and committed effort towards that purpose may act as a powerful antidote for the emotional suffering experienced by people with social anxiety disorder.

One study found that people with social anxiety disorder endorsed lower meaning in life and lower drive toward a life purpose on a daily basis compared to psychologically healthy adults. Yet, on days when people with social anxiety disorder made progress toward a purpose in life, they endorsed greater meaning in life and positive emotions, and their self-esteem was indistinguishable from psychologically healthy adults (Kashdan & McKnight, 2013). Results suggested that strong effort – rather than progress – toward one's purpose was the mechanism driving these benefits for individuals with social anxiety disorder. Although this is only one study, this work suggests that if you give people with social anxiety disorder a reason for getting through the day, there is a reduction in the unhelpful influence of anxious thoughts and feelings. Further evidence for this alternative model of intervention (that does not make anxiety reduction a goal) stems from effective clinical trials of ACT for people with social anxiety disorder who are given the skills to be in the present moment, with a curious attitude, pursuing what they care about most despite the presence of pain (Craske et al., 2014; Dalrymple & Herbert, 2007; Kocovski, Fleming, Hawley, Huta, & Antony, 2013).

Schizophrenia

Conventional wisdom suggests that people with schizophrenia have obstructed views of the world around them, resulting in significant functional impairment and thus, a diminished sense of meaning (e.g., Roberts, 1991). However, even people diagnosed with psychotic disorders can experience profound meaning in life. Qualitative data suggest that there are at least five sources of meaning that can remain intact despite the presence of severe psychological disorder: social relationships, meaningful work, physical health and vitality, nostalgia for life defining moments, and positive experiences (Eklund, Hermansson, & Håkansson, 2012). A greater sense of meaning and purpose can be therapeutic for people with schizophrenia. Inpatients with schizophrenia who have a greater sense of meaning and purpose in life endorse greater adherence to their medical regimen and are less likely to be depressed during their hospital stay (Tali, Rachel, Adiel, & Marc, 2009). Despite difficulties deriving meaning from external sources, research suggests that some people with schizophrenia construct meaning from their delusions and hallucinations - integrating these experiences into a coherent framework of who they are. This allows these individuals to better understand and accept their aberrant and otherwise disturbing experiences, which may ultimately improve their symptomatology and well-being. One study found that people with schizophrenia reported decreased meaning in life from pretreatment to posttreatment (Roberts, 1991). For those who successfully integrated delusions and hallucinations into their sense of self, the loss or reduction of these symptoms precipitated confusion and the fear and sadness of a lost identity. If delusions and hallucinations are reduced or altered, this research suggests that treatment must go beyond symptom reduction to aid in the reformulation of their self-concept.

Rich, descriptive studies of people with schizophrenia are needed to gain a deeper understanding of their perspectives on life-sustaining sources of meaning. Notably, a fundamental sense of personal meaning - which offers explanatory power to make sense of one's life, exists at the core of one's identity, and allows one's existence to be significant and of value to the world - appears to be invariant across people with and without schizophrenia. Treatments such as ACT have been tailored toward people with schizophrenia, showing promise in reducing the believability of hallucinations and delusions while simultaneously reconstructing lives to revolve around commitment toward goals aligned with a person's central values (Gaudiano & Herbert, 2006; Gaudiano, Herbert, & Hayes, 2010; Veiga-Martínez, Pérez-Álvarez, & García-Montes, 2008). For example, one study compared ACT to enhanced treatment as usual (Gaudiano & Herbert, 2006) for inpatients with psychotic disorders. Upon discharge, the ACT group exhibited improvements in affective symptoms, distress related to hallucinations, and social impairment. More patients in the ACT group experienced significant symptom reduction at discharge compared to those receiving enhanced standard care. Notably, reductions in the believability of hallucinations were only seen in the ACT group, and these reductions were strongly associated with decreased distress. It appears that changing people's attitudes toward delusions and hallucinations – rather than trying to eradicate them– is

particularly important in helping individuals with schizophrenia live meaningful lives.

Trauma-Related Disorders

Meaning and purpose play a complex role in trauma-related disorders such as PTSD (Fontana & Rosenheck, 2004). Trauma has been referred to as a "crucible of meaning" in which one's sense of meaning is tested, transformed, and often torn asunder, with the potential for a new meaning system to emerge with the explanatory power to make sense of both losses and discoveries (Landsman, 2002). It is not uncommon for survivors to search for meaning in the wake of their trauma, as traumatic events disrupt assumptions about the self and world (Janoff-Bulman, 1989). For some, this search for meaning allows for a re-examination of life and opportunities for growth in various domains including personal strength, interpersonal relationships, appreciation of life, and a sense of possibility (e.g., Joseph & Linley, 2006; Tedeschi & Calhoun, 1996).

Some people report positive changes in their self-perceptions and feel they improved as a person for having experienced a traumatic event (e.g., Andreasen & Norris, 1972; Tedeschi & Calhoun, 1996). To be clear—these are the subjective experiences of trauma survivors and any data on post-traumatic growth should be interpreted cautiously (Jayawickreme & Blackie, 2014). After all, researchers are unable to explore an alternative life trajectory without the trauma. Perhaps the majority of trauma survivors would have achieved equal or even greater personal growth over the course of time without the presence of trauma. Perhaps the subjective experiences are a strategy to cope with the difficulties that arise from experiencing a traumatic life disruption. As scientist-practitioners, we are less interested in the veracity of trauma survivors statements that their life trajectory has been significantly improved as a result of lessons learned and more interested in the multiple paths to acquiring well-being, dissecting the mechanisms that increase the possibility of positive change.

A study of adults with a recently deceased parent found that approximately 50% experienced a strengthening of their relationships with others, as they reported more fully appreciating the transience of meaningful connections with others (Malinak, Hoyt, & Patterson, 1979). Another study of survivors of a sinking cruise ship found that 94% of people reportedly "stopped taking life for granted" and 71% noted that they now strive to "live each day to the fullest" (Joseph, Williams, Yule, 1993). In some cases, positive changes can manifest rapidly after traumatic events. One study of sexual assault survivors found that many participants reported positive changes including increased empathy, stronger relationships, and a greater appreciation of life as early as two weeks following the assault (Frazier, Conlon, & Glaser, 2001). Another caveat is warranted, as this research does not suggest that any traumatic event is good/positive/healthy or the cause of positive changes; rather, this research describes the psychological management of the emergent distress and change (Coyne & Tennen, 2010).

Data suggest that two reasons that combat veterans seek services through the VA are weakened religious faith and a search for meaning in purpose, rather than the severity of PTSD symptoms (Fontana & Rosenheck, 2004). In some cases, traumatic exposure appears to strengthen religious faith (e.g., Calhoun, Cann, Tedeschi, & McMillan, 2000). While the exact mechanisms are unclear, theories suggest that people suffering from and working to overcome traumatic events may view their suffering as a form of redemption - a common theme emphasized by many religions (e.g., Frankl, 1962; McAdams & McLean, 2013). A strong sense of purpose may lead to healthier, more resilient trajectories following traumas (e.g., Bonanno, Papa, Lalande, Zhang, & Noll, 2005). Purpose leads to greater psychological flexibility, which allows individuals to adapt more effectively to changing environmental demands and thus experience fewer psychological symptoms in the wake of trauma (McKnight & Kashdan, 2009b). As a whole, the above research points to the paradoxical effect of traumatic events. While these experiences can shatter assumptive views that the world is a safe and benevolent place (Janoff-Bulman, 1989), they also can offer people a renewed sense of meaning and purpose as they rebuild their lives.

Social Relationships

Social alliances have served as important, life-sustaining resources throughout human history. If obtained, social support has allowed individuals to not only survive, but also expand their resources, perspectives, strengths, and skills by including other people within their self-concept (Aron & Aron, 1996). With this more expansive self, goal pursuits are more efficient and effective, and it becomes easier to fulfill basic psychological needs for belonging, competence, and autonomy (Deci & Ryan, 2000). To build a strong social support network, one must possess sufficient social competence and be driven to develop, negotiate, and maintain satisfying, meaningful social relationships. It is at this juncture that psychopathology can impede social functioning and dampen well-being. Psychological disorders cast a wide net of suffering affecting not only the individual, but also their friends, family, and caregivers (e.g., Maurin & Boyd, 1990). And in the same vein as every other human being, anyone with a mental illness can benefit from social support. Research suggests that greater social support and community integration can

lead to better social functioning and life satisfaction among people with severe mental illness (e.g., Lam & Rosenheck, 2000; Rosenfield & Wenzel, 1997). Below, we review research in social functioning among people with depression, bipolar disorder, social anxiety disorder, schizophrenia, and trauma-related disorders.

Depression

Evolutionary theories offer insights into the interpersonal nature of depression (e.g., Allen & Badcock, 2003; Watson & Andrews, 2002). These theories state that when confronted with the threat of being viewed unfavorably by important people, one views their social value as systematically declining, increasing the risk of rejection, ostracism, and isolation. Sadness, anhedonia, loss of appetite, psychomotor retardation, and other forms of disengagement offer a moratorium on social activity. Energy is consolidated for future interactions whereby one's social attractiveness can be showcased via hard work, intelligence, humor/wit, or other desirable behaviors. Concerns about social risk and the depressive symptoms evoked impact communication, as a depressed person sends behavioral signals of withdrawal and elicits safe forms of support from others within the social group. Long ago, these behaviors were life-sustaining, as social exclusion almost certainly resulted in death. In modern times, these risk-management strategies are less effective and can shut off opportunities to fully engage with loved ones, form new social bonds, and derive positive emotions from one's social world.

Depressed mood may have an adverse impact on others via emotional contagion effects. A large body of evidence suggests that people with depression can socially transmit their depressed mood and other depressive symptoms to those with whom they interact (e.g., Joiner & Katz, 1999). Interestingly, face-to-face interaction may not be necessary to transmit negative mood states. A large-scale study of Facebook users found that when intentionally trying not to read the positively valenced posts of friends, people in turn produced fewer positive and more negative posts (Kramer, Guillory, & Hancock, 2014). More research is needed to explore the social behaviors of individuals who effectively "catch" negative moods from others, and how this relationship unfolds within social media platforms. Irritability is another unhelpful social behavior found among nearly half of patients with major depressive disorder (e.g., Fava et al., 2010; Perlis et al., 2005). Animal studies suggest that neurotransmitters implicated in the pathophysiology of depression, such as serotonin, play a role in inhibiting aggressive behavior (Carrillo, Ricci, Coppersmith, & Melloni, 2009), which may partially explain this heightened irritability. Other studies suggest that antidepressants targeting serotonin reduce quarrelsome behaviors and promote cooperation during group tasks (Knutson et al., 1998; Tse & Bond, 2006). Together, these studies offer an illustration of the potential neurobiological underpinnings of social deficits among people with depression.

Caring for people with depression can be particularly challenging for romantic partners or spouses, who must take on new roles and responsibilities that formerly belonged to their depressed partner, thus restricting their own social activities and leading to high subjective burden (Fadden, Bebbington, & Kuipers, 1987). One study of 260 spouses and relatives of depressed patients found that 20-50% of caregivers worried about the depressed person's general health, treatment, safety, and future. Caregivers also reported strained relationships with the depressed person and often reported seeking mental health treatment themselves (Van Wijngaarden, Schene, Koeter, 2004). Interestingly, the stage at which the depressed person is at in the trajectory of their illness can influence caregiver burden. Data suggest that families tend to have marked difficulties at one year and 3-4 years after the onset of depression - due to lost hope about their loved one returning "back to normal" (Muscroft & Bowl, 2000). These may be important intervention junctures to offer support and foster hope. Research shows promise for family-based interventions aimed at alleviating distress and enhancing knowledge among those caring for patients with Alzheimer's disease (e.g., Brodaty, Green, & Koschera, 2003; Eisdorfer et al., 2003), but research is lacking in the domain of caring for those with depression. Much can be learned from interventions targeting those who care for patients with other illnesses (such as schizophrenia, detailed in the section below). Well-being interventions must move beyond the individual to the family unit and even the community for managing psychological disorders that affect such a sizeable minority of the population.

Bipolar Disorder

Emotion dysregulation is a hallmark of bipolar disorder. One might assume that the positive emotion persistence characteristic of bipolar disorder leads to deeper social relationships, but research suggests that this persistence only encompasses positive emotions related to reward and achievement, not those related to prosocial behaviors (e.g., love and compassion; Shiota, Keltner, & John, 2006). It is now understood that people with bipolar disorder have difficulties processing and understanding other people's emotions as well as their own. Data suggest that people with bipolar disorder are equally skilled as healthy controls at recognizing faces, but are significantly less skilled at recognizing and accurately labeling emotional facial expressions (Getz, Shear, & Strakowski, 2003). Issues with facial emotion recognition

among this population may underlie difficulties in recognizing and resolving interpersonal problems (Getz et al., 2003). Research supports the notion that deficits in social perception predict poor social functioning (e.g., Penny, Mueser, & North, 1995), an issue that extends to children and adolescents with bipolar disorder. Relationships between people with bipolar disorder and their families are often strained. People with bipolar disorder are more likely to be separated, widowed, or divorced relative to healthy adults (Sanchez-Moreno et al., 2009). One explanation for this is potential stigma and rejection from family members due to misinformation and/or lack of understanding about the disorder (Elgie & Morselli, 2007). Caring for someone with bipolar disorder can be burdensome. Caregivers of people with bipolar disorder (relative to those with unipolar depression) show higher levels of expressed emotion (i.e., being overly critical, hostile, and over-involved). Caregiver burden is associated with depressive symptoms, which negatively impact the prognosis for the person with bipolar disorder and creates a strained home environment (for a review, see Ogilvie, Morant, & Goodwin, 2005).

Social Anxiety Disorder

People with social anxiety disorder experience marked impairments in virtually every relationship domain, from friends (Rodebaugh, 2009) to family (Schneier et al., 1994) to romantic relationships (Sparrevohn & Rapee, 2009). People with social anxiety disorder tend to have fewer friends and are less satisfied with their friendships (Schneier et al., 1994), even more so than people with major depressive disorder (Rodebaugh, 2009). These individuals have persistent fears of evaluation when in social situations or performance settings (Rapee & Heimberg, 1997). While studies suggest that these fears are largely the product of negative biases regarding one's social performance (e.g., Alden & Wallace, 1995), these individuals may actually perform poorly in social interactions and thus garner negative evaluations from others (e.g., Kashdan & Wenzel, 2005). It may be that negatively biased perceptions of one's social performance are not initially founded, but carrying such beliefs into social interactions leads to a self-directed focus (e.g., to monitor one's own performance and protect the self from social threat; Wells & Papageorgiou, 1998) and a subsequent inability to attend to interaction partners.

Behaviorally, people with social anxiety tend to be less dominant and appear less well-adjusted according to informant reports (Rodebaugh et al., 2014). They are also less likely to disclose personal information with others, hindering intimacy development. One study found that socially anxious people were less likely to reciprocate in a role-play interaction with escalating personal disclosures (Meleshko & Alden, 1993). Instead, socially anxious participants continued to disclose at a moderate level despite the magnitude of their partner's disclosures. Of course, the onus of intimacy building does not fall on one individual. Data suggest that in dyads, the presence of at least one highly socially anxious individual alters the quality of an interaction. In a lab-based social interaction, researchers found that during a personal disclosure condition, closeness was ranked highest when two strangers, both high in social anxiety, were paired together (Kashdan & Wenzel, 2005). In a small-talk condition, however, greater closeness was reported when two strangers, both low in social anxiety, were paired together. Across conditions, partners with marked discrepancies in their levels of social anxiety reported less closeness than those with similar levels of social anxiety (Kashdan & Wenzel, 2005). This study suggests that socially anxious individuals may be comforted by mutual anxiety when making personal disclosures, while less socially anxious people are better able to navigate awkward small talk and still form close bonds.

Positivity deficits among people with social anxiety disorder are evident in their difficulty engaging in intimacy-building behaviors with romantic partners. One correlational study found that men and women with social anxiety disorder reported less emotional expression, self-disclosure, and intimacy with their romantic partners compared with psychologically healthy adults from the community (Sparrevohn & Rapee, 2009). People with social anxiety disorder also struggle to be curious and enthusiastic in their support when romantic partners disclose positive events that happened to them. When a partner is curious and enthusiastic, the partner who disclosed the good news experiences more intense and enduring positive emotions, attributed to the attentive partner and the relationship (Gable, Reis, Impett, & Asher, 2004). In a laboratory study of 174 heterosexual couples, people high in social anxiety provided less support for their partner's disclosed positive events as measured by self-, partner-, and observer-report. Interestingly, people high in social anxiety also received less support for their own positive events. Longitudinally, partners of people high in social anxiety who received less support for their positive event disclosures experienced a decline in relationship quality and were more likely to terminate the relationship six months later (Kashdan, Ferssizidis, Farmer, Adams, & McKnight, 2013).

Social anxiety also impedes physical expressions of intimacy in romantic relationships. One daily diary study followed 150 college students over a 21-day span and found that social anxiety was inversely associated with feelings of pleasure and connection during sex (Kashdan et al., 2011). In terms of directionality, stronger feelings of intimacy during sexual activity on a given day led to less socially anxious feelings the following day; an effect that was particularly true for people suffering from greater

dispositional social anxiety (Kashdan et al., 2014). Beyond sexuality, recent evidence suggests that romantic partners with greater levels of social anxiety are less comfortable physically touching someone else and more frequently avoid physical contact with other people (Kashdan, Doorley, Stiksma, & Hertenstein, in press). Together, these studies suggest that socially anxious individuals have difficulty connecting with partners during sex, but stand to benefit the most in terms of anxiety reduction after positive sexual experiences. Touch discomfort and avoidance may be one barrier to enhanced sexual intimacy among people with high social anxiety.

Cognitive-behavioral and pharmacological treatments have received much attention for the treatment of social anxiety disorder (e.g., Rodebaugh, Holaway, & Heimberg, 2004), but other, more nuanced approaches also show promise in directly targeting the social deficits characteristic of social anxiety disorder. Social effectiveness therapy (SET) is a multi-component behavioral treatment for children and adolescents with social anxiety disorder. SET aims to reduce social anxiety and avoidance, increase interpersonal skills, improve self-concept, and increase the frequency of socially enjoyable events (Turner, Beidel, Cooley, Woody, & Messer, 1994). The most innovative element of SET is the recruitment of "super-normal" kids who aid clinicians in helping peers with social anxiety disorder face their social fears, shape social skills, ensure initial positive social experiences, and serve as role models (Turner et al., 1994). Studies suggest that SET is an effective treatment for people with severe social anxiety disorder, teaching crucial skills that maintain high levels of social functioning at a 5-year follow-up assessment (Beidel, Turner, & Young, 2006). The innovative idea of bringing socially intelligent role models into psychological interventions is worthy of exploration in adults with social anxiety disorder. Prior work suggests that engaging family members or romantic partners in therapy improves the outcome of psychological conditions such as obsessive-compulsive disorder (Abramowitz et al., 2013; Renshaw, Steketee, & Chambless, 2005). Possible people to include in an intervention for social anxiety disorder should extend beyond family and romantic partners to anyone with high-level social skill and investment in therapeutic gain. If what a person requires to improve their emotional and social intelligence is deliberate practice with everyday social interactions with high-quality feedback, then an allied health professional alone is insufficient. Interventions can be optimized with access to people who can serve as a guide and role model. As a promising line of research in strength development, people with and without social anxiety disorder might benefit from access to role models who encapsulate behaviors that exemplify courage, curiosity, creativity, compassion, or other ideal personality profiles.

Schizophrenia

Schizophrenia leads to severe and wide-ranging deficits in social functioning (e.g., Hooley, 2010). These deficits become prominent early in the course of disorder, when symptoms have not yet fully manifested (i.e., the prodromal phase) (Ballon, Kaur, Marks, & Cadenhead, 2007). Interpersonal problems are evident among people at heightened risk for developing schizophrenia (Hans, Auerbach, Asarnow, Styr, & Marcus, 2000), suggesting social problems are not simply a result of disorder symptoms, medications, or hospitalizations. People with schizophrenia are often ostracized and avoided by others, making it extremely challenging to form close friendships (Hooley, 2010). One study paired research assistants with people with schizophrenia and tasked them with forming friendships over a two-week span. By the end of the study, there was a considerable increase in negative comments by research assistants directed toward patients with schizophrenia (Nisenson, Berenbaum, & Good, 2001). This study reflects broader relationship impairments; people with schizophrenia are six times less likely to get married than the general population (MacCabe, Koupil, & Leon, 2009). They are much less likely to enter into meaningful, long-term relationships, even when compared to others with severe mental illnesses (Hooley, 2010).

Research suggests that deficits in theory of mind may underlie social dysfunction among people with schizophrenia, as they are less able to reason about and appreciate other people's mental states compared to healthy individuals (Corcoran, Mercer, & Frith, 1995; Frith & Corcoran, 1996). In addition to duration of illness, poor verbal fluency, and the presence of both negative and positive symptoms, deficits in theory of mind is one of the strongest predictors of poor social and community functioning (Roncone et al., 2002). People with schizophrenia have difficulty perceiving social cues; deficits that are unrelated to age, gender, or medication usage (e.g., Kline, Smith, & Ellis, 1992; Poole, Tobias, & Vinogradov, 2000). Most studies have focused on deficits in facial and vocal affect recognition. For example, data suggest that people with schizophrenia perform worse than healthy controls on tasks that require accurate perceptions of facial emotional expressions. These deficits may be indicative of broader perceptual problems concerning human faces (e.g., Kerr & Neale, 1993). People with schizophrenia also struggle to perceive emotional prosody in speech compared to controls (e.g., Murphy & Cutting, 1990). Again, this may be a function of overarching impairments in vocal recognition (Kerr & Neale, 1993). Various studies suggest that deficits in facial and vocal perception may be driven by both negative symptoms such as alogia and avolition (e.g.,

Kohler et al., 2003) and positive symptoms such as hallucinations and delusions (Kohler, Bilker, Hagendoorn, Gur, & Gur, 2000; Schneider, Gur, Gur, & Shtasel, 1995). Despite general facial and vocal recognition deficits, one study found that only facial and vocal *affect* recognition was positively associated with social dysfunction (Hooker & Park, 2002). Taken together, people with schizophrenia have significant difficulties perceiving facial cues, emotions, and changes in vocal tone. As a result, they are more likely to miss the subtleties in social conversations that facilitate intimacy and foster strong interpersonal connections.

The social environment in which people with schizophrenia live influences their symptomatology. Data from several large-scale surveys by the World Health Organization (e.g., Jablensky et al., 1992; Harrison et al., 2001) have offered a tantalizing finding - individuals with schizophrenia in developing countries exhibit fewer symptoms with a better prognosis than people with schizophrenia in first-world countries. Prognosis differences are partially explained by the quality of daily social interaction. Families and caregivers of people with schizophrenia tend to communicate using overly critical and intrusive comments, also known as high expressed emotion (EE). High EE often leads to negative, emotionally intense experiences for people with schizophrenia. When a person with schizophrenia shows signs of recovery and moves from inpatient hospitalization to outpatient or community care, high EE is one of the strongest predictors of relapse (e.g., Butzlaff & Hooley, 1998). While social interactions characterized by high EE clearly play a role in schizophrenia, the quality of data collected on EE in the developing world is much lower than in Western first-world countries (Bhugra & McKenzie, 2003). Thus, it is unclear the degree to which family EE is a factor in the course of schizophrenia in different countries; an alternative explanation is that EE findings are primarily a research methodology artifact.

High levels of EE and caregiver burden often go hand-in-hand (e.g., Barrowclough & Parle, 1997; Scazufca & Kuipers, 1996; Tarrier et al., 2002). Given the debilitating nature of schizophrenia, the high burden experienced by caregivers is unsurprising. Burden tends to be especially high for caregivers who are mothers, have less education, and care for younger patients (Gutiérrez-Maldonado, Caqueo-Urízar, & Kavanagh, 2005). In addition to objective indicators, caregivers' perceptions of the person's symptoms influence their perceived level of burden. Interestingly, caregivers' perceptions of negative symptom severity are associated with caregiver burden, while perceptions of positive symptom severity are not (Provencher & Mueser, 1997). One explanation is that positive symptoms are more commonly viewed as uncontrollable whereas negative symptoms are viewed as more malleable and manageable by the person. Family interventions for people with schizophrenia and caregivers aim to reduce EE, improve caregiver coping abilities, and enhance caregiver knowledge (including correcting misbeliefs) (Pharoah, Mari, Rathbone, & Wong, 2010). These interventions have shown promise in alleviating caregiver distress and stigmatizing beliefs and behaviors (e.g., Szmukler, Herrman, Bloch, Colusa, & Benson, 1996); these interventions appear to be less effective at improving caregiver coping abilities (Szmukler et al., 1996; Szmukler et al., 2003). More research is needed to tease apart what works and what should be changed with regard to family-based interventions in an effort to better support patients with schizophrenia, aid family members, and promote positive social communication and functioning.

Trauma-Related Disorders

Post-traumatic stress disorder (PTSD) is associated with a wide range of social problems including social anxiety (Crowson, Frueh, Beidel, & Turner, 1998), anger (Jakupcak et al., 2007), sexual dysfunction (Cosgrove et al., 2002), family discord (Galovski & Lyons, 2004) and strained romantic relationships (Renshaw & Caska, 2012; Renshaw, Allen, Carter, Markman, & Stanley, 2014). Social support plays a critical role in the onset, course, and severity of trauma-related symptoms. A lack of social support has been cited as a risk factor for PTSD among war veterans (e.g., King, King, Fairbank, Keane, & Adams, 1998; Schnurr, Lunney, & Sengupta, 2004) and survivors of disasters and violent crimes (Johansen, Wahl, Eilertsen, & Weisaeth, 2007; Zoellner, Foa, & Brigidi, 1999). One study found that negative reactions from other people following a traumatic event were strongly associated with PTSD symptoms and partially explained the association between victim-blame and PTSD (Ullman, Townsend, Filipas, & Starzynski, 2007). Strong social support networks can bolster resilience and reduce PTSD severity in the aftermath of traumatic events (Pietrzak, Johnson, Goldstein, Malley, & Southwick, 2009; Schumm, Briggs-Phillips, & Hobfoll, 2006).

Data suggest that male veterans with chronic PTSD self-disclose less frequently, are less emotionally expressive with romantic partners, and have more intimacy problems compared to veterans without PTSD (Carroll, Rueger, Foy, & Donahoe, 1985; Riggs, Byrne, Weathers, & Litz, 1998). Veterans with, compared to without, PTSD report higher divorce rates (Cook, Riggs, Thompson, Coyne, & Sheikh, 2004). Of greater concern, male veterans with PTSD compared to without PTSD are more likely to be emotionally and/or physically abusive toward partners and children (Monson, Taft, & Fredman, 2009). Research has explored possible mechanisms underlying the association between PTSD and relationship

dysfunction. One study of Iraq/Afghanistan and Vietnam veterans found that romantic partners' perceptions of withdrawal and numbness symptoms were associated with greater relationship distress, while partners' perceptions of re-experiencing symptoms were associated with less relationship distress (Renshaw & Caska, 2012). These findings suggest that PTSD symptoms that are less overt and cause individuals to pull away from partners (e.g., an inability to express loving feelings, withdrawal) may be particularly detrimental to relationship functioning, while symptoms that are more directly related to the trauma (e.g., physiological reactions to trauma-related cues) minimize partner distress and pull for supportive responses. Other research suggests that re-experiencing is associated with wives' perceptions that a veteran's PTSD symptoms are out of his control (i.e., external attributions), while withdrawal and numbness are associated with wives' perceptions that the veteran is responsible for his symptoms (i.e., internal attributions) (Renshaw et al., 2014).

Qualitative interviews with veterans suggest that harnessing strong military friendships are effective in navigating the difficult re-integration from combat zones back to the day-to-day family affairs of civilian life (Hinojosa & Hinojosa, 2011). Integrating families and relationship partners into treatment for returning veterans and others suffering from PTSD may be crucial in reducing emotional dysfunction and improving relationship communication, satisfaction, and commitment (Monson, Fredman, & Adair, 2008).

Concluding Thoughts

Generally, people with psychological disorders experience significant impairments in well-being. But this byline fails to capture the complexity of associations between particular disorders and particular dimensions of well-being. Several theoretically meaningful paradoxes exist. People with depression respond to negative events with less distress than healthy adults. People with bipolar disorder experience greater positive emotions than psychologically healthy adults and devote considerable effort to dampen potentially rewarding experiences. People with social anxiety disorder experience chronically low levels of positive emotions in both social and non-social situations; psychological difficulties that can be reduced by the presence of extremely positive sexual experiences or effort towards a purpose in life. People with schizophrenia construct meaning from their hallucinations and delusions, and often treatment leads to a painful reduction in meaning in life. Trauma survivors often derive stronger, appreciative, purposeful lives upon coping with their stressful experiences. The present chapter reviews research that highlights significant impairment across psychological disorders, but also illustrates that across three domains of well-being—positive emotions, meaning and purpose in life, and social relationships—a careful consideration of contextual influences offers new insights and intervention targets. Only by exploring the interplay between psychopathology and well-being will scientists and practitioners meet the demanding challenge of reducing suffering and improving the human condition.

Abstract

In this chapter, we review the literature on the connections between various facets of the broad construct of subjective well-being (SWB) and physical health. We aim to highlight which variables have been explored most, which need more research, and to examine possible overlap or similarities among these variables. We divide these positive psychological constructs into six separate categories: hedonic constructs, eudaimonic constructs, well-being practices, social well-being, motivation and efficacy, and future-oriented constructs. Each construct will be defined and explored in terms of its association with various health outcomes such as morbidity and mortality, and we discuss both the strengths and weaknesses of the literature on each construct. Next, we discuss some possible pathways that may underlie the association between SWB and physical health. Finally, we end with a discussion of the literature as a whole and suggest future directions for research in this area to take.

Keywords: Well-being, Health, Positive affect, Optimism, Mindfulness

To be both happy and healthy is a common goal among many individuals. However, some might not know the extent to which these variables are intricately connected. This chapter details the growing science connecting physical health to subjective well-being (SWB) and, more specifically, the various positive facets within this broad construct. Each positive psychological measure will be defined and explored in terms of its association with various health outcomes such as disease incidence, morbidity, and mortality. We then move to a discussion of possible pathways through which these connections may occur, followed by a general summary about the state of the literature as a whole. First, however, we begin by describing what we mean when we refer to SWB and physical health.

What is Subjective Well-Being?

Happiness is dependent on a number of psychological factors, as demonstrated by an original review of the literature conducted by Wilson (1967). The study of SWB flourished in response to this initial work and has since incorporated research on evaluations of the self, indices of life satisfaction, and emotional responses to life events, among other topics (Diener, Suh, Lucas, & Smith, 1999; Kozma, Stone, & Stones, 2000; Lyubomirsky, King, & Diener, 2005). Life satisfaction and positive—rather than negative—aspects of psychology are the primary focus of SWB, although in some cases, low negative affect (NA) may be considered an indicator of SWB as well (Diener et al., 1999; Ryff, 1989).

What is Physical Health?

While difficult to define, physical health can be broadly described as the systems of the body carrying out physiological functions properly, with "good" physical health frequently indicated in research by the lack of illness or disease (Breslow, 1972; Idler & Kasl, 1991), as opposed to the preferred World Health Organization definition that health is more than the absence of disease (World Health Organization, 1948). Objective physical health outcomes are characterized by measures that can be confirmed by medical tests such as the presence of a disease like cancer or a disability like a traumatic brain injury. Furthermore, there are a number of health-related risk indicators, such as binge drinking or not exercising, which can be measured in order to attain an estimate of physical health. Many of these physical health outcomes, however, do not typically encompass mental health variables like depression (Howell, Kern, & Lyubomirsky, 2007). To correct for this, physical health can also be assessed subjectively and with self-report. For example, subjective health is frequently assessed by an individual's interpretation of symptoms of illness or perceptions of pain. Unlike objective health outcomes that rely on medical testing to determine classification, subjective health outcomes are classified by self-reports. In addition to objective and subjective health outcomes, studies also investigate physiological parameters such as hormone levels or blood pressure. It is important to note that while current physiological parameters may be connected with future health outcomes (Pressman & Cohen, 2005; Steptoe, Wardle, & Marmot, 2005), physiology is *not* a

health outcome in its own right and should be considered separately from outcomes such as morbidity and mortality.

Review

The goals of this chapter are to examine how different positive psychological constructs within the broad umbrella of SWB relate to physical health outcomes. We begin our review with a discussion of hedonic constructs, that is, factors that are associated with the affective component of SWB, including positive affect (PA) and life satisfaction. Next, we go over eudaimonic constructs, or constructs that are associated with the self-realization component of SWB, including autonomy, self-esteem, perceived control, and life purpose. Following this section are constructs that are well-being practices, including mindfulness, self-affirmation, and gratitude. Although some of these constructs have aspects that are dispositional, we chose to categorize them in this section because they are often studied as alterable states. We then move to constructs that are associated with social well-being, including social support and networks and social control, and constructs that are associated with motivation and efficacy, including self-efficacy, determination and grit, and hardiness. The final section of the review focuses on future-oriented constructs, including optimism and hope, and a quick discussion of under-researched positive constructs. While low NA can be considered an aspect of SWB, we focus only on positive constructs given our interest in elucidating the connections between these and physical wellness as opposed to the effects of the absence of negativity. We end our chapter with a discussion of possible pathways connecting SWB to physical health, as well as a number of suggestions for future directions in this area of research.

Hedonic Constructs

The distinction between hedonia and eudaimonia originates from Aristotle's philosophy regarding what constitutes "the good life," and this distinction is still seen in the SWB literature today. Hedonic constructs are driven by the search for pleasure and happiness, whereas eudaimonic constructs are focused on cultivating well-being through long-term emotional processes that focus on meaningful life pursuits (Waterman, 2007; Waterman, 2008). We begin this review by focusing on hedonic constructs, and then move to eudaimonic constructs.

Positive Affect

One of the largest literatures connecting SWB to physical health outcomes is that focusing on PA (for a review, see Pressman & Cohen, 2005). PA varies in time duration and can be assessed as a brief state (positive emotion felt "in the moment") or a dispositional trait. Although state and trait affect are highly correlated, state affect is more variable, easier to manipulate in the lab, and less likely to be tied to long-term health outcomes given the brevity of the experience. Both state and trait affect are almost exclusively measured by self-report with popular scales like the Positive and Negative Affect Schedule (Watson, Clark, & Tellegen, 1988). Only occasional health oriented studies use other PA assessment methods such as facial coding (e.g., Abel & Kruger, 2010; Cross & Pressman, in prep) or positive emotion word usage (Danner, Snowdon, & Friesen, 2001; Pressman & Cohen, 2012).

Overall, both state and trait PA have been connected with a number of physical health outcomes. The area with the most research has shown that healthy individuals with higher levels of PA live longer (see review by Chida & Steptoe, 2008). PA has also been linked to decreased mortality within a number of diseases that have longer prognoses, such as coronary heart disease and diabetes (Moskowitz, Epel, & Acree, 2008; van Domburg, Pedersen, van den Brand, & Erdman, 2001). In well-designed exposure to infectious illness studies, people high in PA are less likely to develop a cold or flu after being infected (Cohen, Alper, Doyle, Treanor, & Turner, 2006; Cohen, Doyle, Turner, Alper, & Skoner, 2003). One area in which the literature is more mixed, however, is for diseases with short-term prognoses, such as end-stage renal disease and advanced cancer, where sometimes benefits are not found or disease survival is reduced (Cassileth, Lusk, Miller, Brown, & Miller, 1985; Devins et al., 1990), although in some cases, PA does help (e.g., Svebak, Kristoffersen, & Aasarød, 2006). One explanation for this is that high levels of PA in the face of life threatening disease may lead to not adhering to medical regimens or seeking help as frequently due to the concomitant reduced perceptions of threat or negativity. Finally, it is clear that there are many subjective benefits of high PA. Individuals with high PA report fewer symptoms of illness and less pain in chronic and experimental studies (Pettit, Kline, Gencoz, Gencoz, & Joiner, 2001; Zautra, Johnson, & Davis, 2005). However, it is not clear to what extent these differences are biological versus perceptually based.

On top of the known objective and subjective connections between PA and health, much work has been done examining plausible pathways that might be responsible for these associations. As outlined by Pressman and Cohen (2005), there are ample connections between PA and immune, endocrine, and cardiovascular function that might underlie health effects, in addition to behavioral and social pathways that might also be responsible. PA is also known to ameliorate the negative consequences of stress, which may also lead to better health (Fredrickson & Levenson, 1998; Pressman & Cohen, 2005).

More work in this area is needed to understand the precise timeline and diseases most helped by PA. While there are many mortality studies of healthy samples, research investigating morbidity (incidence of disease) and survival needs to be replicated within specific diseases. Another important aspect in this work is how NA is treated. Recent work has begun to control for NA within analyses in order to allow researchers to isolate the unique impact of PA on health (e.g., Pressman, Gallagher, & Lopez, 2013). However, in some cases, measures such as depression are also used due to high PA-NA overlap, leaving the question of what the appropriate statistical and theoretical approach might be. As alluded to above, there is also overuse of self-report as a method to assess PA, which may be a problem due to biases in self-presentation (Wojcik, Hovasapian, Graham, Motyl, & Ditto, 2015), and an overreliance on white North American and Western European samples, leaving many important directions for this area.

Life Satisfaction

Life satisfaction is a measure tapping into a cognitive evaluation of one's life; all things being considered, is it satisfactory? We chose to classify life satisfaction as a hedonic construct in this chapter because of its role in overall SWB (discussed in the earlier section defining SWB), but it is important to note that the cognitive component of life satisfaction can also be considered a eudaimonic construct (Kashdan, Biswas-Diener, & King, 2008). Higher life satisfaction has been connected to better subjective outcomes such as higher levels of perceived health and reductions in self-reported pain (Einvik, Ekeberg, Klemsdal, Sandvik, & Hjerkinn, 2009; Kreitler, Chaitchik, Rapoport, Kreitler, & Algor, 1993; Laborde & Powers, 1985), in addition to differences in objective health outcomes (see review by Strine, Chapman, Balluz, Moriarty, & Mokdad, 2008) such as asthma prevalence in clinical populations (Huovinen, Kaprio, & Koskenvuo, 2001) and longer life span (Collins, Glei, & Goldman, 2009; Kimm, Sull, Gombojav, Yi, & Ohrr, 2012; Lacruz, Emeny, Baumert, & Ladwig, 2011). There are, however, some inconsistencies in the literature. For example, despite relative consistency in the longevity literature, one study of Finnish participants found that life satisfaction was only protective for men (Koivumaa-Honkanen et al., 2000), and other studies found no relationship between cancer survival rate and life satisfaction, despite measurements using multi-item scales (Cassileth, Walsh, & Lusk, 1988; Lillberg et al., 2002). Two additional studies observed that life satisfaction failed to significantly predict better recovery from physical disability (Corrigan, Bogner, Mysiw, Clinchot, & Fugate, 2001; Dijkers, 1999). Further research is needed to disentangle these disparate findings. Is it the case that some measures of life satisfaction (e.g., single item assessments with poorer reliability) predict differently than more validated measures (e.g., the Satisfaction with Life Scale; Diener, Emmons, Larsen, & Griffin, 1985)? Are certain populations such as older samples or individuals with certain illnesses helped more by life satisfaction? Finally, what is the pathway by which life satisfaction could improve physical health? Do individuals with more life satisfaction feel happier, and, in turn, is it the PA-associated physiological and behavioral benefits driving these associations?

Eudaimonic Constructs

Autonomy

Autonomy is defined as the freedom to be self-determined and to act upon intrinsic motivations (Ryan & Deci, 1987). Health psychologists are mostly concerned about the environmental or social cues that facilitate and support autonomy. For example, the Health Care Climate Questionnaire (Williams, Grow, Freedman, Ryan, & Deci, 1996) asks (typically adult) participants to rate whether their practitioner acted in ways that supported their autonomy. Increased feelings of practitioner autonomy support can lead to better health outcomes, possibly through patients feeling personally motivated to improve their own health**.** Diabetic patients who reported greater levels of personal motivation and greater levels of practitioner support had improved blood glucose levels over time. Moreover, personal motivation appeared to explain the relationship between practitioner autonomy support and health outcomes (Williams, McGregor, King, Nelson, & Glasgow, 2005). Practitioner autonomy support alone, however, does not necessarily always lead to better glucose levels across diabetic samples (e.g., Lee & Lin, 2010; Ng et al., 2012). Thus, research on autonomy must determine whether health outcomes are driven by supportive systems or by personal motivation.

Few studies have examined how parental autonomy support can influence blood glucose levels in diabetic children (Hanna & Guthrie, 2003). While results favored positive outcomes, Wysocki and colleagues (1996) note one limitation to supporting child autonomy: adolescents who were excessively responsible for their self-care reported more hospital visits, poorer blood glucose control, and worse treatment adherence compared to adolescents with parents who shared diabetes management responsibilities and adolescents with parents who were more controlling of their child's diabetes management responsibilities. Sociological factors such as cultural ideology are also important in this area. Women's autonomy exemplifies this interdisciplinary approach and is usually measured as a woman's ability to make decisions in her household or her cumulative years of education. Lower levels of this construct have

been linked to higher rates of infant mortality and undernutrition in South Asia (Adhikari & Sawangdee, 2011; Shroff et al., 2011). While autonomy has succeeded in incorporating cultural and developmental considerations in its construct measures, the research examines a narrow range of objective health outcomes and should diversify its reach given the likely importance of perceptions of autonomy on any disease that requires a high level of self-management or behavioral change.

Self-Esteem

Self-esteem, almost exclusively measured with the Rosenberg Self-Esteem Scale (Rosenberg, 1965), is the subjective evaluation of a person's self-worth. Despite the age of this established scale, the scope of literature examining the relationship between self-esteem and physical health is neither extensive nor consistent. Whereas higher levels of self-esteem have been connected to better self-rated health (Cott, Gignac, & Badley, 2014) and functional status (Blake, 1991; Chang & Mackenzie, 1998), self-esteem has failed to predict improvements in blood glucose levels for diabetics (Bryden et al., 2001; Johnston-Brooks, Lewis, & Garg, 2002) and has not been singularly predictive of all-cause mortality. One study found that feelings of hopelessness, among other negative psychosocial factors, appeared to confound the protective potential of self-esteem (Stamatakis et al., 2004). For example, Weaver and colleagues (1997) observed that depressed moods mediated the relationship between self-esteem and functional status for individuals with chronic obstructive pulmonary disease. Another study demonstrated that the relationship between self-esteem and the risk of mortality attenuated after adjusting for feelings of hopelessness (Stamatakis et al., 2004). To develop a clearer understanding as to how self-esteem can influence physical health, future studies should account for the influence of both positive and negative emotions and examine whether self-esteem in its own right has a health effect independent of affective pathways.

Perceived Control

Perceptions of control are surprisingly important to medical outcomes. While multidimensional, control is typically assessed as either "locus of control" (i.e., do people explain events as due to internal or external reasons; Rotter, 1966) or as a perception that one has control over certain aspects of one's life. Behaviorally, control can also be assessed or manipulated in the laboratory by allowing participants to manipulate a stimulus, allowing participants to choose between alternatives (Averill, 1973), or removing the ability to control a stimulus (e.g., noise bursts; Pennebaker, Burnam, Schaeffer, & Harper, 1977).

Control has an overwhelmingly positive effect on chronic conditions. For example, lower perceptions of control are predictive of poorer reports of health (e.g., Bobak, Pikhart, Hertzman, Rose, & Marmot, 1998; Lachman & Weaver, 1998), higher incidences of cardiac-related events (Bosma, Marmot, & Hemingway, 1997; Siegrist, Peter, Junge, Cremer, & Seidel, 1990), and reduced blood glucose control in diabetics (e.g., Band & Weisz, 1990; Broadbent, Donkin, & Stroh, 2011). These benefits may be partially attributed to the effects of control on stress, given findings showing that the use or feeling of control is related to lower blood pressure and heart rate during stressful laboratory tasks (e.g., DeGood, 1975; Hokanson, DeGood, Forrest, & Brittain, 1971; Peters, Godaert, & Ballieux, 1998).

A seminal study by Rodin and Langer (1977) found that nursing home residents who were manipulated to feel more personal control were less likely to die at a one-year follow-up, a conclusion corroborated by a number of prospective longitudinal studies on control (e.g., Infurna, Gerstorf, Ram, Schupp, & Wagner, 2011; Penninx et al., 1997; Turiano, Chapman, Agrigoroaei, Infurna, & Lachman, 2014). While the presence of control is associated with a longer life, the loss of control may also have severe consequences. For example, a study of nursing home residents found that those who previously had control over the frequency and duration of visits from student volunteers were more likely to die at follow-up, when the study manipulation ended and the control was lost (Schulz & Hanusa, 1978). Altogether, the connections between control and health have been subject to extensive research, in both naturally occurring and experimental settings. Stress reduction is likely one pathway to these benefits, although further research on the mechanisms is warranted, as is continued work on how control can benefit different types of illness and at what points in time.

Life Purpose

Life purpose is defined as the ability to find life meaningful and is most frequently measured with the Purpose in Life subscale in the Psychological Scale of Wellbeing (Ryff & Keyes, 1995). Overall, a greater sense of life purpose has been positively associated with objective indicators of physiological function and physical health. For example, those with greater life purpose report better glucose control (Kim, Sun, Park, & Peterson, 2013), lower cholesterol (Ryff, Singer, & Dienberg Love, 2004), and fewer disabilities (Cohen, Bavishi, & Rozanski, 2015; Kim, Sun, Park, Kubzansky, & Peterson, 2013; Schleicher et al., 2005; Smith & Zautra, 2004). Life purpose has also been associated with increased longevity (e.g., Boyle, Barnes, Buchman, & Bennett, 2009; Cohen, Bavishi, & Rozanski, 2015), even after accounting for factors connected to life purpose such as social relationships and NA (Hill & Turiano, 2014). However,

there may be important sex differences in the connections between life purpose and health. For example, elderly women with greater life purpose show lower inflammatory cytokine responses, which are related to better physical health outcomes (Friedman, Hayney, Love, Singer, & Ryff, 2007; Ryff et al., 2004), and men with greater life purpose have fewer incidences of cardiovascular-related deaths (Koizumi, Ito, Kaneko, & Motohashi, 2008). In sum, the current research on life purpose provides strong evidence that it is largely beneficial for physical health, and, if sex differences do persist, it is important to question how life purpose is unique to men and women.

Well-Being Practices

Mindfulness

Mindfulness is the ability to direct attention to the physical and mental processes that occur in daily life (Epstein, 1999) and can be studied as a malleable behavior or disposition. Dispositional mindfulness, an inherent ability to practice mindfulness, is measured through self-report scales such as the Five Facet Mindfulness Questionnaire (Baer, Smith, Hopkins, & Toney, 2001). The little research connecting dispositional mindfulness to physical health is unconvincing at this point due to its overreliance on non-objective self-reports (e.g., Bränström, Duncan, & Moskowitz, 2011; Tamagawa et al., 2013) and insufficient evidence in any one disease. However, there is a move towards more research on this topic, including new studies examining connections to detrimental cardiovascular events (Loucks et al., 2015) and diabetes (Loucks et al., 2016). Furthermore, measures of dispositional mindfulness have been criticized for lacking content validity. Researchers argue that without a reliable and predictable measure of mindfulness, assertions of the health benefits of mindfulness are weak (Park, Reilly-Spong, & Gross, 2013). Increased attention to objective indicators of physical health and improvements to existing mindfulness scales may remedy this issue.

In contrast, mindfulness as a learned skill is a subject of prolific research and yields a number of positive results for chronic conditions (see reviews by Bonadonna, 2003; Chiesa & Serretti, 2011; Merkes, 2010). A frequently cited mindfulness intervention program, mindfulness-based stress reduction (MBSR; Kabat-Zinn, 1982), uses breathing and yoga exercises (partnered with mindfulness skill instruction, such as a focus on productive coping mechanisms) to engage patients. As reviewed by Grossman and colleagues (2004), there is evidence that this program benefits a wide array of psychological and physical conditions, from depression to cancer, by teaching patients proper coping skills. Impressively, studies have also demonstrated that HIV-positive individuals who complete MBSR programs show improvements in immune system functioning, including critical T-cell numbers (Creswell, Myers, Cole, & Irwin, 2009; Robinson, Mathews, & Witek-Janusek, 2003). While these outcomes are promising, future research should distinguish between the effects of psychological well-being manipulations that result from engaging in mindfulness versus the effects of engaging in the physical activities and behaviors used to facilitate mindfulness practices (e.g., yoga, muscle relaxation, breathing exercises).

Self-Affirmation

When one's self concept is threatened, self-affirmation, or the affirmation of areas that emphasize one's strengths (e.g., values, beliefs, roles), can occur in order to reestablish positive self-worth, integrity, and self-concept (Sherman & Cohen, 2006). Most self-affirmation studies have participants either complete a scale such as the Allport-Vernon-Lindzey Scale (Allport, Vernon, & Lindzey, 1960) that aims to establish how highly one views their personal strengths or manipulate affirmation by having participants write an essay about a value that is important to them (McQueen & Klein, 2006). Studies that utilize scales such as the Allport-Vernon-Lindzey Scale do so in order to determine whether participants can be categorized as having high, moderate, or low self-affirmation, while studies that employ manipulations such as essay writing aim to induce feelings of high self-affirmation.

Most studies that look at a possible relation between self-affirmation and physical health focus on the health-mediating physiological stress response and have repeatedly shown that self-affirmation alters stress trajectories (Creswell et al., 2005; Sherman, Bunyan, Creswell, & Jaremka, 2009). For example, Creswell and colleagues (2005) revealed that higher levels of self-affirmation and personal identification with values were associated with lower cortisol levels after being exposed to stress. Self-affirmation has also been used as a tool to promote behavioral change that could lead to better health. One study found that after three months, women in the self-affirmation condition weighed less, had lower body mass indexes, and had smaller waist measurements versus those in the control group (Logel & Cohen, 2012). Other studies have shown benefits of self-affirmation on smoking cessation (Harris & Epton, 2009). One possible explanation for these behavioral changes is the connection between self-affirmation and self-control, making this tool potentially relevant to many other negative health behavior change programs. However, this research area is still in its infancy and longer follow-ups are needed to determine the downstream health impact of these behavioral effects, as well as studies examining the objective impact of self-

affirmation on illness and disease.

Gratitude

Gratitude is a popular construct in well-being research, and while frequently studied in the context of interventions (e.g., gratitude diaries; Emmons & McCullough, 2003), it can also be conceptualized as a dispositional tendency to recognize and appreciate the benevolence of another person or being (Krause, Emmons, & Ironson, 2015; McCullough, Emmons, & Tsang, 2002). Positive associations between gratitude and physical health are disparate and largely limited to self-report data, such as single item measures of overall health (Krause & Hayward, 2014) or evaluations of physical health symptoms (Emmons & McCullough, 2003; Krause et al., 2015) and functioning (Hill, Allemand, & Roberts, 2013; Millstein et al., 2016). Furthermore, there are some mixed findings, such as one study that found no benefit for neuromuscular disorder related pain (Emmons & McCullough, 2003). Hill and colleagues (2013) suggest that gratitude may impact physical health through mediating factors, such as mental health status and participation in health-promoting behaviors (e.g., exercise and good nutrition). Indeed, past work has found connections between gratitude exercises and better sleep (Emmons & McCullough, 2003). Surprisingly, only one study to date has examined the effects of gratitude on objective physiological and physical health outcomes (i.e., inflammatory biomarkers and hospital visits), but failed to provide any conclusive evidence for the benefits of gratitude (Huffman et al., 2016), demonstrating a clear need to do more research connecting both dispositional gratitude and interventions to non self-report health outcomes.

Social Well-Being

Social Support and Networks

While too large a literature to review here, connections between social relationships and health are some of the strongest and most consistent psychosocial correlates of health in the medical literature. Effect sizes are large, with the negative effect of social isolation on mortality comparable to that of regular smoking (see reviews by Holt-Lunstad, Smith, & Layton, 2010; House, Landis, & Umberson, 1988; Tay, Tan, Diener, & Gonzalez, 2013). This literature also boasts a diverse range of study samples, including healthy and ill participants, minorities, and pet owners (e.g., Barth, Schneider, & von Kanel, 2010; Cohen, Kaplan, & Manuck, 1994; Ford, Tilley, & McDonald, 1998; Reblin & Uchino, 2008; Schaefer, Coyne, & Lazarus, 1981; Shumaker & Hill, 1991; Tang, Brown, Funnell, & Anderson, 2008; Uchino, 2006).

SWB definitions frequently include "good relationships" as a component of this broad construct. In the health literature, "good relationships" can be assessed in numerous ways. Social support is broadly defined as the resources provided by one's social sphere (Cohen & Syme, 1985), such as emotional support (e.g., a shoulder to cry on) or objective resources (e.g., being lent money). This type of social wellness is most typically implicated in relation to stress and its ability to reduce the negative sequelae associated with negative experiences (Cohen & Wills, 1985; Thoits, 1982), but is also more generally related to an array of health outcomes such as cardiovascular disease, cancer, and overall mortality, as well as an array of possible physiological and behavioral mechanisms (see reviews by Barth et al., 2010; Cohen et al., 1994; Holt-Lunstad et al., 2010; Lett et al., 2005; Pinquart & Duberstein, 2010; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Structural measures of relationships have also been thoroughly connected to health (e.g., marital status, total number of relationships; Holt-Lunstad et al., 2010; House et al., 1988; Kiecolt-Glaser & Newton, 2001). To complicate things further, subjective characteristics of relationships beyond support, such as emotional feelings of love (see reviews by Green, Shellenberger, & Siegel, 1996; Traupmann & Hatfield, 1981) or cognitive assessments of relationship satisfaction (Krause, 1987; Woloshin et al., 1997), may also matter. Thus, while it is clear that positive relationship characteristics are beneficial for us, one important remaining question is how they are related to or distinct from the effects of other positive psychological factors. PA and related positive constructs are intricately connected to social relationships (i.e., happy people have better relationships, relationships make us happy), making it somewhat difficult to disentangle the effects of these variables.

Social Control

One way that relationships are good for us is via the social control inflicted on us by our relationship partners, that is, the strategies used to regulate and influence another person to adopt positive health practices (Thoits, 2011). Social control might include behaviors such as efforts to manage a specific illness, alter health behaviors, or even promote medication adherence (e.g., August & Sorkin, 2010; Berg et al., 2013). Research has indicated that attempts at social control can be related to positive health behavior outcomes such as a reduction in smoking habits and an increase in physical activity (Umberson, 1992), yet its direct influence on disease outcomes is marginal and has received mixed support (Thorpe, Lewis, & Sterba, 2008; Tucker & Anders, 2001). One critical aspect of social control is how the strategies are received. In most cases, when social control is received positively, it leads to better adherence to medical and dietary regimens (August & Sorkin, 2010; Berg et al., 2013; Stephens, Rook, Franks, Khan, & Iida,

2010). Alternatively, unwarranted social control may be perceived as criticism and hinder the development or continuation of positive health behaviors (Lewis & Rook, 1999). Future studies should consider how this aspect of relationships could directly relate to physical health outcomes, as well as variations in populations and methods that might influence when social control is helpful versus harmful for physical well-being.

Motivation and Efficacy

Self-Efficacy

Self-efficacy is defined as one's perceived ability to set and complete goals to achieve a specific outcome, and it has been linked to better overall health and coping in studies ranging from cancer to health promoting behaviors (see review by Strecher, McEvoy DeVellis, Becker, & Rosenstock, 1986). Beyond studying self-efficacy as a perception, a rich area of research introduces self-efficacy interventions to those who are seeking to change a health behavior (Stuart, Borland, & McMurray, 1994). For example, one study found that individuals who successfully completed a self-efficacy smoking cessation program were less likely to relapse a year after completion (O'Leary, 1985). Studies such as this have been replicated and have produced consistent results that link high self-efficacy with successful smoking cessation (Stuart et al., 1994). Self-efficacy is effective at helping individuals institute and maintain change and is also an effective tool to help individuals complete short-term and long-term health oriented goals (Strecher et al., 1986). Unfortunately, while the health promoting behavior literature is strong, much less work has taught us what self-efficacy can do for long-term health due to the focus on this construct as a coping and behavior altering mechanism (e.g., Schwarzer & Renner, 2000). Thus, there is a need for intervention studies that alter behavior with long-term follow-ups examining the downstream effects on disease as well as behavior change.

Determination and Grit

Determination, or one's ability to initiate and maintain a desired behavior or outcome, is understudied in relation to health but has recently begun to attract attention due to its possible use in health behavior change (Deci & Ryan, 2008; Ryan, Patrick, Deci, & Williams, 2008). Therefore, similar to self-efficacy, studies in this area emphasize health behaviors rather than objective health outcomes (e.g., goal adherence and maintenance of health promoting behaviors; Deci & Ryan, 2008; Ryan et al., 2008; Williams, Rodin, Ryan, Grolnick & Deci, 1998). Similar to determination is the relatively new construct of grit, defined as the ability to persevere to pursue one's long-term goals in spite of challenges (Duckworth & Gross, 2014). It is not hard to imagine that these constructs will have downstream impacts on health due to their ability to increase and maintain positive health behaviors, even when willpower is low or behavior is difficult, but this area is in its infancy. Furthermore, some investigators challenge the claim that grit is a positive trait for certain underrepresented populations such as African American students because the construct ignores the toll that societal racism can take on these individuals (e.g., McGee & Stovall, 2015). Thus, future research on this topic should investigate grit within different ethnic groups in order to understand for whom it is beneficial and for whom it is not.

Hardiness

Hardiness is a personality type that consists of three elements thought to aid individuals to successfully cope with stress: commitment, control, and challenge (Ouellette Kobasa, Maddi, Puccetti, & Zola, 1985). Those high in hardiness are able to commit to a goal, feel they have control over their environment, and will likely engage in situations or activities that challenge them. Thus, this construct overlaps with other previously discussed measures such as control, determination, and efficacy. Research has confirmed that high hardiness is linked to less stress related chronic illness (e.g., cardiovascular conditions; Kobasa, Maddi, & Kahn, 1982) and less stress related acute illness (Nowack, 1989), even in studies accounting for possible alternative explanations like high social support or more exercise (Kobasa et al., 1982). Despite the clear benefits for stress and stress-related illness, little research has connected hardiness to objective disease outcomes (see Okun, Zautra, & Robinson, 1988, for an exception examining arthritis symptoms). Thus, like many other constructs in this section, for hardiness to be considered important in the medical realm, research will have to determine its impact on disease and other objective health outcomes and physiological and behavioral pathways. Due to its conceptual overlap with many other constructs, future research also needs to determine to what extent it predicts above and beyond other measures more thoroughly examined in the health arena.

Future-Oriented Constructs

Optimism

Many studies have sought to determine the relationship between optimism and various health conditions, ranging from cancer to chronic pain. While optimism can be specific to a given situation, what is most commonly studied in health research is dispositional optimism, or the general tendency to believe

that good things happen more frequently than bad things (Scheier & Carver, 1985) as assessed by self-report (e.g., the revised Life Orientation Test; Scheier, Carver, & Bridges, 1994). This literature has previously been reviewed (Rasmussen, Scheier, & Greenhouse, 2009), and typically focuses on the effects of optimism for individuals who have already been diagnosed with a particular illness or health condition, for example, cancer or heart disease. Studies follow patients longitudinally to determine whether those with higher optimism are less likely to face complications with their disease, show better disease prognosis, and better overall health outcomes, with many studies showing positive outcomes (see review by Rasmussen et al., 2009). There are limits to the benefits of optimism, however. For example, to the best of our knowledge, no study has found optimism to aid in cancer remission (De Moor et al., 2006; Schofield et al., 2004; Schulz, Bookwala, Knapp, Scheier, & Williamson, 1996). The cardiovascular literature is perhaps more consistent, with many studies revealing faster recovery rates after surgery (e.g., fewer days in the hospital) and better disease prognosis (Conway, Magai, Springer, & Jones, 2008; Matthews, Räikkönen, Sutton-Tyrrell, & Kuller, 2004; Scheier et al., 1989). In addition to these chronic illnesses, other studies have found benefits for chronic pain patients (Costello et al., 2002), as well as patients with diabetes and carotid atherosclerosis (Fournier, de Ridder, & Bensing, 2002; Matthews et al., 2004).

Mechanisms that might lead to better health outcomes for those high in optimism overlap with some of the previously discussed pathways (e.g., alterations in immune function, behaviors). However, there are some differences. People high in optimism may be more confident that they can successfully engage in healthy behaviors, which may be why past studies have found optimistic university students to be more likely to engage in health promoting behaviors, recover more quickly from the flu, and actively attempt to prevent the flu compared to those who were pessimistic (Hamid, 1990). Optimism may also partially operate via the pathways influenced by positive emotion, and, thus, may not be entirely independent from affect (Segerstrom, 2007). Optimism also differs from other positive constructs in an important way in that it can be harmful when unrealistic. For example, a study of law students (a high stress sample) found that immunity was either strengthened or compromised depending on the students' current outlook on their law school experience. When students were more optimistic about a period of law school where their studies were going well, their immunity improved, while when these students were experiencing difficult periods during their studies, their immunity would plummet (Segerstrom, 2007). Few studies of positive constructs show harm, but it is important to consider how and when SWB levels may have a cost rather than a benefit in future work. In general, replication is also a problem in the study of optimism and physical health, and there is a need for more research on the same physical outcomes.

Hope

While colloquially hope is often conflated with optimism, in positive psychology research, hope is defined by an emphasis on determination that is goal-oriented, characterized by planning and perceived controllability (Snyder, Irving, & Anderson, 1991). Hope has rarely been connected to physical health, but there are some relevant self-report studies. For example, studies have investigated the relationship between hope and cancer with the idea that high hope might enable better coping with the stress of this threatening disease. One large study of individuals with either gastrointestinal, breast, head and neck, or hematologic malignancy cancer found that those with high hope were able to successfully cope with their disease as indicated by self-reported data collected using the Herth Hope Scale and the Jalowiec Coping Scale (Felder, 2004). This finding, while distinct from objective health outcomes, is important, as coping with a disease can result in better quality of life (Manne et al., 1994; Osowiecki & Compas, 1998; Stanton et al., 2000). Interestingly, several studies have also linked hope to faster rates of healing, for example, after spinal surgery (Elliott, Witty, Herrick, & Hoffman, 1991) and after getting burned (Barnum, Snyder, Rapoff, Mani, & Thompson, 1998). This is possibly due to better adherence to medical instruction and self-care, which is echoed in work showing the connection between hope and preventive health behaviors (e.g., doctor check-ups and medical screenings; Salovey, Rothman, Detweiler, & Steward, 2000). Together, the literature on hope is exciting but very small. Outcomes need replication, and there should be a focus on outcomes most likely to be influenced such as healthy behavior change (and diseases most likely influenced by this change). Many studies in this area use convenience samples; thus, future work should include power analyses and utilize targeted and meaningful participant samples.

Under-Researched Positive Constructs

There are a number of additional positive constructs that are under-researched in the domain of physical health, including factors like courage, creativity, and passion. Researchers need to investigate the relationship between these constructs and physical health more closely, as it may be the case that not all of these constructs are beneficial for physical health. For example, obsessive passion may lead people to engage in risky behaviors at a higher rate, hence leading to negative outcomes such as injury (Vallerand et al., 2003). As we have emphasized in this chapter, it is important to research each positive psychological construct separately in its relation to physical health, as not all constructs will have the same beneficial or

detrimental effects.

Pathways Connecting Subjective Well-Being with Health

Throughout this chapter, we have discussed outcomes that are more appropriately described as pathways to health as opposed to health in their own right. These include factors like cardiovascular and circulatory physiology (e.g., blood pressure, cholesterol), immune function (e.g., wound healing, antibody levels), endocrine activity (e.g., cortisol), and other less studied physiological pathways. While many positive factors are known to induce change in these variables experimentally (e.g., PA inductions alter physiology; Dockray & Steptoe, 2010), any SWB measures might influence these physiological pathways via alterations in health behaviors (e.g., sleep, exercise, diet). Furthermore, SWB, by definition, includes social relationships, which can influence physiological function, health behaviors, and more. For example, as described in the social control section, relationships serve an important role in encouraging medical care and adherence.

What may also be a common mechanism for altering health in many SWB-health connections is the indirect effect of SWB on preventing downstream negative effects of stress. As described in many sections above, SWB components may have effects on stress perceptions, reactivity, or recovery. Social support has long been implicated in reducing the negative effects of stress (Cohen & Wills, 1985), and, more recently, PA has been posited to play a similar role (Fredrickson & Levenson, 1998; Pressman & Cohen, 2005). While not all SWB components may play a role here, and certainly the research is not deep in many of these areas, conceptually, many components could help with stress. For example, hope and the goal setting that goes with it may prevent future stress from occurring. Perceptions of control, efficacy, determination, and grit might enable reduced reactivity during a stressful period, as might feelings of mindfulness or social support that change stress and coping appraisals. Finally, recovery from stress is aided by positive emotions, and even a simple positive behavior like smiling has been shown to help in this context (Fredrickson & Levenson, 1998; Kraft & Pressman, 2012). Other positive facets may help as well; for example, self-affirmation or stable self-esteem might enable a person to get over the stress faster, as might the ability to focus on a positive future with dispositional optimism. Unfortunately, at this point, studies specifically testing associations between SWB components and the different components of stress are rare, as are studies that contrast different SWB measures against each other to determine their relative and possibly unique effects.

Work on possible pathways continues to progress and develop, especially with the advent of cheaper assays and easier to assess samples (e.g., saliva), new and interesting biomarkers with plausible SWB connections (e.g., telomeres), and growing interest in health relevance. Behavioral and physiological pathways are also getting easier to sample with the advent of new technologies for mobile assessments such as motion sensors, portable heart rate variability, and even facial expressions, which may also play a role in health via their influence on physiology and social relationships. Together, there is a far way to go before we have a thorough understanding of how, when, and why SWB can influence health, but with a conscientious effort to probe this question and attention to new methods (see review by Diener, Pressman, Hunter & Delgadillo-Chase, 2017), this literature will grow and improve our understanding of this area as well as inform future intervention design.

Discussion

Research on the connections between SWB and physical health has drastically increased over the past twenty years, demonstrating a surge of interest in this topic. Overwhelmingly, SWB is positively connected with physical health, revealing an impressive diversity of wellness benefits related to positive states and traits. While it is important to take an omnibus approach in some cases to document the breadth of these findings (e.g., Boehm & Kubzansky, 2012), future work will need to search for specificity. Different constructs might be related to health and physiology in unique ways and should therefore be investigated separately to inform interventions and/or provide precision in our knowledge of this area. It is also important for researchers to know the extent to which certain constructs overlap, such as PA with life satisfaction or hardiness with determination and grit. It may be the case that more specific definitions or advanced measurement tools are needed to capture the distinctness of different SWB constructs, given the high degree of overlap between many of them. To this end, one direction for future research is to determine whether overlapping constructs have separate effects on physical health. For example, the PA and social support literatures are the largest literatures connecting specific SWB constructs to physical health. It is likely, however, that these literatures are connected, since happy people tend to have more and better social relationships, and relationships confer well-being in many ways. Furthermore, studies need to focus on determining the unique versus common variance of all positive constructs as they predict physical health. However, this requires large samples and longitudinal designs, two methodological strengths that do not appear in much of the SWB and physical health literature. Investigating both the separation and overlap of

positive psychological constructs will help clarify the sometimes conflicting literature involving different SWB constructs and physical health and inform targeted health intervention designs.

While making distinctions among SWB constructs, it is also important to separate state and trait constructs. Some SWB constructs, such as state PA and mindfulness, are more state-like in that they can be manipulated readily. For example, state PA can be induced in the lab through various methods like videos and writing exercises. However, other SWB constructs such as self-esteem and optimism are more trait-like and, thus, are less readily and meaningfully altered within a short experimental session. Researchers should be cognizant of how long it takes to alter the specific construct in which they are interested and plan their experiments or interventions accordingly. They should also consider that state and trait constructs influence physical health differently. While state constructs may influence quick moving physiological processes (e.g., cardiovascular reactivity and recovery), trait constructs may be more likely to influence far off health outcomes such as morbidity and mortality. This is likely due to the increased opportunity over years for lasting SWB factors to influence behaviors, relationships, and physiological systems that influence long term health. There are many experimental studies that manipulate SWB constructs and examine physiology or other health-relevant outcomes in the short term, but longitudinal studies are much more rare. There are a number of reasons for this, such as difficulty in following up with participants years later, but this does not change the fact that longitudinal studies are desperately needed to understand how and if changes in SWB influence disease processes versus whether only stable traits underlie future health.

There are a number of additional important new directions for this area of work. One key consideration is how negative constructs (e.g., NA, depression, stress) should be factored into analyses on SWB and health. Early reviews on this topic (e.g., Pressman & Cohen, 2005) highlighted the importance of adjusting for NA so that findings can be attributed to the presence of the positive rather than the absence of the negative. However, how to appropriately include negative constructs in analyses is still an open question in the field. Because of the overlap between PA and NA, many researchers opt to utilize other assessments (e.g., depression) as a covariate in their analyses, but this may not have the same meaning. Alternatively, is it appropriate to adjust for negative factors when part of the reason SWB constructs may be helpful is due to their ability to ameliorate the negative effects of these measures (e.g., the stress buffering hypothesis of PA)? Thus, how to analyze and treat negative psychosocial measures in these studies is still an important and understudied area. Another methodological issue within this literature that we have referred to within this chapter is the overreliance on self-report, sometimes with single item assessments. Questions about SWB are often thrown haphazardly into existing medical studies, and the most appropriate measures are sometimes not used. Thus, more studies should be specifically designed with the main goal of determining the effects of SWB constructs on health so that there is a rationale behind the measures that are chosen.

As this chapter has demonstrated, SWB and physical health are intimately linked. Many different SWB constructs have been investigated in this context, but much more work within each construct is necessary. When examined as a whole, many associations between SWB and physical health are found, but a number of SWB constructs have only a handful of studies. Are there truly replicable effects of some of these measures on health outcomes? Would these effects withstand more rigorous adjustments for factors like NA or related positive constructs? To date, many of the research areas are in their infancy and, thus, replication, expansion, and a more thoughtful approach to study analyses and designs are needed. The ultimate goal of many researchers in this area is to better understand how to keep the populace healthy. While this area is clearly promising, we encourage researchers to hold a magnifying glass to the broad construct of SWB to unpack what types of well-being are most helpful for certain individuals, certain illnesses, and certain constructs.

RESOURCES

Time, Money, and Subjective Well-Being

By Cassie Mogilner, Anderson School of Management at UCLA; Ashley Whillans, Harvard Business School; Michael I. Norton, Harvard Business School

Abstract

Time and money are scarce and precious resources: people experience stress about having insufficient time, and worry about having insufficient money. This chapter reviews research showing that the ways in which people spend their time and money, the tradeoffs that people make between having more time or having more money, and the extent to which people focus on each resource can have a significant impact on happiness. Considering subjective well-being (or "happiness") as a combination of high positive affect, low negative affect, and high feelings of life satisfaction, we explore when, how, and why time and money impact peoples' anticipated, momentary, and lasting happiness.

Keywords: Time, Money, Trade-offs, Happiness, Subjective well-being

Time and money are both precious resources that matter for happiness. Many people feel temporally and financially constrained in their day-to-day lives (Goodin, Rice, Bittman, & Saunders, 2005; Perlow, 1999; Rheault, 2011), wishing that they had more time and more money (Hershfield, Mogilner, & Barnea, 2016). Having more money is associated with experiencing greater daily happiness up to approximately $75,000 of household income per year, with additional gains in life satisfaction beyond that amount (Kahneman & Deaton, 2010). Having more spare time is also associated with greater happiness and life satisfaction, even after controlling for income, and even amongst people who say they like being busy (Kasser & Sheldon, 2009).

Beyond the absolute amount of free time and money they have (Kahneman & Deaton, 2010; Kasser & Ryan, 1993; Kasser & Sheldon, 2009), the extent to which people value each resource and the ways people spend their discretionary time and money can significantly impact their well-being. For example, recent findings show that even after controlling for the amount of time and money people have available, those who value time over money report greater happiness (Hershfield et al., 2016; Whillans, Weidman, & Dunn, 2016).

Still, there are many related open questions pertaining to the relationships between time, money, and happiness—such as when and how valuing time over money impact happiness, as well as the meaning that each resource assumes in people's daily experiences and their lives more broadly. For instance, research suggests that inexpensive, everyday pleasures, such as drinking a cold beer on a warm day, may predict happiness beyond major life events, such as winning the lottery or starting a new job (Gilbert, 2006). It has been similarly argued that the key to unlocking long-lasting changes in happiness involves spending time on activities that do not require a lot of money, but do provide small frequent boosts in mood, such as exercise and religious practice (Mochon, Norton, & Ariely, 2008). More specifically, the extent to which people prioritize time versus money within each day or in their broader life decisions might have important yet differential effects for subjective well-being. Similarly, the happiness that follows from decisions about how to spend each resource may depend on when happiness is measured.

Using a definition of subjective well-being (i.e., "happiness") as a combination of high positive affect (i.e., feeling happy in the moment), low negative affect (i.e., not feeling sad in the moment), and high life satisfaction (i.e., evaluating one's overall life as positive; Diener, 1994; Diener et al., 2017; Diener & Lucas, 1999; Sheldon, 2013), this chapter will explore when, how, and why time and money impact people's momentary and lasting happiness.

Some Differences between Time and Money

Benjamin Franklin encouraged people to equate time and money in his adage, "Time is money." Yet, mounting research shows that people think about time and money in vastly different ways. Moreover, the ways that people think about these resources can have significant implications for how people behave, with consequences for their daily and overall happiness.

In particular, money has a readily exchangeable market and can be saved and borrowed across time periods, which is not true of time. Whereas a loss of $100 today has the potential of being earned back

tomorrow, a lost hour cannot be recuperated, and the 24 hours comprising each day renews every morning. Because money is more fungible than time (Leclerc, Schmitt, & Dube, 1995; Soster, Monga, & Bearden, 2010; Zauberman & Lynch, 2005), people are more prone to carefully plan their temporal expenditures than their financial ones (particularly for the short run; Lynch, Netemeyer, Spiller, & Zammit, 2009), and are more averse to the risk of losing or wasting their time than their money (Leclerc et al., 1995). For instance, people are less likely to select the chance of waiting 90 minutes over waiting 60 minutes for sure than they are to select the chance of losing $15 over losing $10 for sure (Leclerc et al., 1995).

It is also harder to account for expenditures of time than money (Saini & Monga, 2008). Because time is more ambiguous than money, people pay less attention to sunk costs involving time than money (Soman, 2001; Soster et al., 2010), and people can more easily rationalize poor or excessive investments of time than of money (Okada, 2005; Okada & Hoch, 2004). As a result, people prefer to invest time rather than money to acquire hedonic goods (Okada, 2005). Similarly, people have greater difficulty predicting future temporal obligations than monetary ones, which makes people more prone to overcommit their future time than their future money (Zauberman & Lynch, 2005).

While these attributes differentiate time and money as resources, time and money also differ in their perceived connection to people's self-concepts. People view their temporal expenditures as more reflective of who they are as a person than they do their monetary expenditures (Gino & Mogilner, 2014; Mogilner & Aaker, 2009). Consequently, people view donations of time as more moral and self-expressive than donations of money (Reed, Aquino, & Levy, 2007), and people often prefer to make donations of time versus money, even when these donations are less effective (Olivola & Shafir, 2013). People also like products more when they think about the time they have spent with that product versus the money they have spent (Mogilner & Aaker, 2009).

Not only are people's experiences more critical to their personal narrative than material goods (Carter & Gilovich, 2012), but the ways people spend their time literally sum up to the days and the life they live (Mogilner, Hershfield, & Aaker, 2017). So, even though people can buy goods to express aspects of their identity (Belk, 1988; Richins & Dawson, 1992), expenditures of money do not constitute people's lives in the same way that expenditures of time do. People who prioritize the accumulation of material goods (materialism) thus typically report lower subjective well-being (Belk, 1985; Kasser & Ryan, 1993, 1996; Richins, 1994; Richins & Dawson, 1992; Van Boven, 2005).

Focusing on Time versus Money

Partly because of these differences between time and money, the extent to which each resource is salient can influence behaviors that have implications for subjective well-being. For example, the extent to which people are focused on time versus money influences moral behavior. In the context of charitable giving, those led to consider giving time (vs. money) give more time *and* more money, because they imagine the happiness they would feel from engaging with the cause (Liu & Aaker, 2008). Being primed with time (vs. money) also reduces people's tendencies to cheat in games that award money or pride (Gino & Mogilner, 2014). Investigations into the effects of focusing on money confirm its deleterious influence on ethicality. Situational reminders of money (and wealth) lead to unethical behavior, particularly when the decision to act unethically has personal benefits (Dubois, Rucker, & Galinsky, 2015; Gino & Pierce, 2009; Kouchaki, Smith-Crowe, Brief, & Sousa, 2013; Miller, Kahle, & Hastings, 2015).

Though ethicality has consequences for subjective well-being (Borgonovi, 2008; Steger, Kashdan, & Oishi, 2008), focusing on time versus money also impacts subjective well-being by motivating behaviors that are directly linked to happiness. Namely, when time (vs. money) is made salient, people become motivated to socialize more and to work less (Mogilner, 2010)—activities that are often tied to immediate happiness and unhappiness, respectively (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004). Furthermore, people who are chronically focused on time rather than money (measured by their likelihood to choose time over money) report feeling happier and more satisfied with life (Hershfield et al., 2016; Whillans et al., 2016). Time-focused individuals exhibit greater social inclinations, preferring to spend their time and money with or on others rather than on themselves (Hershfield et al., 2016; Whillans & Dunn, 2017).

The vast literature on the consequences of money salience similarly reveals anti-social, yet productive, effects of focusing on money. Though not every finding involving money primes has been replicated (Caruso, Shapira, & Landy, 2017; Caruso, Vohs, Baxter, & Waytz, 2013; Rohrer, Pashler, & Harris, 2015), a review of over 150 studies supports two robust categories of effects (Vohs, 2015): compared to neutral primes, reminders of money make people less interpersonally attuned they become unhelpful, stingy, and disinterested in social interaction (Gasiorowska, Zaleskiewicz, & Wygrab, 2012; Vohs, Mead, & Goode, 2006, 2008). On the other hand, reminders of money do motivate people to work—they exert more effort on challenging tasks, work longer, demonstrate better performance, and feel more

efficacious (Vohs et al., 2006, 2008).

When people are led to equate time and money by putting a price on their time (by calculating their hourly earnings or receiving hourly vs. salary pay), their behavior changes. They become less willing to spend their time on uncompensated activities, such as volunteering and engaging in pro-environmental behavior (DeVoe & Pfeffer, 2007, 2011; Whillans & Dunn, 2015), they experience greater feelings of psychological and physiological stress (Pfeffer & Carney, 2017), and there is some debated evidence to suggest they become more impatient and less likely to slow down and enjoy leisure activities, such as listening to music (DeVoe & House, 2012; cf. Connors, Khamitov, Moroz, Campbell, & Henderson, 2016).

The vast money priming literature allows the meaning of money to emerge through the conglomeration of findings. The sparser literature on priming time leaves the various meanings of time yet to be fully explored or understood. Future research is needed to identify when and why reminders of time influence behavior and emotional well-being. What features of time reminders lead people to think about their daily schedule (which might be associated with the stress of immediate time pressures) versus their time on Earth (which might motivate more meaningful pursuits; Mogilner et al., 2017)? Thinking about the hours or days that remain before a task is due would likely have different emotional consequences than thinking about the years remaining in one's life. Also, time might mean different things to different people —perhaps varying by culture, geography, or employment. More than money, time is a rich construct that would benefit from further investigation and understanding.

When People Focus on Time versus Money

While the priming findings highlight how people's focus on time or money is subject to situational influence, the extent to which people are focused on time or money also varies by individual (Hershfield et al., 2016; Whillans et al., 2016) and more stable circumstances—such as how much of the resource people have. Having less of a resource, whether it be time or money, makes people focus on it more (Shah, Mullainathan, & Shafir, 2012; Shah, Shafir, & Mullainathan, 2015; Spiller, 2011). Consistent with this theory of scarcity, having less actual or perceived time (or money) increases people's likelihood to choose that resource over the other (Hershfield et al., 2016; Whillans et al., 2016). One study found low income Americans to exhibit similar behavioral intentions as those primed with money, which suggests that money is already highly salient among people who are financially constrained (Mogilner, 2010).

However, in the case of money, abundance also seems to increase its salience. Not only is money more valued (showing a stronger relation to subjective well-being) in richer nations (Tay, Morrison, & Diener, 2014), but very wealthy individuals exhibit similar behaviors as those exposed to reminders of money: savoring simple pleasures less (Quoidbach, Dunn, Petrides, & Mikolajczak, 2010), deriving less meaning from taking care of their children (Kushlev, Dunn, & Ashton-James, 2012), and being less altruistic (Miller et al., 2015).

Though both scarcity and abundance increase people's focus on money, only scarcity draws people's attention to time and its ultimate value. That said, the psychological and behavioral consequences of time scarcity depend on whether time is construed more concretely (e.g., in terms of day-to-day scheduling) or abstractly (e.g., in terms of one's time to be alive; Trope & Liberman, 2010).

The feeling of being pressed for time in people's day-to-day lives (Goodin et al., 2005; Robinson & Godbey, 2010) has been described as a "time famine" (Perlow, 1999). It plagues people of both high and low income (Hamermesh & Lee, 2007), and is particularly acute among working parents (Gimenez-Nadal & Sevilla-Sanz, 2011; Goodin et al., 2005; Strazdins et al., 2011; Sullivan & Gershuny, 2001). Not only does this form of time scarcity produce feelings of stress (Carroll, 2008; Roxburgh, 2004; Strazdins, Welsh, Korda, Broom, & Paolucci, 2016), it also elicits behaviors that undermine subjective well-being. People who feel time-constrained become less helpful, less active, and less physically healthy (Banwell, Hinde, Dixon, & Sibthorpe, 2005; Darley & Batson, 1973; Jabs et al., 2007; Mogilner, Chance, & Norton, 2012; Strazdins et al., 2011).

In contrast, awareness that one's overall time in life is limited improves subjective well-being by encouraging people to find greater enjoyment in life's ordinary pleasures and close relationships (Bhattacharjee & Mogilner, 2014; Carstensen, Isaacowitz, & Charles, 1999; Cozzolino, Sheldon, Schachtman, & Meyers, 2009; Cozzolino, Staples, Meyers, & Samboceti, 2004; Kurtz, 2008; Mogilner, Aaker, & Kamvar, 2012; Mogilner, Kamvar, & Aaker, 2011). For instance, when people perceive their future time as more limited (which tends to happen with age; Carstensen et al., 1999), they derive greater happiness from ordinary experiences, such as eating a piece of chocolate, basking in a sunny morning, or receiving a text from a friend (Bhattacharjee & Mogilner, 2014). Additionally, the salience of limited time left in life leads people to feel greater happiness from feeling calm than from feeling excited (Mogilner et al., 2011), to pursue emotionally relevant goals (Fung & Carstensen, 2006), to behave more generously (Cozzolino et al., 2004), and to prioritize close interpersonal connections (Carstensen et al., 1999). It is in

realizing that one's time in life is limited that people become more deliberate in how they spend their time and extract greater happiness from those activities.

Happier Ways to Spend Time

Though happiness is partly influenced by inherited temperament (Lykken & Tellegen, 1996; Nes & Røysamb, 2015) and circumstances (Fujita & Diener, 2005; Lucas, 2007), the way people choose to spend their time within and across days is also a substantial determinant of happiness (Lyubomirsky, Sheldon, & Schkade, 2005).

To promote daily happiness, people should consider spending more time engaging in activities that elicit positive vs. negative mood (e.g., Krueger, Kahneman, Schkade, Schwarz, & Stone, 2009). To identify what activities promote positive (and negative) mood, researchers have conducted studies using the Day Reconstruction Methodology (DRM). In DRM studies, respondents are asked to reconstruct the activities filling their last 24 hours, episode by episode. Respondents are then asked to report their mood during each episode. Through these studies, researchers have found initial evidence that, on average, people feel more positive emotion when they are engaged in leisure activities, such as exercising and socializing, than when they are engaged in commuting, work, and housework (e.g., Kahneman, Krueger, Schkade, Schwarz & Stone, 2004, 2006). Yet, it is worth noting that in one of the seminal DRM studies on this topic (Kahneman et al., 2006), some respondents reported feeling happier at work (vs. leisure or other activities), suggesting there are individual differences in which time-use activities promote happiness.

Using more sophisticated data collection methods, such as experience sampling and mobile sensing, researchers have further expanded on these DRM findings by exploring what kind of leisure activities people should engage in to reap the greatest happiness. In experience sampling studies, respondents are asked to report how they feel "right now" during randomly selected episodes throughout the day (Csikszentmihalyi & Hunter, 2003; Csikszentmihalyi & Larson, 2014; Hektner, Schmidt, & Csikszentmihalyi, 2007; Napa Scollon, Prieto, & Diener, 2009). In mobile sensing studies, cell phone technology stealthily records participants' activities. Meanwhile, participants respond to messages throughout the day indicating their current mood (Berke, Choudhury, Ali, & Rabbi, 2011; Killingsworth & Gilbert, 2010; Lane et al., 2010; Lathia, Sandstrom, Mascolo, & Rentfrow, 2017; Ma, Xu, Bai, Sun, & Zhu, 2012; Maisonneuve, Stevens, Niessen, & Steels, 2009; Rabbi, Ali, Choudhury, & Berke, 2011).

These state-of-the-art methodologies suggest that more active forms of leisure, such as exercising and volunteering, are linked to greater daily positive mood compared to more passive forms of leisure, such as watching TV, relaxing, and napping (Lathia et al., 2017; see also: Smeets, Whillans, Bekkers, & Norton, 2017; Richards et al., 2015; Wang et al., 2012). For example, new research using a mobile app that measures activity level through smart phones shows that people feel happier when they have been moving in the past 25 minutes than when they have been sitting or lying down, regardless of the activity they were engaging in (Lathia et al., 2017). Most participants' movement involved gentle walking, light jogging, and casual cycling, suggesting that even minimal physical exertion can enhance daily mood.

Cultivate social connection. Another time-use activity that can promote happiness is spending time with others: Time spent connecting with others tends to be the happiest part of most people's day (Kahneman et al., 2004; Mogilner, 2010), and experiences that are shared produce greater happiness than those experienced alone (Caprariello & Reis, 2013). High quality social relationships are essential for mental and physical health (Diener & Seligman, 2002). Meta-analyses suggest that the health benefits of social connection are comparable to those of exercising regularly and not smoking (Holt-Lunstad, Smith, Baker, Harris, & Stephenson, 2015; Holt-Lunstad, Smith, & Layton, 2010). Even fleeting social interactions, such as chatting with one's Starbucks barista or a fellow commuter on a bus, can make people feel connected and therefore bolster happiness (Epley & Schroeder, 2014; Sandstrom & Dunn, 2013).

Help others. Spending time helping others is another activity that can enhance mood and physical health (Dunn, Aknin, & Norton, 2008; Gimenez-Nadal & Molina, 2015; Liu & Aaker, 2008; Weinstein & Ryan, 2010; Whillans et al., 2016, cf. Whillans, Dunn, Smeets, Bekkers & Norton, 2017). One way that helping others can promote subjective well-being is by reducing the stress associated with feeling time-constrained. Study participants who spent time helping someone else (vs. who spent time on themselves) reported feeling like they had more time, in part because it made them realize all they could accomplish with their time (Mogilner et al., 2012).

Be active. As already discussed, engaging in active leisure activities seems to reliably promote happiness (Lathia et al., 2017). Consistent with these findings, people also report greater happiness when they are busy, especially when they can justify their busyness (Hsee, Yang, & Wang, 2010). In North America, busyness is now a status symbol (Bellezza, Paharia, & Keinan, 2016). Idleness, on the other hand, is extremely upsetting. People would rather shock themselves than be left alone with their own thoughts (Wilson et al., 2014). These findings might help to explain why people who are unemployed (despite their

abundance of free-time) report lower levels of daily happiness than those who are employed (Young & Lim, 2014). Notably however, once busyness transforms into feelings of time stress, people experience lower positive mood and life satisfaction—and this effect holds even among people with a stated preference to be busy (Kasser & Sheldon, 2009).

Increase variety. Across the activities that fill people's lives, greater variety increases excitement and engagement (Etkin & Mogilner, 2016), which helps to offset the threat of hedonic adaptation (Lyubomirsky et al., 2005). Notably, however, though filling one's day or week with highly varied activities increases happiness, fitting highly varied activities into shorter time periods (e.g., an hour) reduces happiness by making people feel like they have accomplished less (Etkin & Mogilner, 2016). These findings provide initial evidence that multitasking can undermine feelings of productivity and happiness.

Variety across emotional experiences can also have benefits for overall subjective well-being. "Emodiversity"—the variety and relative abundance of the emotions that people typically experience—predicts decreased depression and doctor's visits, over and above mean levels of positive and negative emotion (Quoidbach et al., 2014). Other research has shown that experiencing moderate variability in one's emotional experiences (vs. too much or too little variability) positively predicts happiness and is associated with improved physical health (e.g., Human et al., 2015; Kashdan & Rottenberg, 2010). Too much variability in positive emotion predicts lower life satisfaction and greater depression (Gruber, Kogan, Quoidbach, & Mauss, 2013).

Relatedly, current research suggests that spending too much time engaging in social activity can undermine well-being (Kushlev, Diener, Heintzelman & Oishi, 2017). In light of this possibility that over-investing in "positive" time-use pursuits can come at a cost to well-being, more research is needed to understand individual differences and social/cultural factors that determine people's happiness from working versus leisure, as well as the optimal amount of time that people should spend at work versus engaging in social and leisure activities.

Savoring Time Spent

In addition to what people spend their time doing, the extent to which people are mentally engaged in those activities can influence resulting happiness (Nakamura & Csikszentmihalyi, 2009). This speaks to the importance of savoring daily experiences. One strategy for savoring daily experiences is turning them into rituals. For example, study participants rated a chocolate as more flavorful and worth savoring when they had completed a ritual prior to consumption (e.g., by unwrapping the chocolate in a specific way; Vohs, Wang, Gino, & Norton, 2013). Also, engaging in the creation of products can make the experience of those products more satisfying—an observation called "the IKEA effect" (Norton, Mochon, & Ariely, 2012).

Another strategy to help people savor experiences includes taking photos of the experience. Taking photos enhances enjoyment of positive experiences by increasing people's engagement with the experience (Diehl, Zauberman, & Barasch, 2016). Notably, however, taking photos with the intent of posting them on social media pulls people out of the experience and reduces enjoyment of the experience (Barasch, Zauberman, & Diehl, 2017). Photos taken during such events as concerts and nights out with friends facilitate rediscovery of previously experienced events, which enhances positive mood (Zhang, Kim, Brooks, Gino, & Norton, 2014).

When people are aware their time is running out, they are more likely to savor whatever time they spend. For instance, people imagining it is their last month in their current city derive greater enjoyment from their day-to-day experiences (Layous, Kurtz, Chancellor, & Lyubomirsky, 2017); college students focused on the imminence of graduation engage more in their typical college-related activities and experience greater happiness from them (Kurtz, 2008); and people who temporarily give up something pleasurable derive greater pleasure from it the next time it is consumed (Quoidbach & Dunn, 2013). While extraordinary experiences produce high levels of happiness regardless of the amount of time left in life, ordinary experiences produce high levels of happiness among older people and younger people who perceive their future as limited (Bhattacharjee & Mogilner, 2014). Realizing the preciousness of time encourages people to extract greater happiness from even the most mundane activities.

Extracting Meaning from Time

Thus far, we have reviewed findings identifying ways to spend time that promote positive mood and immediate feelings of happiness. Yet, a more lasting sense of purpose and meaning in life is also an important factor in subjective well-being (Catapano, Quoidbach, Mogilner, & Aaker, 2017; Diener et al., 2010; Ryan & Deci, 2001). Therefore, in addition to understanding how people should spend their time to maximize their daily mood, it is also important to clarify what activities help to maximize a sense of

meaning.

Time-use activities that are rated as low in positive affect (e.g., working or spending time with young children; Kahneman et al., 2004) can be rated high in meaning (Nelson, Kushlev, English, Dunn, Lyubomirsky, 2013; White & Dolan, 2009). These "objectively unpleasant" daily activities can indirectly contribute to greater well-being by enhancing meaning in life (White & Dolan, 2009). People presumably spend their time to satisfy various components of well-being. For instance, they may watch TV seeking pleasure, but they may volunteer at a food bank to feel a greater sense of meaning. To advise people how they should spend their time to maximize subjective well-being, it is therefore important to understand *why* people are engaging in a given task, in addition to *what* people are doing and how they feel while doing it.

Collectively, these findings highlight important areas for future research. More research is needed to understand how best to spend time to maximize daily happiness, as well as life satisfaction. Since moment-to-moment happiness does not simply sum up to one's memory of the experience or one's overall evaluation of the experience (e.g., Diener, Wirtz, & Oishi, 2001; Fredrickson & Kahneman, 1993; Wirtz, Kruger, Scollon, & Diener, 2003), an important question then becomes which source of well-being should be optimized to translate into greater well-being each day and over the course of people's lives (Mogilner & Norton, 2017). Relatedly, more research is needed to understand *when* it is best to prioritize one form of well-being over another. For example, research on psychological flexibility suggests that changing one's goals to meet the needs of the current situation will likely produce the best results (Kashdan & Rottenberg, 2010).

Happier Ways to Spend Money

One way to change how people spend their time is to change how they spend their money. The products and services that people purchase (or not) are essentially purchases of time: buying a television is buying time watching TV, paying for housecleaning is buying several hours of free time, and saving for retirement is buying improved future time. Therefore, research identifying what uses of money "pay off" in the most happiness focuses on ways to spend money—such that people spend their time in happier ways (Dunn & Norton, 2013). More specifically, mounting research suggests that the material purchases people make for themselves—from cars to houses to gadgets—often fail to pay off in increased happiness (Dunn & Norton, 2013; Van Boven & Gilovich, 2003). Yet, spending money on others (instead of on the self) and buying experiences (the opposite of tangible possessions) can promote happiness. Finally, a third area of research explores the benefits of using money to directly buy more free time.

One caveat to note is that people who lack discretionary money and are struggling to make ends meet will not often confront decisions for whether and how to spend their money to maximize happiness. Still, many people do have some discretionary income, which makes these insights relevant for a significant portion of the population. Indeed, a large proportion of people living in developed countries have non-trivial discretionary income (OECD Economic Survey of Canada and the United States, 2016), with the average North American household taking home approximately $30,000 of discretionary income each year (Statistics Canada, 2016; US Census Bureau, 2015).

Spend on others. Dunn, Aknin, and Norton (2008) conducted a simple experiment designed to test whether spending on the self or spending on others leads to greater happiness. On a university campus in Canada, people were given either $5 or $20 and instructed to either spend it on themselves or on others by the end of the day. When contacted that night, those assigned to spend on others were happier than those assigned to spend on themselves, regardless of the amount. The happiness from prosocial spending is not limited to wealthier countries: Large-scale survey data assessing the link between charitable giving and well-being in 136 countries reveals a directionally positive link in 120 of the 136 countries, and a significant correlation in a majority of the sampled countries (Aknin et al., 2013).

In general, prosocial behavior is most apt to positively influence personal well-being when the behavior satisfies at least one of three basic needs: relatedness, competence, and autonomy (Weinstein & Ryan, 2010; see also Dunn, Aknin, & Norton, 2014). Perhaps not surprisingly, then, prosocial spending produces more happiness when the giving is conducted face-to-face (e.g., when people buy a friend a coffee at Starbucks and accompany them there; Aknin, Dunn, Sandstrom, & Norton, 2013) and when people spend on strong ties (such as family) rather than weak ties (such as acquaintances; Aknin, Sandstrom, Dunn, & Norton, 2011). In addition, perceiving the prosocial impact—such that people feel their giving is making a difference in the lives of others—heightens the happiness gained from prosocial spending in both their personal lives (Aknin, Dunn, Whillans, Grant, & Norton, 2013) and their professional lives (Grant & Sonnentag, 2010).

Buy experiences. An impressive body of research suggests that when spending on the self, it is better to buy experiences than material possessions to maximize subjective well-being (see Gilovich &

Kumar, 2015 for a review). In a seminal paper, Van Boven and Gilovich (2003) defined an experiential purchase as "an event or series of events that one lives through" and a material purchase as "a tangible object that is kept in one's possession." In the associated series of studies, people who recalled experiential purchases were happier and felt that their money was better spent than those who recalled material purchases.

There are several reasons for the greater happiness from experiential purchases than material ones. For one, people are slower to hedonically adapt to experiences than possessions. In one study, the happiness of participants who purchased experiences decreased more slowly over the ensuing days and weeks than the happiness of people who had purchased material goods (Nicolao, Irwin, & Goodman, 2009). In another study, happiness with experiential purchases even increased over time (Carter & Gilovich, 2010). Another reason for the greater happiness from experiential purchases is that experiences tend to be more emotionally acute and socially connecting than material goods (Chan & Mogilner, 2017). Recipients of experiential gifts therefore feel more connected to their gift-giver than do recipients of material gifts (Chan & Mogilner, 2017). Moreover, whereas material purchases are more likely to be consumed alone, experiential purchases are more likely to be enjoyed with others (Caprariello & Reis, 2013), and the associated feelings of relatedness are at least partly responsible for the ensuing happiness (Howell & Hill, 2009). Furthermore, experiential purchases are more tightly tied to people's sense of identity, creating happy memories that give people a sense of "who they are" (Carter & Gilovich, 2012). This is yet another reason why people go to great lengths to collect (Keinan & Kivetz, 2011) and protect (Zauberman, Ratner, & Kim, 2009) memories of experiences, and why people find rediscovering those memories so pleasurable (Zhang et al., 2014).

It is worth pointing out that experiential purchases do not always enhance happiness more than material purchases. For example, while experiential purchases produce more intense feelings of happiness (Chan & Mogilner, 2017), material purchases produce more frequent feelings of happiness (Weidman & Dunn, 2016). More research is needed to identify exactly when material versus experiential purchases are more effective at increasing subjective well-being—particularly when looking to maximize happiness in the moment, rather than anticipated or retrospective happiness. More research is also needed to understand whether some material purchases—such as a new car or a home with a view—can promote lasting happiness by helping facilitate positive daily experiences.

Buy time. An emerging body of research has explored the benefits of using money to buy more free time. Whillans et al. (2017) document three primary findings. First, people are surprisingly unlikely to report using money to buy time (e.g., paying to delegate common household chores like cleaning, shopping, and cooking), which suggests that buying time is not a common use of money. Second, large-scale surveys of countries ranging from the United States to Denmark to the Netherlands involving both representative samples as well as samples of millionaires demonstrate that buying time is correlated with well-being. Third, an experiment in which people were given $40 and asked to make a time-saving purchase versus buy a material good showed that buying time led to greater happiness, and these results were driven by the buffering role that buying time played in alleviating time stress. Across studies, the least wealthy participants benefitted the most from spending money on time-saving purchases. These results suggest that people who are pressed for money might also be more likely to be pressed for time, potentially because they must commute farther to work or are single parents. More research is needed to further understand when and why buying time produces greater levels of well-being.

This review of findings identifies an exploration into the correct balance in spending across the multitude of domains as one clear avenue for future research. Taking just the four spending categories reviewed here, research suggests that while material purchases typically do not pay off in happiness, prosocial spending, experiential purchases, and buying time do. Yet, people clearly must make some material purchases (e.g., they need clothing). So the question remains: What percentage of spending should be allocated across these categories? Second, the research reviewed offers several mediators of the money-happiness link, but which is most important? And even if we assume, for instance, that relatedness is most critical, what spending category best increases feelings of relatedness? Is it spending directly on an experience with someone else, or giving to charity, or even buying time to free up more time to spend with family and friends? More research is needed to compare the relative benefits of different methods for using money to buy happiness. More research is also needed to understand *who* stands to benefit most from spending money in each category. Recent research suggests that personality can moderate the benefits of spending on others and on material purchases (Matz, Gladstone & Stillwell, 2016). Thus, future research should seek to understand how both personality factors and available income interacts to predict the benefits of various spending choices.

Conclusion

This chapter reviews how thinking about and spending time and money shapes subjective well-being. Notably, many of the effects depend on the temporal context of subjective well-being—is happiness being optimized in the moment or when remembering the past or anticipating the future? Going forward, researchers should more precisely delineate the role of time and money in day-to-day feelings of happiness, forward- and backward-looking feelings of happiness, as well as assessments of living a happy life overall. Researchers should also increase the representativeness and generalizability of the time-use and happiness findings reported in this chapter by conducting research among non-Western samples and respondents from both lower and higher income brackets (Henrich, Heine & Norenzeyan, 2010).

Also, though we focused on individuals' happiness as the unit of analysis, future research should consider the implications of time and money for the happiness of relationship pairs, families, organizations, and societies. For example, how do various means of managing, sharing, and giving time and money impact relationship satisfaction? Findings in the relationship literature on shared novel experiences (Aron, Norman, Aron, McKenna & Heyman, 2000), expressions of gratitude (Algoe, Gable, & Maisel, 2010), and rituals (Sezer, Norton, Gino, & Vohs, 2016) highlight this as a ripe area for research. From an organizational perspective, companies might similarly consider how compensating employees with time (e.g., vacations, sabbaticals, flex hours) versus money (e.g., salary, 401k options) translates into job satisfaction.

Time and money are arguably life's most precious resources. Continuing to understand how people spend, think about, and value their time and money will help to answer the broader and more fundamental question of how to maximize individual and societal well-being.

Abstract

To advance research on income and subjective well-being (SWB), we review and synthesize the research on this topic. There is robust evidence showing a substantial association between income and SWB. However, addressing the question of whether income *leads to* happiness requires an explication of the underlying processes for how income may enhance or undermine happiness. A symbolic view of income (e.g., signaling status) proposes that income has little relation to SWB. On the other hand, a functional view of income (e.g., resource-buffer and a means for need fulfillment) proposes a stronger relation to SWB. In seeking to integrate this literature, we present a multilevel model of symbolic and functional views of income and SWB accounting for: (a) different levels of analysis; (b) income expenditure/distribution; and (c) the income generation context. The purpose is to provide an overarching conceptual model that captures the key factors influencing income and happiness that requires greater clarity and precision in order to advance future scientific endeavors.

Keywords: Income, Well-Being, Happiness, Money

Although both societies and individuals strive toward material progress, with income being one of the key indicators, there is considerable debate on whether income leads to, or is substantially associated with, happiness. This has arisen in part due to different deeply held philosophical, religious, and ethical viewpoints. Value judgments on materialism and money notwithstanding, burgeoning empirical research on this issue from the fields of economics and psychology appear poised to resolve this debate. Yet surprisingly, scientists are similarly divided, with some holding up evidence that little relation holds while others point to a strong association.

In our review of the literature, there is robust evidence showing a substantial association between income and subjective well-being (SWB). However, addressing the question of whether income *leads to* happiness requires an explication of the underlying processes for how income may enhance or undermine happiness. To this end, we review contrasting psychological and economic mechanisms that have been proposed to explain how income may (or may not) enhance happiness and clarify key moderators that need to be accounted for when empirically assessing this issue. By doing so, we shed greater light into the conditions for when income may or may not exert effects on SWB.

In seeking to integrate this research, we present a multilevel model of income and SWB accounting for: (a) different levels of analysis; (b) income expenditure/distribution; and (c) the income generation context. The purpose is to provide an overarching conceptual model that captures the key factors influencing income and happiness which requires greater clarity and precision in order to advance future scientific endeavors.

Origins of Debate and Beyond: Key Factors for Consideration

Seminal work by Easterlin (1974) found that although in the cross-section income is associated with happiness within nations, it was not associated between nations. Further, rising national income was not associated with rising levels of national happiness. To explain these findings, it was posited that an individual's happiness level is contingent on the standard based on one's society rather than an absolute standard across the world. Therefore, as evidenced, relative income within a nation has greater bearing on happiness than between nation income or increases in national income over time.

The relative happiness hypothesis was challenged in a re-examination of the between-nation Easterlin data (Veenhoven, 1991). It was demonstrated that the between-nation correlation for income and SWB in the two data sets were not trivial with magnitudes of .51 (N = 14) and .59 (N = 9), respectively; when a larger number of countries were considered, the correlation was .84 (Veenhoven, 1991). It was argued that national happiness was highly correlated with national income and unlikely to be based solely on relative standing within the nation. Instead, it is more likely that happiness is based on the fulfillment of

basic and psychological needs afforded by income, which is an ***absolute standard***, rather than one's ***relative income standing*** within a nation.

This debate between the two viewpoints – relative versus absolute standards – has continued to the present day. However, the scope of the debate has narrowed as accumulated evidence shows that there is a substantial correlation at the nation level between income and happiness at above .80 (Deaton, 2008; Sacks, Stevenson, & Wolfers, 2012), with little to no evidence of satiation (Stevenson & Wolfers, 2013). Further, time-series and panel analyses of a large number of nations have shown a positive relationship between income and happiness over time (Diener, Tay, & Oishi, 2013; Sacks et al., 2012; Veenhoven & Vergunst, 2014). Currently, it is acknowledged that while in the short run income and happiness may be associated, it is argued that this association does not hold in the long run (10 years or more) as shown in 34 nations (Easterlin, McVey, Switek, Sawangfa, & Zweig, 2010). Different pieces of evidence point to valid arguments from both viewpoints: while there is strong evidence that absolute income contributes to happiness; it suggests that relative income plays a role in happiness over time.

Another source contributing to the debate has stemmed from studies on individual-level income and happiness. Initial work on a small sample of lottery winners showed no long-term increases in happiness and this has been thought to show that individual income does not enhance happiness (Brickman, Coates, & Janoff-Bulman, 1978). Furthermore, meta-analytic evidence revealed a small effect size of .18 (k = 38) between household income and SWB (Howell & Howell, 2008). Despite these initial findings suggesting little to no relation between income and SWB, more recent work proposes otherwise. A longitudinal study with a random sample of about 33,000 individuals, has shown that after two years, lottery winners exhibited greater SWB as compared to non-lottery winners (Gardner & Oswald, 2007). Furthermore, it has been proposed that the correlational effect size between income and SWB can be misleading as it masks actual mean level differences between the rich and poor. Correlations as small as r = .09 correspond to a mean difference of d = .40 between the richest and poorest in representative nation samples; and a low correlation of r = .32 corresponds to a mean level difference of d = 1.23 between the richest and poorest (Lucas & Schimmack, 2009).

Apart from debates on the predictor side of the equation, that is, whether income exerts changes to SWB, debates have also occurred on the outcome side of the equation; that is, whether SWB is changeable in the long-run. A key landmark heritability study on SWB demonstrated that test-retest correlations of SWB over 5 to 10 years has a heritability estimate of 80%, thereby supporting the claim that SWB is fairly immutable (Lykken & Tellegen, 1996). By extension, income effects would have little influence on SWB. Nevertheless, the heritability estimate of 80% is based on the stable variance over time which is around 50% of the total variance. Therefore, around 60% of the total variance in SWB has changed over time and the conclusion of immutability is too strong (Tay & Kuykendall, 2013). Overall, there is evidence that while SWB has some degree of stability, it is also malleable and can systematically change over time (Diener, Lucas, & Scollon, 2006; Tay & Kuykendall, 2013).

In general, the evidence on balance is supportive of a robust relation between income and SWB (Frank, 2012; Veenhoven, 1991; Veenhoven & Hagerty, 2006). Yet, on many accounts, income does not seem to be as strongly related to happiness over time as we would intuitively suppose (Aknin, Norton, & Dunn, 2009). We propose that this is the consequence of concomitant contrasting effects. The relative viewpoint exemplifies the negligible effect of income on happiness (Clark, Frijters, & Shields, 2008; Easterlin, 1974; McBride, 2001) whereas the absolute viewpoint exemplifies the strong positive effect of income (Hagerty & Veenhoven, 2003; Sacks et al., 2012; Veenhoven, 1991; Veenhoven & Vergunst, 2014). Pointing to coexistent and concomitant effects, research has shown that adaptation occurs (attenuated income-SWB relation) in the long-run although income increases with happiness (Hagerty & Veenhoven, 2003). This example suggests that contrasting effects can both hold, but there may be instances or situations when one of these contrasting effects may be stronger or weaker (e.g., short-term versus long-term).

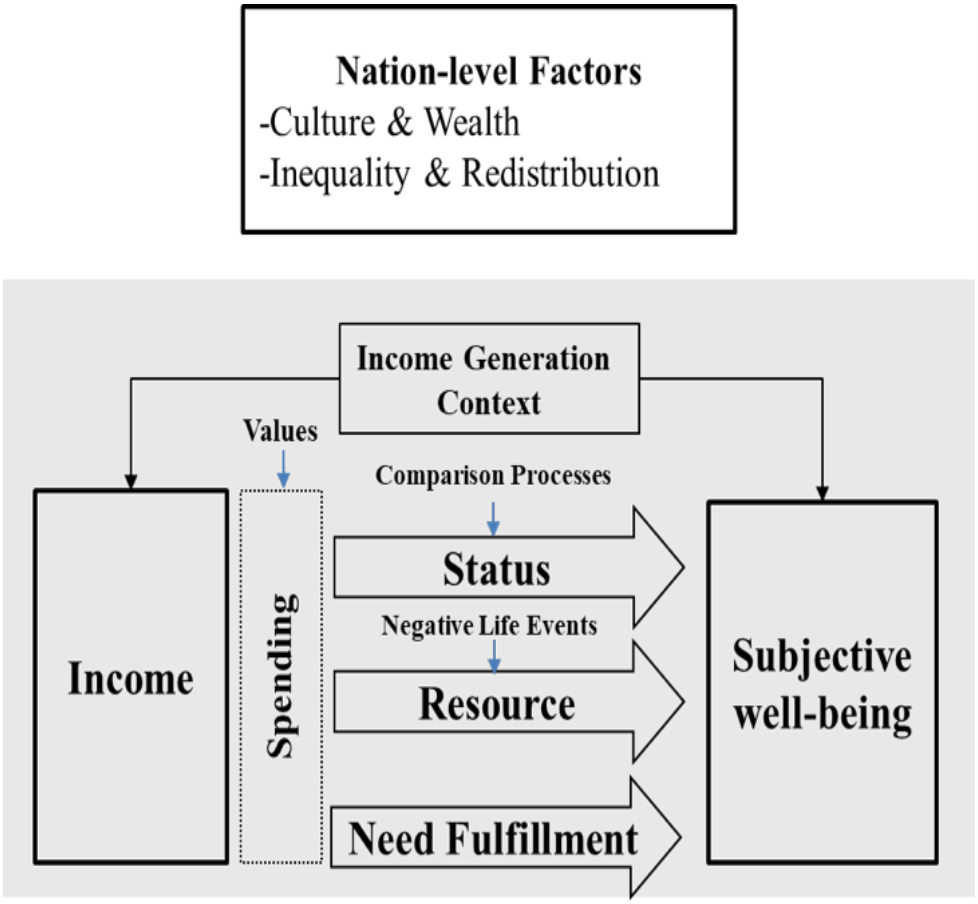
Based on the debate and findings, we highlight several aspects that need to be recognized in organizing this integrative conceptual model. It is important to consider the contrasting posited mechanisms for how income may or may not lead to SWB. Critically, because this debate has emerged from primarily two different levels of analysis (*viz*. national-level and individual-level), the processes of how income may exert effects on SWB would require specificity at different levels. For instance, the issue of income distribution exerting effects on SWB pertains to communities and nations rather than individuals (Oishi & Kesebir, 2015). Moreover, it will also be critical to understand the moderating effects of national-level income on the relation between individual-level income and SWB (Tay, Morrison, & Diener, 2014).

Beyond this debate, there is growing recognition that the way income is spent also contributes to whether individuals achieve SWB (Dunn, Aknin, & Norton, 2008). This issue of how income is spent and

redistributed in society is also relevant at the national level (Diener et al., 2013). Finally, another key factor that has not been thoroughly considered is the context in which income is earned. It has been proposed that the cost of earning income is that it has to be earned and the work context may serve as a source of dissatisfaction (Kaun, 2005; Pouwels, Siegers, & Vlasblom, 2008). However, this issue appears to be more complex as organizational psychologists have shown that work can also be a major source of satisfaction depending on the job attributes (Hackman, Pearce, & Wolfe, 1978). By extension, at the national level, the type of labor market needs to be considered as well as a key confounding variable in the income-SWB model.

Based on aforementioned issues, we propose that key factors for inclusion in the conceptual model include: (a) different levels of analysis; (b) income expenditure; and (c) the income generation context. A multilevel framework of the key mechanisms and moderators is presented in Figure 1. We will expound on aspects of these framework in the following sections. Specifically, we discuss the different contrasting mechanisms, income expenditure, and income generation context at both the individual and national level.

Figure 1. Integrative multilevel framework linking income and subjective well-being



Mechanisms Underlying Positive and Nonpositive Effects of Income on SWB

In this section, we provide an organizing framework for understanding the differences in the relative versus absolute viewpoints of income and SWB. Instead of using the terms relative and absolute, which emphasizes social-cognitive mechanisms, we use the terms positive and nonpositive because these terms cover a broader array of mechanisms. We review and compare the contrasting mechanisms posited by the opposing viewpoints. In doing so, we consider what potential mediators and moderators may underlie the differences in perspective. This can serve to elucidate differences and enable a more rigorous examination of the income-SWB relation. Before presenting the specific mechanisms, however, it is useful to describe different views of income as this is pertinent understanding the proposed mechanisms.

Views of income. We propose that that it is helpful to consider that income has both symbolic and functional properties. Income is symbolic because it can demonstrate social standing (e.g., socioeconomic status) and is a symbol of control, and even viewed as a symbolic resource to obtain love (De Vries, 2007).

Income viewed in this manner corresponds to the first arrow in Figure 1 where income is primarily viewed in a symbolic manner (and high status goods are purchased to signal high income). Generally, a symbolic view of income corresponds to the idea that income does not have positive effects on SWB. Having more income increases SWB, comparison effects reduce the positive effects to nugatory in the long run.

The functional property of income is demonstrated in two ways: (1) as a resource that buffers against major life events (e.g., illnesses, unemployment), daily life hassles, and inconveniences (e.g., purchase of help); and (2) as a means to obtain goods and services that are need fulfilling (Diener et al., 2013; Tay & Diener, 2011). Generally, an emphasis on the functional view of income is often tied to a positive perspective where income enhances SWB. Points (1) and (2) correspond to the "Resource" and "Need Fulfillment" arrows in Figure 1, respectively. Generally, a functional view of income corresponds to the positive view of income on SWB.

Uncovering these viewpoints about income will serve as a focal point linking the different mechanisms outlined. In the following, we discuss the three mechanisms of status, resource, and need fulfillment. The moderators for status and resource mechanisms are comparison processes and negative life events, respectively. These variables are presented in Figure 1.

Status. Income has direct positive effects on SWB through its symbolic value such that, in comparison to the poor, individuals with higher income would be happier. Apart from the raw value of income, this could also occur through the purchase of status-building commodities. For instance, conspicuous consumption is primarily meant to signal high income and greater social status (Corneo & Jeanne, 1997). However, it has been argued that the symbolic value of income can be unhinged from the objective value of income because of inherent subjectivity. This is because happiness is fundamentally dependent on the extent objective income is higher than subjective standards for income, but these subjective standards continually change with context and income level (e.g., Easterlin, 1974). Specifically, the potentially positive status effect of income is substantially moderated by comparison processes such that any positive effects on SWB are negated.

How are comparison processes enacted over different contexts and income levels? With regard to context, a key driver of changing standards is social comparison. It is proposed that the proximal social context in which an individual is situated provides the referent point for acceptable levels of income. For example, the standard of income may be dependent on one's living context so that the affluence of neighborhoods may have negative effects on SWB over and above individual income (e.g., Luttmer, 2005). Nevertheless, proximal social contexts may exert different effects from macro-contexts. It has been shown that the affluence of nation contexts have positive effects on life satisfaction over and above individual income (Tay, Morrison, et al., 2014).

With regard to income, it has been proposed that the higher the income, the higher the aspiration. Therefore, the gap between levels of income and aspired levels of income hinders the extent happiness can be increased through a rise in income (Frey & Stutzer, 2002). Moreover, as income rises, the referents for social benchmarking changes. Indeed, Duesenberry (1949) proposed that individuals tended to compare their own income to the income of others with a similar or higher status. Corresponding research shows that income comparison effects are asymmetric and primarily upward (Ferrer-i-Carbonell, 2005). Finally, as income rises, consumption habits may also change, leading to appetites for better goods and services, thereby raising standards for income (Hudders & Pandelaere, 2011).

The status effect and the moderating comparison processes discussed so far pertain to the individual level as they are psychological in nature. At the nation level, the direct relation between income and SWB is complex. On one hand, it has been proposed that income comparisons occur within a nation leading to positive within-country income-SWB relations but a negligible income-SWB relation between countries (Easterlin, 1974). This assumes that residents within a country have a common national standard by which to compare income to. On the other hand, the rationale for limited direct effects because of changing standards implies that individuals use more proximal standards (i.e., high income individuals use other high income individuals) or more personal standards (i.e., personal aspiration based on income level), with research showing that there is diversity in the reference group (Oswald & Senik, 2010). If such specific proximal/personal standards are used, when aggregating to the nation level, we would expect the effects of income to be limited. Yet, empirical studies show that the between-country income-SWB relation is estimated at $r = .84$ (Veenhoven, 1991). This suggests that comparisons may even occur on a common global standard due to globalization and media access (Diener et al., 2013).

Resource. Apart from its symbolic value, income can also be viewed as a resource. Drawing on Conservation of Resource theory (Hobfall, 1989, 2002), individuals seek to acquire and maintain resources. The possession of resources can exert positive effects on well-being and buffer against negative life events; a reduction in resources however can exert negative effects on well-being. Therefore, income

can generate well-being and buffer against stress generated from negative events (e.g., accidents, unemployment). On the other hand, having low income or experiencing a loss of income will be detrimental to well-being. Past research has shown that having the resource of money was predictive of life satisfaction (r = .30) and its magnitude not far behind social resource (r = .40) (Diener & Fujita, 1995). As a resource, income can also serve to overcome inconveniences and hassles thereby improving or maintaining happiness as individuals can engage in more enjoyable activities and obtain paid help for less enjoyable activities such as chores (cf. Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004).

A key moderator of income from a resource-buffering perspective would be the degree to which individuals experience negative life events. High income individuals who have a large pool of financial resources are protected from life "shocks" by maintaining or compensating for negative life events or conditions. For instance, Philippe Pozzo di Borgo became a paraplegic after a car accident. However, due to his wealth, he was able to maintain his quality of life by obtaining the service of a full-time domestic assistant. As such, the resource view of income is indicative of an ameliorative function (i.e., a safety net) such that downturns more visibly reveal the relation between income and happiness.

A further consideration when viewing income as a resource is that the strength of effects may be modulated by the level of income. At higher levels of income, where income serves primarily as a resource-buffer, the accumulation of wealth may not exert strong direct effects as these effects are contingent on the occurrence of negative life events and serve an ameliorative function. Therefore, at the upper range of income levels, we may not see robust income effects. On the other hand, at low levels of income, individuals would constantly experience stress and lowered SWB because of the insecurity of insufficient financial resources according to Conservation of Resource theory. This may even be compounded with negative life events. As such, at lower levels of income, we would observe stronger direct effects of income on SWB.

At the national-level, national income can serve to buffer against national and local negative events. For example, in the event of a natural disaster, nations have greater economic capacity to mobilize necessary financial aid and provide material needs for individuals affected by the event. Income serves as a buffer. From an analysis of how disasters affect poor and rich countries, United Nations Secretary General Ban Ki Moon underscores this point in the 2016 International Day for Disaster Reduction, "High-income countries suffer huge economic losses in disasters, but people in low-income countries pay with their lives."

Need fulfillment. From both organismic (Maslow, 1943) and evolutionary perspectives (Kenrick, Griskevicius, Neuberg, & Schaller, 2010), money can be viewed as a means to obtain payment for goods and services and possessing higher income can enable individuals to fulfill physical and psychological needs. The idea that need fulfillment is tied to well-being has been borne out in multiple studies (Oishi, Diener, Lucas, & Suh, 1999; Sheldon, Elliot, Kim, & Kasser, 2001). Strong evidence for this idea was demonstrated in a global study of 124 nations, where the effects of income were fully mediated by the fulfillment of basic and psychological needs (Tay & Diener, 2011).

At the national-level, it has been shown using cross-lagged analyses that national income predicts SWB, but not the converse. Importantly, when income rises along with national need fulfillment, there is a greater increase in SWB (Diener et al., 2013). This suggests that income increases SWB via need fulfillment at both the individual and nation level.

Comparison of perspectives and mechanisms. Differences in the perspectives and the mechanisms provide an integrative view of how income may lead to happiness – and the moderators that potentially affect the causal strength. There appears to be a weaker proposed effect of income when viewed as symbolic compared to functional. The symbolic view emphasizes status is a means for enhancing SWB, but comparison effects reduce the positive effects. Although if comparison effects are based on global standards due to globalization, income may still be linked to SWB. The functional view espouses income as a potential resource that could provide security and buffer against potential negative events, and as a means to fulfill fundamental human needs. Between the mechanisms of resource and need fulfillment, stronger arguments can be made for need fulfillment as exerting more robust effects on SWB. Resources fundamentally serve to provide some level of basic security and ameliorative function in hardship but do not address a range of psychological needs that would lead to greater happiness.

Spending and Distribution

While past work has often focused on whether income is associated with or leads to SWB, a critical mediator of how income is spent – as shown in Figure 1 – has recently attracted more attention (Dunn, Gilbert, & Wilson, 2011). We believe that this variable is crucial because it specifies how income is allocated among the different mechanisms (e.g., status, resource, need fulfillment) – which may or may not have strong promotional effects on SWB.

At the individual level, when income is symbolically used and allocated toward increasing status, its effects on SWB are weaker compared to allocating to as a resource or toward need fulfillment. An experimental study has shown that reminding individuals of wealth reduces the extent individuals savor experiences, which refers to the enhancement or prolongment of positive emotional experiences (Quoidbach, Dunn, Petrides, & Mikolajczak, 2010). On the other hand, when income is allocated as a resource, its effects are made especially manifest by buffering against negative events. The salutary effect on SWB of the resource mechanism is not as pronounced as when it serves to protect decrements in SWB. Finally, when income is allocated toward need fulfillment, positive effects are likely to hold. The current literature on spending demonstrates that prosocial spending can promote happiness (Dunn et al., 2008). This relationship between autonomous prosocial behaviors – which would include prosocial spending – has been shown to be mediated through psychological need satisfaction (Weinstein & Ryan, 2010).

In our model, values are a potential moderator of spending patterns. Individuals who have greater values and identity placed on prestige would allocate income toward conspicuous consumption (Ottmar & Wicklund, 1989). Emphasizing appearances of financial success could be lead to habitual compulsive purchases that do not promote SWB in the long term (Roberts & Pirog, 2004). By contrast, individuals who place less value in these would place more emphasis the functional aspects of income rather than the symbolic aspect of income. As a resource, individuals who develop values toward thrift would likely allocate income into savings (Anderson & Nevitte, 2006). Further, prosocial values would direct individuals toward spending on others that can fulfill needs of autonomy, relatedness, and competence which promote SWB (Weinstein & Ryan, 2010).

We note that values themselves provide an implicit or explicit weighting of what matters to individuals for their well-being. Individuals with higher levels of extrinsic work motivation (i.e., working for pay and rewards) exhibited a strong relation between income and SWB than individuals with intrinsic motivation (Malka & Chatman, 2003). Further, individuals living in richer nations, which likely emphasize income, demonstrated a stronger association between personal income and SWB (Tay, Morrison, et al., 2014). While this may reduce some of the effects of allocation between income and SWB, this does not completely negate the effects.

At the national level, values can also guide how nations spend and distribute the financial resources which in turn has effects on SWB. In a review of inequality and SWB (Tay, Oishi, & Diener, 2017), cross-sectional, and longitudinal evidence revealed associations between income inequality and lower life satisfaction. An analysis of the Gallup World Poll of 163 nations (2005 to 2013) showed that the GINI index calculated from annual household income correlated -.44 with national life satisfaction (Diener & Tay, 2015). Moreover, a cross-national study found that greater national progressive taxation was related to higher life satisfaction and this association was in part mediated by availability of affordable housing, public transportation system, education system, and even air quality (Oishi, Schimmack, & Diener, 2012). This strongly suggests that how nations spend and distribute their financial resources will matter for SWB.

Income Generation Context

A key issue that is often neglected in understanding the relation between income and SWB is the income generation context. At the individual level, for a large proportion of people, full-time or part-time employment is the primary means by which they earn their income. At the same time, these same individuals spend a large proportion of their waking hours at work. Therefore, it is important to examine how this income generation context can possibly lead to both income and (un)happiness. This is analogous to the idea that individual differences may lead to the association between both wealth and SWB (Luhmann, Schimmack, & Eid, 2011).

From the context of work, income and SWB may be positively related because the types of jobs that pay more also provide greater psychological need fulfillment. From the perspective of the Job Characteristics Model (Hackman & Oldham, 1976), high-paying professional and management-level jobs often have characteristics such as skill variety, task significance, task identity, autonomy, and feedback, resulting in greater fulfillment of psychological needs and hence SWB. In this sense, it may be that income and SWB are reflections of the type of work one engages in. This is not to suggest that higher income would not lead to greater job satisfaction and overall SWB, as pay satisfaction and pay equity are important components of overall satisfaction (Hulin, 1991).

Higher income jobs may also be tied to higher prestige occupations. In seeking to disentangle the effects of income and work status, Di Tella and colleagues (2010) found that status change in terms of occupational prestige had more robust and longer lasting effects on happiness as compared to income change (Di Tella, Haisken-De New, & MacCulloch, 2010). This suggests that to the extent that income and occupational prestige are tied together, we would observe a stronger relation between income and happiness. It also suggests that the prestige of the occupation may be more proximal to happiness than

income itself.

Conversely, there alternate reasons to suspect that income may also be detrimental to SWB. This is because income as an extrinsic reward of work has been argued to be ultimately dissatisfying for individuals according to Self Determination Theory (Ryan & Deci, 2000). Further, having goals for financial success at work can undermine more important needs such as relatedness (Kasser, 2002). Another reason for why income does not lead to happiness is framed from a motivational perspective whereby the narrow pursuit of income-generation activities through work may be at the expense of other key happiness inducing life domains such as leisure and family. It has been proposed that because of higher opportunity costs of time use, individuals often forsake relationships and even health (Becchetti, Trovato, & Bedoya, 2011; De Vries, 2007). For example, it has been shown that individuals primed with money spent more time working rather than socializing (Mogilner, 2010); they also spent less time savoring experiences (Quoidbach et al., 2010).

At the national level, the income generation context may be represented by the national labor force (i.e., participation in labor, and the types/levels of occupations) and types of industries (i.e., broad occupational contexts) in which most individuals within the national economy are in. In addition, there needs to be a consideration of employment rates within the population as these labor market conditions also predict national SWB (Tay & Harter, 2013). Future research needs to consider whether controlling for these factors will show a similarly robust and strong relation between GDP per capita and SWB at the national level (Diener, Ng, Harter, & Arora, 2010).

Future Issues to Consider

The review and synthesis of the literature has also led to new questions that we have about income and SWB both methodologically and conceptually. We note several issues to consider for future research. Foremost, while most of the research has been on income and SWB, there has been a recognition that income is only one aspect of wealth, more broadly reflecting the economic circumstance of individuals and societies. Some research has now shown that both income and wealth predict SWB (Headey & Wooden, 2004), although it appears that the relation between broader economic status variables have a greater relation to SWB (Howell & Howell, 2008). This suggests that research should consider the wealth-SWB relation (e.g., Fischer, 2007) and other types of economic status variables such as consumption (Headey, Muffels, & Wooden, 2007), debt (Tay, Batz, Parrigon, & Kuykendall, 2016), and spending (Dunn et al., 2011).

Given the multilevel context of income and SWB, an important aspect to consider in examining national, community, or group level income is the distribution of income among members. The way income is distributed or skewed can have differential effects over and above the average level of income on SWB (Berg & Veenhoven, 2010; Diener & Tay, 2015). The other implication is in deciding whether the mean or median is a better representation of group level income. In an examination of the neighborhood income, it was presented that median rather than mean level income was a better proxy for studying the effects of neighbor income effects on personal happiness (Firebaugh & Schroeder, 2009). Others have conceptualized the importance of the range and skew of income within a community as affecting personal happiness (Hagerty, 2000). The idea of income distribution should also lead to care when targeting specific groups of individuals as the relation between income and SWB may be attenuated due to range restriction. For example, research has shown that the relation between income and SWB is low in extremely poor and moderately poor groups (Lever, 2004).

A multilevel understanding of income and SWB should also help researchers to consider the national and community contexts in moderating the effects of income and SWB. Past research has shown that national income boosts life satisfaction in wealthier nations beyond personal income (Tay, Morrison, et al., 2014). This is likely because national income provides infrastructure and conveniences that poorer nations do not have. However, at the level of communities, higher levels of community income appear to lower SWB due to social comparison effects (Firebaugh & Schroeder, 2009; Luttmer, 2005). More research will need to further examine the extent national or community contexts exert positive or negative effects on SWB beyond personal income.

As suggested in Figure 1, a multilevel context implies a consideration of culture as well. This may moderate the effects that are found in the relation between income and SWB. For instance, Caporale and colleagues (2009) found that the income reference group effect on happiness was negative for Western Europeans, but it was positive for Eastern Europeans (Caporale, Georgellis, Tsitsianis, & Yin, 2009). This may be because Eastern Europeans may regard a higher income within their reference group as a source of inspiration. This parallels a more recent finding that hope mediates that link between a positive relation between inequality and happiness in rural China, but not urban China (Cheung, 2015).

The strongest effects found for income and SWB are primarily for life satisfaction as compared to

the affective components of SWB, which include positive and negative emotions (Diener et al., 2010). In part, this may be because of income satiation effects on the affective dimensions of SWB as compared to the evaluation dimension of SWB (Kahneman & Deaton, 2010). Further, evaluations may be more closely linked to external global conditions as opposed to personal daily circumstances which are more closely linked to affect (Tay, Chan, & Diener, 2014). More research needs to examine how income can be effectively used in daily circumstances to promote SWB, including prosocial spending (Dunn et al., 2008) and experiential spending (Van Boven, 2005; Van Boven & Gilovich, 2003) to even investing in structural changes that can reduce daily hassles and increase conveniences (e.g., reducing commuting time).

Finally, another important aspect to consider is the valence of income and SWB as a possible moderator. Given that people are loss averse (Kahneman & Tversky, 1979), income gains over time may be less likely to raise SWB to the same degree as compared to losses in income. Indeed, there is now evidence that there is an asymmetry between the impact of economic gains and economic declines at the national level over time, with economic declines exerting twice the effect of economic gains (De Neve et al., 2015). Future research should seek to further validate this at the level of individuals over time. In addition, one can examine whether the impacts are similar depending on the valence of SWB indicators (e.g., positive vs. negative affect). Using a single measure of life satisfaction, there is some evidence that income is not as strongly related to high satisfaction, but more related to reducing dissatisfaction (Boes & Winkelman, 2010).

Conclusion

Interest and research on income and SWB has grown over the decades and we expect that this trend will continue to grow. Understanding and explicating when and how income will give rise to SWB will strengthen scientific knowledge and policy implications. We hope that this review and synthesis into a multilevel conceptual framework will advance research and understanding of this domain.

Abstract

In this chapter I review theory and evidence linking socioeconomic status in society to subjective well-being. Research on this topic includes studies across countries and cultures and two primary theoretical perspectives that make predictions about the direction and strength of the relationship between SES and subjective well-being—need theory and social comparison theory. This chapter suggests that both need theory and social comparison theories can explain some of the patterns of associations between SES and SWB but that both theories are underspecified to fully predict the ways in which associations between SES and SWB shift as a function of situation, culture, and context. Notably, social cognitive tendencies and cultural definitions of the self that arise from SES, may elicit differential bases for SWB and constrain researchers' ability to make complete conclusions about how SES relates to SWB. The chapter closes with an examination of lay beliefs about links between SES and SWB and their capacity to elicit future directions in research in this important domain of inquiry. This added complexity is an important next step in understanding the bidirectional relationships between money and happiness.

Keywords: Subjective Well-Being, Happiness, Social Class, Socioeconomic Status, Inequality

"It's a kind of spiritual snobbery that makes people think they can be happy without money." – Albert Camus (1956)

"I don't know what they want from me. It's like the more money we come across the more problems we see." –Christopher Wallace, Sean Combs, and Mason Betha (1999)

Earlier this year I was teaching a classroom of 65 first year MBA candidates at Yale University about the evidence linking high social status to reduced stress and greater well-being. Usually I discuss the famous Whitehall II studies, the examination of well-being and longevity of British civil service workers that has been ongoing since 1967. The work itself is perhaps the best available evidence that positively links social status with health and well-being because of the meticulous social status ranking system that the civil service uses, the huge sample size (i.e., ten thousand), the longitudinal nature of the design, and that the sample individuals all have government provided health benefits (Marmot et al., 1991). Links between higher social status at work and better outcomes with respect to stress, health, and mortality clearly suggest the role of social status in predicting well-being outcomes over time. Despite the strength of this evidence I often get vigorous pushback from the students, who will soon be entering into 60-hour work weeks at jobs in consulting, finance, and law. In these jobs, the monetary rewards are high but so is the stress: Many newly minted MBAs will burnout from these firms within the first couple of years working there, and face stiff travel demands, pressure filled deadlines, and long hours throughout their first years (Rivera, 2016).

My experience in the MBA classroom underscores why research on socioeconomic status and subjective well-being captivates the attention of scholars and lay people alike. How precisely does social status, defined based on position in society due to socioeconomic indicators like income, education, and occupational prestige, influence feelings of happiness and life-satisfaction? Is there any evidence suggesting that the anecdotes from MBAs are indicative of broader trends in large scale empirical studies? What should we make of the size of the association between social status and subjective well-being?

In this chapter I consider these questions and others related to the ongoing science linking socioeconomic status to subjective well-being (Lyubomirsky, King, & Diener, 2005). I start with a review of the basic empirical evidence suggesting links between socioeconomic status (SES) and subjective well-being (SWB) are positive and small to moderate when compared against traditional effect size metrics (Cohen et al., 1994). I approach this literature from two fundamental theoretical perspectives, the first based on resource needs and the second based on social comparisons (Diener, 1984; Diener & Biswas-Diener, 2002; Diener, Diener, & Diener, 1995; Diener, Tay, & Oishi, 2013; Ng & Diener, 2014; Pinquart & Sorensen, 2000). Finally, I return to a consideration of the initial questions that launched this chapter: Specifically, I draw on research and theory on the psychological experience of SES (Kraus, Piff, Mendoza-Denton, Rheinschmidt, & Keltner, 2012) to answer the question: Why might people high in SES believe their lives are worse in terms of well-being? In particular I am concerned in this final section with

attempting to understand what scholars might be missing from examinations of SES and SWB, in order to anticipate new areas of future research.

SES, SWB, and Individual Needs

Theoretical arguments for links between SES and subjective well-being are numerous and varied (Diener, Ng, Harter, & Arora, 2010; Diener, Oishi, & Lucas, 2003). Here we provide a detailed summary of the arguments that suggest how large SES and subjective well-being associations can be expected to be, and in turn, what factors might moderate these associations.

Links between SES and subjective well-being may depend in part on whether people's basic needs are being met by their available resources. As the argument goes, as people are able to afford the resources necessary to meet the demands and threats inherent in their environments, the impact of SES on well-being should be diminished. This theoretical argument was originally discussed by Easterlin (1974; 1995; 2001), and finds similar logic in recent work in psychology (Diener & Biswas-Diener, 2002; Diener & Lucas, 2000; Veenhoven, 1988; 1991). Importantly, this needs based explanation for links between SES and subjective well-being elicits an expectation that links between SES and well-being will be smaller in developed countries like the USA relative to developing countries where basic resource would be used to obtain physical needs, such as food, sanitation, and shelter (c.f., Maslow, 1974).

Admittedly, there is only mixed support for this needs-based explanation of links between subjective well-being and SES. Several studies conducted across different countries have provided support for this needs-based explanation (e.g., Biswas-Diener & Diener, 2001; Camfield, Choudhury, & Devine, 2009; Diener, Oishi, & Lucas, 2003; Fuentes & Rojas, 2001; Kim, 1998; Zavisca & Hout, 2005). For instance, within country analyses tended to produce smaller associations between SES and subjective well-being (r = .06 to .15; Diener & Oishi, 2000; Diener, Sandvik, Seidlitz, & Diener, 1993; Easterlin, 1974; 1995; 2001; Rojas, 2004) than do studies in developing nations (r = .10 to .36; Howell & Howell, 2008). In more recent work, surveys of 123 countries found that reports of need fulfillment accounted for income associations with SWB (Tay & Diener, 2011). However, these patterns are not always observed: A recent meta-analysis updating these findings with a far larger database of research finds no moderation by development status and a small association (r = .11; Tan, 2016). This meta-analysis is notable because of its total sample size (N = 3,249,838) and number of independent samples (k = 144).

Overall, then we find only mixed support for need based explanations of associations between SES and SWB. The evidence is not yet definitive and thus more work needs to be conducted in this domain of research. One point of contention appears to be how people might define needs. For instance, cross-national comparisons involve a complex calculation of whether or not an individual's needs are being met, without potentially thinking critically about how need is culturally bounded and situated (Henrich, Heine, & Norenzayan, 2010). That is, both the costs of fulfilling ones needs might shape the strength of association between SES and SWB as well as how an individual defines those needs, or sees them as central to living (e.g., Diener, Suh, Lucas, & Smith, 1999). Relatedly, the detail at which researchers assess subjective experiences of need might explain some of the inconsistency in research testing need theory. Studies that examine individual differences in daily experiences of need might be better equipped to answer the question of need-based influences on SWB. Such studies would also be a remarkable advance on prior research because such fine-grained analyses of need could show associations with SWB in longitudinal designs that could delineate the directionality of associations between SES and SWB.

Aligning with this perspective on obtaining finer detail in need experiences, the second perspective on SES links with SWB relies on understanding daily experiences in comparisons between self and others. How these experiences of economic comparison shape basic feelings of subjective well-being is a rich and growing area of research.

Beggars and Millionaires: Social Comparison and SWB

"Beggars do not envy millionaires, just other beggars who are more successful." –Bertrand Russell (1930)

A second theoretical perspective indicates that links between SES and subjective well-being may depend on the relevant comparisons people make to others, to past circumstances or selves, or to some fluctuating standard of living. Theories that rely on some form of social comparison make a few different predictions about SES and subjective well-being links. First, expectancy based arguments would indicate that the strength of the association between SES and SWB depends on changing standards, such that individuals are higher in SWB when their current level of economic resources is greater than what they expect it to be based on an assessment of their current social group (Clark, Frijters, & Shields, 2008; Clark & Oswald, 1998; Diener & Fujita, 1997).

Several lines of evidence find both direct and indirect support for this expectancy argument. For instance, Black Americans, a low status racial group in America, might have lower standards for how much

resources they can attain in society due to prejudice and discrimination. Thus, they may derive higher SWB from lower levels of SES (Diener et al., 1993). In support of this assertion, data from the general social survey finds that Black people tend to report higher self-esteem than other racial groups in America, despite having lower levels of income and education (Cohen et al., 2017).

Expectancy effects may also lead individuals to feel enhanced SWB if their achievement outstrips some objective standard. Consistent with this prediction, higher income levels are likely to predict increased happiness only in conditions where income changes are rapid enough to outstrip people's expectations (Diener et al., 1993; Graham, 2005). Similarly, the discrepancy between current and future desired resource levels tends to predict SWB more than the discrepancy between current and actual resource levels (Stutzer, 2004). All told, this research indicates that expectations based on future selves play a role in shaping links between SES and SWB.

Social comparisons may influence SWB with respect to comparisons to others in one's relevant social groups (Festinger, 1954). Comparisons of resources between the self and others are a frequent and unavoidable part of social life. Several studies suggest that aspects of wealth and social status are visible in the clothes people wear (Kraus & Mendes, 2014; Gillath, Bahns, Ge, & Crandall, 2013), in nonverbal behaviors (Kraus & Keltner, 2009) and physical characteristics of individuals (Mast & Hall, 2004; Bjornsdottir & Rule, 2017). More recent work finds that people can provide others with information about how much money they make and their educational attainment based on paralinguistic cues in speech (Kraus, Park, & Tan, 2017; Labov, 1972). Certainly, societal segregation based on schools and neighborhoods is also a source of accurate perception of SES (Desmond, 2016; Massey & Denton, 1993).

All told, there are many means by which individuals can compare on SES dimensions, and thus, these comparisons can influence SWB in a variety of ways (Bourdieu, 1979). For instance, nurses who made frequent comparisons to colleagues at work about income and status tended to be less satisfied with their jobs than did those who made fewer comparisons (Buunk, Schaufeli, & Ybema, 1994). As well, in the aforementioned meta-analysis, subjective perceptions of social class which require participants to compare and rank themselves relative to other community members tend to predict SWB at twice the magnitude ($r = .21$) of objective indicators of income and educational attainment ($r = .11$; Tan, 2016), though common method variance (i.e., self-reports of both social class and SWB) may be a potential source of the size difference in this association (Cohen et al., 2008; Adler, Epel, Castellazzo, & Ickovics, 2000; Kraus, Adler, & Chen, 2013).

The Whitehall II data can also be thought of as evidence for social comparisons influencing well-being. In these data, civil service workers differ in rank much more than they do in terms of income and not at all in terms of health benefits (Marmot et al., 1991). And yet, even with these stark similarities of needs being met, higher ranked civil services workers have much more positive health outcomes in terms of self-reports related to SWB, and objective health indices such as heart disease and mortality rates.

Other indirect evidence in the realm of economic inequality is indicative of the influence of comparison processes on SWB. For instance, even when controlling for objective material resources, several studies find that unequal resource sharing predicts increases in broad societal problems related to poor health care practices, delinquencies, and societal dissatisfaction (Wilkinson, 1992; Wilkinson & Pickett, 2006), as well as reports of lower SWB (Oishi, Kesebir, & Diener, 2011; Cheung & Lucas, 2015a; 2015b). Related work finds that living near wealthier neighborhoods is associated with poorer health among people living in less wealthy neighborhoods (Pellowski, Kalichman, Matthews, & Adler, 2013), and living around wealthier neighbors is associated with lower levels of SWB (Luttmer, 2005).

Studies more directly testing comparison accounts of associations between SES and SWB yield similar converging evidence. Boyce and colleagues (2010) used more than 86,000 respondents from the British Household Panel Survey to calculate a ranking based on whether an individual had higher income relative to others. The researchers then compared this ranking metric's association with life-satisfaction to the association between absolute income level and life-satisfaction. The results showed that relative ranking predicted life-satisfaction more strongly than did absolute income (Boyce, Brown, & Moore, 2010).

In more directly related work examining social comparisons, Anderson and colleagues (2012) examined associations between SWB and sociometric status, defined as prestige and respect within ones important social groups. Sociometric status, the logic goes, is a locally defined form of social status that is determined through interactions with people and groups that an individual cares about and spends a great deal of time with. Across the studies, sociometric status with friends, co-workers, and class mates tended to predict SWB more strongly than did absolute SES (Anderson, Kraus, Galinsky, & Keltner, 2012).

Despite this consistent evidence there are a few studies where comparisons do not predict SWB (e.g., Diener & Fujita, 1997). For instance, among a sample of county employees in Wisconsin, social comparisons contributed virtually nothing to pay satisfaction ratings after accounting for equity concerns,

occupation type, past employment, and noneconomic job standing (Berkowitz, Fraser, Treasure, & Cochran, 1987). Whether social comparison effects emerge after accounting for related constructs like social status, occupation type, and equity concerns is a topic of future research. Related to this point, that people high in trait neuroticism compare more than others is also an area of future research (Gibbons & Buunk, 1999), in that social comparison effects related to SWB may emerge in part because of the elevated trait anxiety levels of the people doing most of the comparing.

Overall, there is systematic and fairly consistent evidence linking social comparison perspectives to patterns of associations between SES and SWB, and this theoretical perspective remains promising in helping researchers to predict these relationships. Still, there is sufficient work that needs doing in this research. Notably, social comparison theories are not particularly specific about which comparisons are likely to be most important or most active in predicting SWB, and thus, thinking critically about how cultures and position influence these comparisons is a topic of future research. As some studies suggest, cultural beliefs about the importance of objective standards of social judgment might influence whether people compare their resources to objective criteria about wealth (e.g., median income) or to more subjective criteria (e.g., status symbols, educational prestige, dress). For instance, in one study objective standards of SES predicted well-being reports more in Japan than they did in the USA, where subjective reports of social class were a better predictor (Curhan et al., 2014). That Japanese participants relied more on objective standards of economic standing rather than their own subjective assessments potentially illustrates a cultural differences in the sorts of economic and social comparisons that people may value (e.g., Choi, Kim, & Park, 2015; Chung & Mallery, 1999; Hofstede, 1984; Markus & Kitayama, 2003; 2010).

Lay Beliefs about SES and SWB

Popular narratives in the USA tend to associate hard work with success, and in fact, the American Dream of equal opportunity and the possibility of prosperity for all is predicated to an extent on individuals obtaining valued economic and psychological states based on their merits alone. This narrative is a powerful influence on the ways in which individuals explain the structure of society. For instance, beliefs in the American Dream tend to lead people to see societal inequalities as more fairly and justly determined than they could possibly be given the sheer magnitude of inequality in society. That is, despite wide disparities between CEO pay relative to the average worker (Kiatpongsan & Norton, 2014), or the accumulation of wealth in the top income decile (Norton & Ariely, 2011), people tend to see societal inequality as fundamentally determined by effort, talent, and merit (Jost, Banaji, & Nosek, 2003; Kay & Jost, 2003; Kraus & Tan, 2015). In some ways these beliefs in meritocracy motivate striving and achievement (Anderson, Brion, Moore, & Kennedy, 2012; Johnson, Blumstein, Fowler, & Haselton, 2013), whereas they also obscure real trends in inequality—that society is much more unequal than we want it to be or that we realize (Norton & Ariely, 2011), or that intergenerational mobility is low (Davidai & Gilovich, 2015). How these beliefs systems may shape beliefs about links between SES and SWB is the topic of this third section.

Just as narratives of mobility and the American Dream are inconsistent with reality so too are narratives about stress and work-related well-being: With only a cursory examination of articles in leading business magazines (e.g., Petrie, 2017) and books (e.g., Seppala & King, 2017) one finds a wealth of advice about how CEOs and managers can cope with the tremendous amount of stress their jobs place them under. In fact, popular lists of stressful jobs indicate jobs as military personnel and firefighter have similar stress levels as higher SES jobs such as broadcaster, public relations executive, and senior corporate executive (Renzulli, 2016). However, despite these lay beliefs about job stress, empirical investigations of associations between SES and subjective well-being, many of which we have reviewed above, clearly delineate a positive association between SES and SWB.

Research on stress finds an even stronger positive relationship: In an examination of high level corporate managers and their subordinates, managers consistently felt less anxiety and showed lower levels of glucocorticoids in their saliva, a measure of physiological stress (Sapolsky, 2004), than did their subordinates (Sherman et al., 2015). As well, all-cause mortality is consistently higher among lower, relative to higher, SES people (Adler et al., 1994; Kawachi & Kennedy, 1997; Kennedy, Kawachi, & Prothrow-Stith, 1996) even in studies like Whitehall II where all participants share the same health benefits (Marmot et al., 1991).

Where does this disconnect between lay beliefs about links between stress or SWB and SES and the actual associations come from? Critically, we contend that beliefs suggesting that it is more stressful and less satisfying at the top serve to promote adherence to the American Dream and increase tolerance for inequality in society. In effect, lay beliefs that CEOs face stress feed into beliefs about the merit-based organization of society and suggest that success is built primarily based on hard work and effort.

Inequalities, even ones of huge scale, are justified given the theoretical magnitude of the physiological toll they might take on the highest status individuals. In effect, if CEOs suffer high stress lives, non-CEOs might not begrudge their 300 to 1 salary advantage relative to the average factory worker (Kiatpongsen & Norton, 2014).

This explanation aligns with recent work suggesting that individuals tend to highlight the headwinds they tend to experience in their lives, which serve these ideologies of merit and deservingness. For instance, empirical work finds that people have a much easier time of bringing to mind the things they struggle with (i.e., headwinds) rather than the advantages they have benefited from in the past (Davidai & Gilovich, 2016). In related work, a recent ethnography of elite business hiring in law, consulting, and finance, successful job applicants tended to perform better to the extent that they crafted relatable stories about their capacity to overcome significant personal obstacles (Rivera, 2016).

This disconnect between lay beliefs and actual connections between SES and SWB also highlights the importance of future research providing finer detail assessments of both daily experiences of SES and of SWB. On the side of SES, linking shifts in attainment of basic needs or in comparisons with important others to fluctuations in experiences of SWB, particularly through the use of experience sampling methods, is likely to provide significantly greater understanding of lay beliefs about SWB. For instance, it is possible that the job stressors experienced by high SES individuals do lead to reductions in well-being for these individuals that are temporary or that significantly change moods or cognitive assessments of life-satisfaction in enduring and persistent, but these shifts nevertheless stay higher on average, than the SWB reports of lower SES individuals. Likewise, it might be the case that the monetary rewards received by higher SES workers account for the satisfaction of needs that then reduces the psychological impacts of any stress experienced at work. An experience sampling methodology that takes into account both need fluctuations and the comparisons one experiences in important social situations might highlight how differential correlates of SWB operate in opposition versus in unison. Along similar lines, high SES jobs may disproportionately expose workers to opportunities for job crafting and autonomy that predict enhanced SWB (Wrzesniewski & Dutton, 2001; Wrzesniewski, McCauley, Rozin, & Schwartz, 1997).

Lastly, it is possible that lay beliefs are disconnected from the reality of links between SWB and SES because people tend to discount the role of power and autonomy in experiences of SWB. In short, there is a wealth of research indicating that having some control over life outcomes, even if it is mundane or illusory, can have positive benefits on feelings of happiness and well-being. In survey research, feelings of power and control are strongly related to feelings of authenticity and autonomy (Kifer, Heller, Perunovic, & Galinsky, 2013), which are also strongly correlated with subjective well-being (Kraus, Chen, & Keltner, 2011). For instance, in the aforementioned study on high ranking manager stress, a sense of control tended to explain why managers felt less anxiety than their subordinates (Sherman et al., 2012). In the research on sociometric status and SWB, people who were higher in sociometric status tended to experience heightened SWB in part due to its correlation with heightened sense of power and autonomy (Anderson, Kraus, Galinsky, & Keltner, 2012). Given these data, it is likely that individuals do not account for their elevated control and autonomy relative to others, nor do they account for how much this freedom plays a role in eliciting positive SWB. In fact, prior research indicates higher SES individuals tend to overemphasize the controllability of everyday life events and circumstances relative to their lower SES counterparts (Kluegel & Smith, 1986; Kraus, Piff, & Keltner, 2009; Kraus, Piff, Mendoza-Denton, Rheinschmidt, & Keltner, 2012; Varnum, 2015; Varnum, Shi, Chen, Qiu, & Han, 2014). Based on this work, a lack of understanding of cultural or positional differences in control beliefs may account for some of the discrepancy in lay beliefs about SES and SWB.

Caveats and Future Directions

Overall then, this chapter has examined prior theory and research linking SES and SWB. Importantly this is a rich and influential empirical literature with a number of direct and conceptual replications that allow us to get a clearer picture of the magnitude and direction of associations between SES and SWB. Uniquely, statistical examinations of publication bias in the SES and SWB literature, conducted in the aformentioned meta-analysis show low levels of publication bias (Tan, 2016)—which suggests that this literature allows for a tighter fit between the empirical evidence and reality than many psychological literatures can muster. With that as backdrop, the evidence indicates that SES and SWB show small to moderate positive associations. This chapter makes the point that social comparison processes play a central role this association whereas the role of need fulfillment is less clear based on the literature.

Despite the considerable amount of knowledge that has been accumulated linking SES to SWB more work is necessary. For instance, both SES and SWB are broad bundle variables that encompass a number of social and psychological correlates that are hard to pin down in any large scale study with a goal

of comprehensive data collection using large samples. This means that researchers may still be decades of study away from truly describing the intricacies of connections between SES and SWB, their cultural variations, and the role of daily fluctuations in SES related variables and their causal influence on SWB. Experience sampling methods offer a way forward, although these methods might lead to a conscientiousness sampling bias or might bias mood reports (Scollon, Prieto, & Diener, 2009). Nevertheless, these methods allow for more fine-grained analysis of local comparison processes that, in prior research, are linked most strongly to SWB (Anderson, Brion, Moore, & Kennedy, 2012). Daily experience sampling may also provide a window into how cultural differences shape SWB in that cultures may not shift SWB itself but may instead, shift according to unique types of comparisons (Curhan et al., 2014).

Lastly, our understanding of lay beliefs about the American Dream and societal opportunity are rarely invoked when examining links between SES and SWB, and this dearth of connection in the literature is an important point of potential theoretical advancement. In short, how individuals theorize about happiness and well-being may differ from how they actually experience happiness and well-being. These differences have implications for how people think about health care and health benefits and their availability to all members of society, as well as, potentially providing justifications for the levels of SES disparities in society. Broadly, improving lay belief accuracy in associations between SES and SWB has a number of direct benefits—most directly, that it uncovers the real impact that economic advantages have on the subjective experiences, mood, and meaning of the lives of individuals.

Abstract

This chapter surveys evidence documenting positive linkages among social capital, prosocial behaviour, and subjective well-being. Whether in the workplace, at home, in the community, or among nations, better and deeper social connections, and especially higher levels of trust are linked to higher subjective well-being, even beyond the effects flowing through higher incomes and better health. Prosocial behaviour is also shown to be a robust predictor of well-being in both correlational and experimental contexts. These two lines of research are connected, as prosocial acts are most likely to increase well-being when they are delivered in ways that improve social capital, and reflect intentional generosity free of either compulsion or personal gain. We infer that these deep links between prosocial acts and well-being have an evolutionary benefit in maintaining the quality of social capital and thereby delivering cooperative human responses in times of crisis.

Keywords: Social capital, Prosocial behavior, Happiness, Well-being

Humans are extremely social creatures, spending much of their lives in the company of others. Indeed, social connections are one of the greatest sources of human well-being (Diener & Seligman, 2002; Lyubomirsky, Sheldon & Schkade, 2005) and, as such, this chapter surveys a range of studies showing positive linkages running from social connections, trust, and prosocial behaviour to higher subjective well-being. Although the magnitude of these effects can, at times, be difficult to establish because happier individuals are more likely to make friends, marry, and help others, this type of positive feedback loop is desirable for human welfare because it amplifies the well-being consequences of positive interventions. The reported results are primarily based on research in which we have been involved, but also set within a broader range of related studies.

That humans should gain happiness from social and prosocial behaviour has been doubted by some who think that evolutionary fitness requires a sharper sense of self-interest than is implied by the evidence we survey. To resolve these doubts requires an evolutionary theory that provides greater evolutionary fitness for individuals, groups and societies that adopt and prefer prosocial behaviour. Humans are generally more social and co-operative than other mammals and their own ancestors. Such exceptional levels of social and prosocial tendencies have been linked to rapid growth of the pre-frontal cortex, the size of which has been matched to the capacity and willingness to adopt social and prosocial behaviour (Shultz & Dunbar, 2007). The 'social brain hypothesis' (Adolphs, 2009; Dunbar, 1998) suggests that across mammalian species, and especially among anthropoid species, pre-frontal cortex size is linked both to social group size and pair-bonding, both of which are argued or presumed to require the evaluative powers conferred by the larger neo-cortex. One evolutionary puzzle is that the neo-cortex (the 'slow brain'; Kahneman, 2011) requires more energy than the more instinctive 'fast brain'. Thus planning for the long term, with the required intelligent attention to the interests of others, uses more energy, placing survival at risk when times are tough.

It is precisely at this point where we see an evolutionary role for social connections and prosocial actions. Social and prosocial activities provide psychological benefits, evidenced by positive emotions and higher life evaluations, beyond those directly attributed to the material rewards they enable. These additional psychological rewards help to sustain their energy costs, and hence favour the survival of societies that can combine high trust and benevolence even in the face of scarce resources and prevalent risks. Social connections can come in many forms, of course, but we focus primarily on social capital, which is defined by the OECD as "social networks, together with shared norms, values and understandings that facilitate cooperation within and among groups" (OECD, 2001, p.41).

In the review that follows we summarize the existing evidence for social capital and prosocial behaviour as sources of well-being. We divide our review of the evidence as follows. First, we provide examples of the well-being benefits of social capital at work and at home, followed by discussion of results

at the community, regional, and national levels. Second, we turn to the specific areas of health, the provision of public services, and the special role of trust. Finally, we conclude with a brief review of the burgeoning literature, based on both survey and experimental evidence, of the emotional benefits of prosocial behaviour.

Social Capital at the Individual Level of Analysis

At work. Many people spend a large portion of their waking hours at work (Schor, 2008), suggesting that social connections in the workplace may be an important predictor of well-being. And they are. Canadian data has shown that to work where trust in management is one point higher on a ten-point scale has an effect on life satisfaction equal to that from a one-third increase in household income (Helliwell & Huang, 2011). Workplace social capital seems to be more important for women than men; women attach more value to trust in management and less to income than do male employees (Fortin, 2008; Helliwell & Huang, 2009). These differences combine to make the income-equivalent value of workplace trust in Canada twice as high for women as for men. The Gallup-Healthways Daily Poll in the United States shows that happiness reports differ by day of week, while evaluative questions about life as a whole do not. For most workers, weekends and holidays are significantly happier than weekdays. However, for workers who think of their immediate superior as a partner rather than a boss, and who report a high level of workplace trust, the weekend effects are very small, falling to zero for those who manage to achieve the same number of social hours on weekdays and weekends (Helliwell & Wang, 2014; 2015).

The impact of social connections in the workplace may even help explain large age-related differences in life satisfaction. While life evaluations typically follow a U-shaped curve, peaking in one's 20s and 60s and dropping in between, employees who regard their superior as a partner show no such dip in middle age in the Gallup Healthways Daily Poll. Figure 1 shows that for workers of all ages the quality of social capital on the job, as measured simply by how one's immediate supervisor is perceived, has a large and highly significant relation to life satisfaction. For workers under 30, the effect is about 0.2 points on the 10-point scale, rising to 0.4 points for older workers. Note that for workers in high social capital workplaces, with partner-like supervisors, the middle-age drop in life evaluations is absent, with average ladder scores being the same for those aged between 45 and 54 as they are for workers under the age of 30.

Figure 1. Average life satisfaction reported by individuals seeing their immediate supervisor as a boss, as a partner, and combined for ages <30, 45-54, and >65. Error bars depict 95% confidence intervals.

At home. Relationships with family and friends are among the most powerful correlates of happiness all over the world. Answering "yes" to the question 'If you were in trouble, do you have relatives or friends you can count on to help you whenever you need them, or not?' is the single most important variable explaining differences in life satisfaction among individuals from more than 100 countries (Helliwell, Huang & Harris, 2009). To have that basic amount of social capital in the form of family and friends has, for a sample of 68,000 observations from the first three waves of the Gallup World Poll, the same value as a five-fold increase in household income (Helliwell et al, 2009).[1] That is an average across the globe. When the same relationship was fitted for each country separately, having someone to count on was strongly significant in every global region, and almost every country (Helliwell et al., 2009).

Similar findings emerge on more detailed measures of social capital assessing the size of and reliance upon one's social networks. Indeed, individuals with larger and more widely used networks provide more positive life evaluations. Interestingly, however, the beneficial impact of large social

networks may be limited to in-person friendships. Few surveys ask respondents parallel questions about the sizes of their networks of real and on-line friends, but one survey that has done so found that life satisfaction increases with the size of the network of face-to-face friends, but not with the existence and size of their networks of on-line friends, even in a large sample of on-line respondents (Helliwell & Huang, 2013).

The relationship between marital status and subjective well-being has been widely studied. Cross-sectional correlations between marriage and life satisfaction in western nations are almost uniformly positive. To some extent these correlations are likely due to selection effects, because individuals in good circumstances, or with genetic makeup favouring happiness, may also be more likely to find and attract marriage partners (De Neve, Diener, Tay, & Xuereb, 2013; Stutzer & Frey, 2006). Studies using individual fixed effects in longitudinal datasets have been used to avoid this risk, and have sometimes shown happiness after marriage to revert to baseline levels within a few years (Clark & Georgellis, 2013, Lucas, 2007; Lucas, Clark, Georgellis, & Diener, 2003). But subsequent research has shown that, when due account is taken of a happiness U-shape that is deeper for the unmarried than the married (Anusic, Yap & Lucas, 2014a; 2014b; Yap, Anusic, & Lucas, 2012), marriage can protect against the midlife blues. It is also important to compare happiness within marriage to that of a period sufficiently far in advance of the marriage to remove the pre-marital happiness boost (Zimmerman & Easterlin, 2006) from the baseline. These adjustments fully restore the positive well-being effects of marriage, at least for those industrial countries with longitudinal surveys suitable for such analysis. The positive impact of marriage on well-being also depends on the comparison group, since alternatives are quite diverse, including those who are separated, divorced, widowed, single, and or living as a cohabitating couple. The last category is substantial and growing in many western countries, and non-existent in some other cultures. Where it is prevalent, non-married but cohabitating couples rate their well-being only slightly below that of married individuals, suggesting that the happiness benefits of marriage may be due to its provision of social capital more than to its legal structure.

Looking across world regions, the value placed on marriage as an institution differs considerably, and so do its correlations with life evaluations. When the data from the Gallup World Poll (GWP) are divided into the 10 global regions used in the World Happiness Report series, separate estimation using individual-level cross-sections for each global region shows significant positive effects of marriage (relative to all other alternatives) in most regions, with notable exceptions: the effects are significantly negative in Latin America and Sub-Saharan Africa, while there are no significant correlations in South and South-East Asia (Grover & Helliwell, 2014). This diverse relationship between marriage and life satisfaction deviates from what is found for the effects of having family or friends to count on in times of trouble, which are strongly positive in all global regions. We hypothesize that cross-cultural differences in the role of marriage as a social institution are at least partly responsible for the diversity of results. If so, then we would expect to find that the well-being effects of marriage are greater in circumstances where marriage contributes to the quality of an individual's social capital. This possibility is supported by results from a UK survey where respondents were asked to locate their best friend from a number of categories, including "spouse" as an option. The results show that although marriage and friends are both important sources of subjective well-being, the effects of marriage on life evaluations are twice as large for those who also regard their spouse as their best friend (Grover & Helliwell, 2014).

Social Capital at the Community Level of Analysis

The interpersonal relationships that form the basis of an individual's social connections exist within the larger social context of neighbourhoods, cities, regions and nations. Here, we review how the quality of social connections at the community level affect subjective well-being. This is sometimes done by comparing average well-being for communities and nations, both across communities and over time, and sometimes by two-level modelling that attempts to separate the individual-level and contextual effects that are lumped together when the analysis is done using aggregated data.

Comparison effects - "keeping up with the Joneses"- are generally believed to generate negative spillovers which undermine the well-being effects of income (Easterlin, 1974, 1995; Kingdon & Knight, 2007; Luttmer, 2005; Stevenson & Wolfers, 2008). By contrast, the inherently collective nature of social capital can induce positive spillovers, thereby increasing the benefits to local and national communities (Helliwell & Putnam, 2004). Indeed, the effects of social trust on life satisfaction at the national level have sometimes been found to be more pronounced in wealthier countries (Bjørnskov, 2003; Ram, 2010). Nonetheless, positive aggregate effects of various forms of social capital have been found throughout the international income distribution (Delhey & Dragolov, 2016), as well as within countries over time (Bjørnskov, 2008; Helliwell, Huang, & Wang, 2014; 2017).

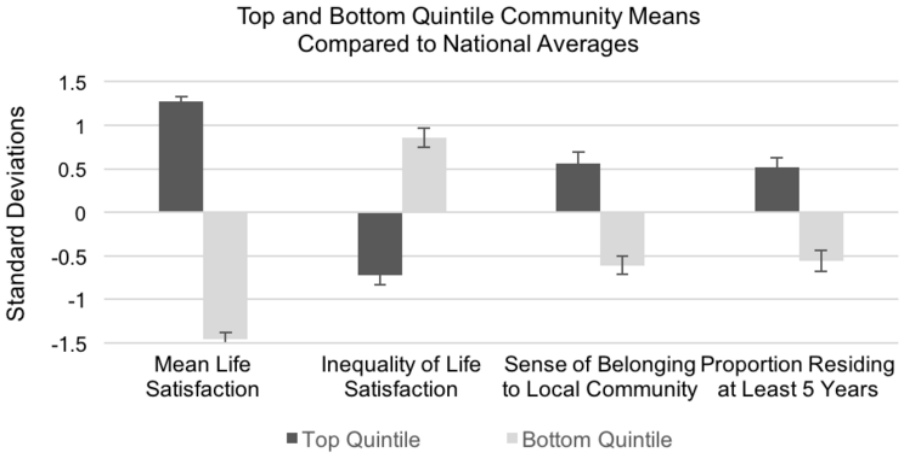
The role of social capital in explaining aggregate well-being at the national level is also substantial

and extends well beyond its effects on health and economic outcomes. In a study of 158 countries sampled by the Gallup World Poll, Helliwell, Huang, and Wang (2015) found that measures of social support and generosity collectively explain 37% of the variation in national average life evaluations after controlling for GDP per capita, healthy life expectancy, and perceptions of freedom and corruption. Using data from the GWP, European Social Survey (ESS), and World Values Survey (WVS) to estimate wealth-equivalent values of social capital, Hamilton, Helliwell, and Woolcock (2016) estimate that social capital, as measured by trust, comprises approximately 20% of total national wealth. Across regions, estimates range from as low as 12% for Latin American countries, to as high as 28%, for OECD countries.

In the important case of social trust and other self-report assessments of social capital, the validity of these international results requires that measured social capital reflect the quality of the underlying social fabric, rather than cultural biases in reporting. Providing some direct evidence for the former, Knack (2001) finds that average answers to the standard trust question across 14 European and 12 US cities in the WVS were highly correlated with the actual probability of a stranger returning a wallet in the region in question. Lending further support to this view, social trust among first-generation immigrants tends to reflect the levels of natives in the host country more closely than stayers in the source country (Dinesen, 2012; Helliwell, Wang, & Xu, 2016; see Dinesen & Sønderskov, 2017, for a recent review), suggesting that levels of trust respond to the local context. The importance of the social context may also explain why new immigrants to Canada report means and distributions of life satisfaction similar to those of Canadian-born respondents (Helliwell, Bonikowska, & Shiplett, 2016). The smaller differences that remained could come from cultural 'footprint' effects, or from differences in the social capital available to immigrants. In support of the latter view, others have found that gaps between the life satisfaction of immigrants and natives in developed countries can be explained by lower social support (De Vroome & Hooghe, 2014), by natives' perceptions of immigrants (Hendriks & Bartram, 2016), and by immigrants' own perceptions of discrimination (Safi, 2010).

While international differences in social capital clearly play a large role in well-being, social capital also accrues and influences well-being through more local channels. Investigating sub-national variation in well-being can help to illuminate these channels while holding the national context fixed. Using the large samples of life satisfaction available in the Canadian Community Health Survey and General Social Survey, Shiplett, Helliwell, and Barrington-Leigh (2017) estimated levels of life satisfaction across more than 1,200 Canadian communities. In the happiest dozen communities (the 99th percentile in the sample of 1,215 communities) average life satisfaction is above 8.5, compared to less than 7.5 in the dozen least happy communities, a difference of 1.0 points on the 10-point scale. Comparing the happiest and least-happy communities in Figure 2, salient differences are apparent in residents' reported sense of belonging to the local community, a direct measure of the level of local social connectedness, as well as inequality in life satisfaction (the within-community dispersion of life satisfaction, measured by the standard deviation of the distribution of individual life satisfaction responses), and residential tenure[2], both of which provide plausible support for social capital.

Figure 2. Life satisfaction is higher in communities where more people feel a sense of belonging.



Multi-level models, in which measures of social capital are entered at both the individual and regional levels, provide an opportunity to separate individual and contextual effects of social capital. Thus, it is possible, for example, to separate the benefits of trusting others from those of living in a trusting

environment. Using this approach, Bjørnskov (2008) finds strong effects of social trust, formal sociability, and informal sociability at the individual level, as well as contextual effects for social trust of a similar magnitude to the individual effects in regressions of residuals at the state-level in cross-section and in a region-level panel in the United States. Aslam and Corrado (2012) find similar regional benefits of general and institutional trust for European regions, and Han, Kim, and Lee (2013) find local contextual effects for organizational membership and social support at the local level in Seoul, South Korea. In the latter two cases, the contextual effects were actually larger than the already substantial individual effects. Having controlled for the potentially confounding effects of optimism through the individual responses, these significant contextual effects also provide stronger support for a causal role of social capital, especially through social trust.

When measuring contextual effects in a multi-level framework, results may be sensitive to the geographic scale at which contextual variables are measured (Flowerdew, Geddes, & Green, 2001). If, for example, the contextual effects of social connectedness operate primarily through the social context in local neighbourhoods, a regression including individual and state-level measures of social connectedness may show effects for both variables to the extent that they serve as two imperfect measures of the same underlying, but omitted, neighbourhood characteristic, the first potentially imprecise but correctly scaled, the second incorrectly scaled but more precisely measured. This type of scale effect may partially explain why Bjørnskov (2008) and Aslam and Corrado (2012) do not find significant contextual effects for formal or informal sociability measured at coarser geographic scales, while Han, Kim, and Lee (2013) do find contextual effects for formal sociability in the form of organizational memberships measured at a much finer level of geographic detail.

The evidence presented so far supports the positive effects of social capital on well-being, both individually and collectively. But the benefits of living in a trusting and socially cohesive environment extend even further. In addition to providing support to individuals facing adversity, as we have seen, social capital provides a resource that can be tapped into collectively in times of need, supplementing or even standing in for more formal institutions. Helliwell and Huang (2014) showed in a panel of US cities that the contextual effect of aggregate unemployment was reduced by approximately one third in cities where levels of broad engagement were one-standard deviation above average, compared to those where it was one standard deviation below average. Furthermore, Helliwell, Huang and Wang (2014, 2015) argue that the small effect of the 2008 financial crisis on life evaluations in hard-hit Ireland and Iceland[3] when compared to the large decreases observed in Spain, Italy, and Greece, can be explained by the exceptionally high levels of social capital in the former.[4]

Communities with high social capital, particularly social trust, have also been documented to recover more quickly from natural disasters, such as the Tokyo earthquake of 1923 (Aldrich, 2012) and the 2004 tsunami in southern India (Aldrich, 2011). Coping with natural disasters, which requires cooperation, has been shown to be associated with subsequent increases in social trust (Toya & Skidmore, 2014), at least when it is not initially too low (Dussaillant & Guzmán, 2014). For instance, Yamamura and colleagues (2015) also show that following the Great East Japan Earthquake of 2011, the effect of trust on happiness approximately quadrupled in areas that were damaged by the earthquake. This large change can be accounted for both by the benefits of support during the disaster, but also by increases in trust, generosity, and the value placed on social connections in the wake of the disaster (Uchida, Takahashi, & Kawahara, 2014; Yamamura, Tsutsui, Yamane, C., Yamane, S., & Powdthavee, 2015).

Social Capital and Health

The epidemiological literature mainly uses social capital at the individual and community levels to explain the incidence of ill-health (Berkman & Glass, 2000; Berkman & Syme, 1979; Evans, Barer, & Marmor, 1994; Kawachi & Berkman, 2000; Kawachi, Kennedy, Lochner, & Prothrow-Stith, 1997; Marmot, 2005; Marmot, Ryff, Bumpass, Shipley, & Marks, 1997). For an example at the individual level, experimental research demonstrates that individuals with robust social connections are less likely to be affected by an experimentally delivered virus (Cohen, 2004; Cohen et al., 1997, 1998). A different line of research emphasizes how building positive social identities helps people achieve better health status, or speedier recovery times (Haslam et al., 2008; Haslam, Cruwys, Haslam, Dingle, & Chang, 2016). Yet another branch shows how the quality of the social context shapes the effectiveness of different health treatment strategies, ranging from the operating room to elder care. These latter studies are worth special attention, partly because they have not previously been seen through the lens of social capital, and partly because they provide a good link to the next section, where parallel evidence is considered for other aspects of public service delivery.

The operating room and elder care are two areas where growing demands and complexity are leading to increasing pressures on budgets, hospital capacity, and the supply of trained professionals.

Gawande (2014) has shown that these stresses are linked, and that giving more attention to the well-being of those receiving care would not only benefit patients, but would increase the well-being of providers as well. To this end, the surgical checklist developed by Gawande and others (Gawande, 2010; Haynes et al., 2009) for the World Health Organization has been widely adopted and credited with making significant improvements in patient outcomes. The role of social capital becomes clear only when researchers analyze how the guidelines are used, and where and why they are most effective. This emerging research has shown that typical application of the checklist procedures may not be enough to significantly improve outcomes (Urbach, Govindarajan, Saskin, Wilton, & Baxter, 2014). What may be most important are improvements in team training (Neily et al., 2010), team involvement (Rydenfält, Johansson, Odenrick, Åkerman, & Larsson, 2013; Walker, Reshamwalla & Wilson, 2012) and teamwork and communication in the operating room (Russ et al., 2013). An important element in building teamwork and improving communications is the timeout, where all members of the team drop their masks, introduce themselves, and discuss the case, thereby achieving the closer connections and flatter structures shown earlier to add to the happiness of team members and the quality of their work.

Gawande (2014) has also argued for the need to rethink elder care by paying more attention to the quality of life of the elderly, their caregivers, and those playing both roles. Gerontologists have spelled out the need for a revolution in elder care (Theurer et al., 2015) with a well-being focus. There is increasing evidence that here, as in the operating room, providing people with social capital and prosocial opportunities is a key ingredient to improving well-being. For example, experiments in an elder care facility in Exeter, in the United Kingdom, showed that enabling residents to take even a small collaborative role in designing their own future social spaces produced improvements in health and well-being greater than those from facilities designed for them by professionals (Knight, Haslam, & Haslam, 2010). Tellingly, these improvements were accompanied by more positive feelings about fellow residents and staff, as well as more prosocial behavior. As such, providing elders with an opportunity to build social capital through interaction in meaningful and helpful ways can yield important subjective well-being benefits.

Social Capital in the Provision of Public Services

In this brief section we look beyond the overall quantity and quality of public services to consider the ways in which the services are designed and delivered. Indeed, if the social context matters in a first-order way for well-being, then we would expect both the sociality and prosociality of the design and delivery of public services to have important consequences for well-being outcomes.

Much of the literature analyzing the quality of government, including trust in public services has focused on the integrity and efficiency of the public services (Charron & Rothstein, 2016; Kaufman, Kraay, & Mastruzzi, 2009; see Holmberg & Rothstein, 2011 for health outcomes), and on the effects of those characteristics on the subjective well-being of the general population. A principal conclusion from this literature is that well-being depends more on the quality of the services provided than on the funds devoted to their provision. Whether the political process itself is democratic appears not to increase subjective well-being unless or until the efficiency and integrity of service provision achieves certain levels (Helliwell & Huang, 2008; Ott, 2010; see Helliwell, Huang, Grover, & Wang, 2014 for review).

We have already seen how flatter workplace structures (where supervisors are seen as partners rather than bosses) are happier places to work. We shall also show later that people are more inclined to generous acts, and happier to do them, where the beneficiaries are known and local. There is some parallel evidence for the design and delivery of public services. For example, people have been found to have higher life satisfaction in those Swiss cantons that rely more heavily on referenda, giving the citizens more direct and immediate participation in government decisions (Frey, Benz, & Stutzer, 2004). It can also be argued that the success of the Singapore prison reforms of 1998 was due in large measure to the efforts made to involve all parties directly in the planning and delivery of services, thereby creating trust and new social norms, permitting not just reductions in recidivism, but also better lives for inmates, employees, families and the community at large (Helliwell, 2011). And a collaborative experimental effort to use workplace training to deliver essential skills (Gyarmati et al., 2014) showed significant gains, especially in higher trust environments, thereby showing the synergy between social capital and the delivery of more effective public services.

Two more examples may help to show how social capital can be created almost anywhere, in ways that improve the well-being of all parties. At least two music schools have partnered with elder-care facilities to provide free accommodation for a small number of music school students, who then live, practice, socialize and perform in the facility, thereby improving lives for all parties (The National, 2016, Farooqui, 2017). To show that these experiments in co-living are not successful just because of the magic of music, co-housing of women soccer stars in an elder care facility was found to deliver better lives for the athletes and their elderly housemates (Gutnick, 2013). What is needed to broaden the scope and prevalence

of such successes? First, it requires inspired commitment to see the opportunities and over-ride the administrative and supposedly risk-avoiding hurdles that often stand in the way of mixing ages, skills, and interests in untraditional ways. Second, the music school examples show the importance of success stories being told, as the Canadian example (Farooqui, 2017) was inspired by a CBC story (The National, 2016) on the earlier experiment in Cleveland. Although the co-living examples involve social experiments in the field of elder-care, and thus could have been recounted in the health care section of the chapter, we include them here to emphasize that opportunities for the creation of happiness-inducing social capital exist in all institutions, communities and workplaces, whether public or private, large or small.

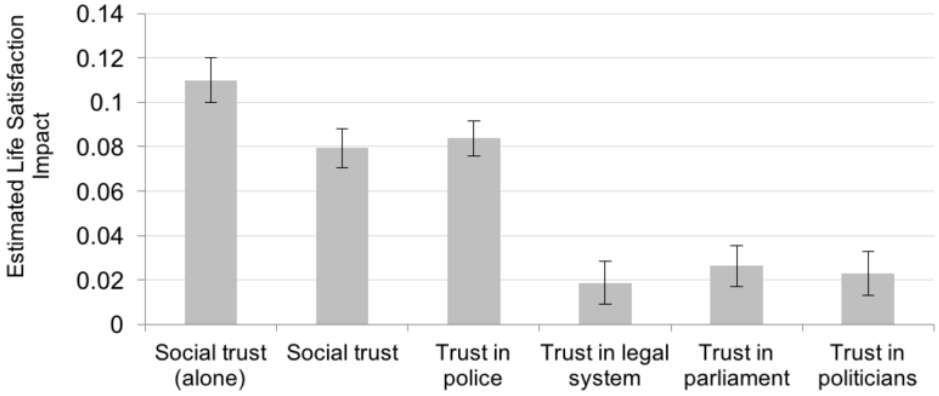
Trust and Well-Being

Trust is sometimes treated as a part of social capital and sometimes as independent but co-determined, with causal arrows running from high trust to other forms of social capital, and from other forms of social capital to high trust. We do not think there is any need to prefer one or the other of these two definitional approaches, as long as the various types and dimensions of trust are distinguished, and their links to well-being established. Analysts are slaves to what is measured, and that applies especially to trust, where measurement is often absent or rudimentary.

The most long-standing measure of trust, often referred to as 'social trust', is based on answers to the question "Do you think that other people can generally be trusted, or (alternatively) that you cannot be too careful in dealing with people?' Social trust, measured using this question, has been found to be highly correlated with subjective well-being in previous studies (Helliwell, Huang, & Wang, 2014; Helliwell & Wang, 2011). It has become and remains the canonical survey question on trust partly because of its long-standing use (since Almond & Verba, 1963), and partly because, as we show below, it is a reasonable but under-stated proxy for a wider range of more specific measures of trust.

Some large surveys have begun to include more detailed measures of the different dimensions of trust. For example, the ESS (Huppert el al., 2009) asks a number of trust questions (unfortunately not yet including the neighbourhood and the workplace) on a 0 to 10 response scale that provides a more information-rich set of responses than are available from the binary response scale frequently used for the social trust question. Using the ESS data, Helliwell, Huang and Wang (2017) recently found significant individual-level partial correlations with life evaluations for five separate trust measures, even when they were all simultaneously included. These included social trust, trust in police, trust in the legal system, trust in parliament and trust in politicians. The two largest effects were for social trust and trust in police, with each providing an effect larger than the sum of effects provided by the other three variables. Social trust, if entered on its own, and hence standing in for the other forms of trust, attracts a significantly higher coefficient than when entered in parallel, reflecting the ability of the general measure to capture some of the missing measures. But it is not a complete substitute for the other measures, since social trust used on its own delivers an estimated well-being effect that is only half as large as the combined effect of an improvement in all five measures of trust, as shown in Figure 3.

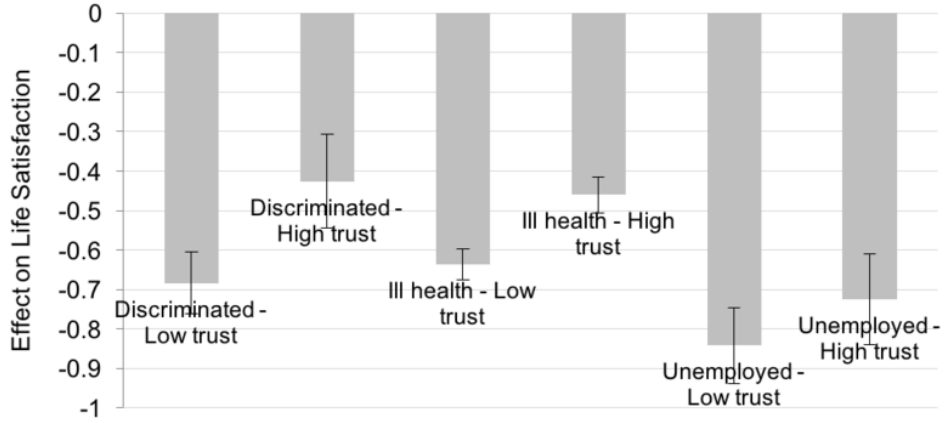
Figure 3. Social trust captures only some of the well-being effects of trust. Estimated life satisfaction effects from an increase of 1 point on ESS 10-point trust scale. Error bars depict 95% confidence intervals.



Earlier sections have already shown how workplace and neighbourhood trust levels provide additional subjective well-being above and beyond that due to their impacts on incomes[5] and health. We also showed how high trust communities demonstrate more resilience in the face of natural and other community-level shocks. In addition, individuals living in what they feel to be a high-trust environment are

more resilient to shocks that are specific to them (Helliwell, Huang, & Wang, 2017). By way of example, ESS data allow this to be shown for three quite different unfortunate circumstances faced by individuals: unemployment, ill-health, and feeling subject to discrimination. Figure 4 depicts three pairs of bars, each showing the loss in SWB from one of three adversities- discrimination, ill-health and employment, with two bars for each condition, one with and one without high social trust. Being subject to any one of these circumstances is associated with significantly lower life evaluations. But the effects are smaller, by about 14% for unemployment, and up to 38% for discrimination, for those who rate the trustworthiness of others at 7 or above on the 0 to 10 scale used for the ESS trust question.

Figure 4. Resilience is higher for individuals reporting higher levels of social trust.



Much of the preceding evidence is correlational, or makes use of natural experiments. There is also an extensive literature (Ostrom, 2000) documenting the prevalence (but not universality) of prosocial and trust-building behavior in the context of prisoner's dilemma games and in the development of co-operative solutions to common property management problems. Although the outcomes are typically not measured directly in terms of subjective well-being, they include improved trust, better social norms, more effective solutions for water-management, and other important collective action problems. Two features of this large literature are especially relevant in the context of this chapter. First, face-to-face personal communications have been repeatedly found (Balliet, 2010) to increase the probability of co-operative behavior in prisoner's dilemma games and resource management problems. Second, rules for cooperative management developed internally by co-operating groups have been shown to be more efficient than are externally developed and imposed rules, despite the greater enforceability of the latter (Bardhan, 2000; Frohlich & Oppenheimer, 1996; Cardenas, Stanlund & Willis, 2000). Both findings show how important it is for people to participate in the design and improvement of the social norms and institutions governing their lives.

Both of these strands of experimental evidence show that social trust and co-operation can be created and employed in ways that improve well-being. There are many policy areas where these lessons can be applied – but they require more attention to the social context of decision-making, and the need to build upon the innate human capacities for social and pro-social behaviour.

Generosity and Other Prosocial Behaviour

If humans are extremely social beings and meaningful connections with others are one of the most reliable predictors of happiness (Diener & Seligman, 2002; Lyubomirsky et al., 2005), how do people manage to create, maintain and strengthen social connections with other people? One way is by assisting others through prosocial action. Indeed, engaging in acts of kindness and generosity can improve connections with others and thereby promote the well-being of all parties, including the giver.

Consistent with this logic, a large and growing body of research demonstrates that giving leads to greater well-being for the giver. For instance, data from nearly 30,000 people across 29 states in the United States demonstrates that people who volunteer more frequently are both healthier and happier than those who do not volunteer, even after controlling for well-known predictors of well-being, such as age, gender, relationship status, education, and income (Borgonovi, 2008). This association between volunteerism and happiness extends beyond the United States and has been documented in several countries around the globe. Data from over 30,000 people in 12 countries indicates that individuals who have volunteered within the last month reported higher life satisfaction and lower depression than those who did not volunteer (Haski-Leventhal, 2009). Beyond volunteerism, providing informal care or support to one's spouse, family, and friends yields benefits for the care provider. Indeed, in a sample of older married adults, Brown and

colleagues (2003) found that mortality rates were lower for individuals who provided instrumental support to family, friends, and neighbours as well as emotional support to their spouse (also Schwartz & Sendor, 1999; Thomas, 2009). Interestingly, receiving support did not predict morality rates when support provision was controlled for along with other demographic variables. Finally, using one's financial resources to help others, called *prosocial spending*, is associated with higher well-being as well. For instance, individuals who donated money to charity reported higher levels of life satisfaction, in most countries around the globe, than those who did not (Aknin, Barrington-Leigh et al., 2013).

Critically, the impact of prosociality on well-being is causal. For instance, Lyubomirsky and colleagues (2005) found that participants randomly assigned to engage in five acts of kindness in a single day weekly for six weeks reported higher subjective well-being relative to a control group who did not engage in prosocial behavior. More recently, Nelson, Layous, Cole, and Lyubomirsky (2016) report that participants randomly assigned to one of two prosocial conditions, completing kind acts for other people or for the world, reported greater positive emotions and decreased negative emotions over a 6-week span than individuals randomly assigned to do a nice thing for themselves or keep track of their daily activities. Experimental evidence also demonstrates the benefits of support provision. Individuals randomly assigned to hold their romantic partner's hand while the partner received electric shocks displayed greater activation in pleasure centers of the brain, such as the ventrial striatum and septal area, than individuals not able to support their partners (Inagaki & Eisenberg, 2012). Finally, engaging in prosocial spending yields hedonic rewards (Dunn, Aknin & Norton, 2008; 2014). For instance, when students were randomly assigned to spend a windfall of either $5 or $20 on themselves or someone else by the end of the day, those who spent the money on someone else were happier, regardless of the dollar amount (Dunn et al., 2008). Similar experimental findings have been demonstrated in rich and poor countries (Aknin, Barrington-Leigh et al., 2013), and in small-scale traditional villages (Aknin, Broesch, Hamlin & van de Vondervoort, 2015). Thus, even though the prevalence of pro-social behavior has been shown to depend on genes (Kitayama et al., 2014), culture (Bell, Richerson & McElreath, 2009), environmentally shaped differences in farming crops (Talhelm et al., 2014) and interactions among them, the emotional rewards appear robust, emerging in a variety of different cultural contexts. Even toddlers under the age of two smile more when giving away edible treats than when receiving treats themselves (Aknin, Hamlin & Dunn, 2012).

When is prosociality most likely to promote well-being? Four key factors have been identified. First, prosocial behavior yields the greatest emotional rewards when it facilitates social connection. For instance, individuals randomly assigned to engage in prosocial spending were happiest at the end of the day when their actions allowed for time spent with the recipient (Aknin, Dunn, Sandstrom & Norton, 2013). If giving with social connection is more emotionally rewarding, this may help explain why people prefer to support local causes and charities to which they have a personal connection (Small & Simonsohn, 2008). Moreover, social connection may also explain why giving items that are closely tied to oneself, such as a previously owned item or blood, leads to greater commitment and subsequent generosity than giving gifts with minimized personal connection (Koo & Fischbach, 2016).

Prosocial action is also more likely to promote subjective well-being when generosity is motivated by altruistic, as opposed to selfish, motives. Supporting this claim, correlational research reveals that volunteering is associated with lower mortality risk in older adults, but only when volunteering is motivated by other-oriented (as opposed to self-oriented) motives (Konrath, Fuhrel-Forbis, Lou, & Brown, 2012). Similarly, other-oriented motives reported by a sample of volunteer healthcare workers predicted life satisfaction, but self-oriented motives did not (Veerasamy, Sambasivan & Kumar, 2015). Experimental evidence points to similar conclusions. For instance, participants randomly assigned to recall a time they engaged in helping behavior motivated by concern for others reported higher positive emotions than participants assigned to recall a time they engaged in helping behavior to benefit themselves (Wiwad & Aknin, under review). This may be why introducing opportunity for self-benefit undermines the emotional rewards of giving. Indeed, Wang and Tong (2015) found that people report greater happiness after making private (as opposed to public) donations, potentially because public donations are more likely to be motivated by self-focused concerns.

Two final factors that make the benefits of giving more likely are volition and impact. When people feel that their kind acts are compelled by others, giving does not translate into well-being benefits (Weinstein & Ryan, 2010). This may be at least part of the reason why required volunteer work, such as community service learning programs, have no detectable benefits on subjective well-being in experimental tests (Whillans et al., 2016); making prosocial actions mandatory undermines an actor's volition, which is important for experiencing the emotional rewards of giving. Finally, feeling as if one has made a positive impact on others also enhances the well-being benefits of giving. When donors know how their dollars will be used to help others, larger donations lead to greater well-being. Importantly, however, when information about impact is absent, larger donations do not predict greater well-being (Aknin, Dunn, Whillans, Grant, &

Norton, 2013). This offers another, complementary explanation for why people prefer to give to local charities – because they are more likely to see the impact of their gift and experience emotional rewards as a result (Touré -Tillery & Fischbach, 2017).

The warm glow of giving not only offers an immediate reward for prosociality, but may prompt subsequent generous action. Indeed, consistent with classic research demonstrating that positive affect predicts helping behavior (Isen, 1970; Isen & Levin, 1972), more recent work has shown that positive affect experienced after recalling a previous prosocial spending purchase predicts future generous spending (Aknin, Dunn & Norton, 2011). To the extent that emotions serve to signal and promote adaptive behavior, this positive feedback loop makes sense. Giving allows us to create and maintain meaningful relationships with others. Since relationships are so essential to our survival and well-being, positive emotions serve to make this prosocial action more likely in the future.

Concluding Summary

This chapter shows how the quality of the social fabric can affect subjective well-being. Whether in the workplace, in the home, in the community, or among nations, tighter and more reliable social connections are linked to happiness, whether measured by positive affect or higher life evaluations. Governments were shown to enable higher life evaluations when they develop and deliver policies in ways that build social capital in the process. Our review of prosocial acts showed them to be most effective at increasing happiness, and therefore most likely to be repeated, in situations where social capital, as measured by trust and shared social norms, is high. This synergy linking social capital, prosocial behaviour and subjective well-being both underlies and supports our presumption that such a combination is likely to be successful, even on an evolutionary time scale, wherever it is found.

Footnotes

[1]In Table 4 of Helliwell et al. (2009), the coefficient on the log of household income is 0.54, compared to 0.91 on the availability of family and friends. Hence the income multiple to offset the absence of helpful family and friends is 5.4 (=exp(0.91/0.54)).

[2]While residential tenure has also been found to have a positive effect on subjective well-being by Shields, Price, and Wooden (2009), at least for males, the aggregate effects may differ according to scale and context. Talhelm and Oishi (2014), for example, find that rates of residential mobility are positively associated with happiness in states with more extroverted populations, but negatively for states with more introverted populations, suggesting that the balance between the benefits of variety and stability may depend on the social context.

[3]See also Gudmundsdottir (2013) for an account of the well-being effects of the financial crisis in Iceland.

[4]Based on GWP data, Spain Italy and Greece ranked among the largest decreases in life evaluations from 2005-2007 to 2012-2014, while Iceland and Ireland rank at the top of the distribution in terms of the proportion of individuals who reported having someone to count on in times of adversity.

[5]Evidence linking social trust with the levels and rates of growth of GDP is reported by, among others, Algan & Cahuc (2010), Bjørnskov (2012), Helliwell & Putnam (1995), Knack & Keefer (1997) and Zak & Knack (2001).

Abstract

The topic of meaning in life is coming to the fore in well-being research. From an arcane existential idea to a cornerstone of wellbeing, the path from obscurity to recognition was established through empirical research. This chapter summarizes the development of theory and of measurement in meaning scholarship over the past 70 years, and highlights replicated research results. Among the relationships that have been found repeatedly in the literature are positive correlations between meaning and happiness, life satisfaction, positive emotions, hope, self-esteem, autonomy, positive relationships with others, competence, extraversion, conscientiousness, health, and longevity. Negative correlations have been replicated between meaning and negative emotions, depression, anxiety, stress, hopelessness, neuroticism, substance use problems, and suicidality. The body of evidence regarding meaning is large and growing quickly, and appears to reliably demonstrate the importance of meaning to human wellbeing and flourishing

Keywords: Meaning, Meaning in Life, Purpose in Life, Well-Being, Meaningfulness

Conceive yourself, if possible, suddenly stripped of all the emotion with which your world now inspires you, and try to imagine it as it exists*, purely by itself, without your favorable or unfavorable, hopeful or apprehensive comment… No one portion of the universe would then have importance beyond another; and the whole collection of its things and series of its events would be without significance, character, expression, or perspective. Whatever of value, interest, or meaning in our respective worlds may appear endued with are thus pure gifts of the spectator's mind.*

William James, *The Varieties of Religious Experience*

William James, like scores of psychologists since, sought to understand the psychological nature of humanity's most profound and deep experiences. By speculating on the role of emotions in giving life its savor and significance, he presaged modern interest in how the seemingly fleeting and earthly (emotions) contributes to the seemingly enduring and transcendental (meaning). Emotions, of course, seem fundamental to well-being (Diener, 1984). However, despite being proposed to be a defining feature of well-being nearly 30 years ago (Ryff, 1989), meaning only recently has been a serious and common part of conversations and research about well-being. Given that meaning is supposed to be a path to living well and enjoying rich, fulfilling lives, it is important to examine how consistently and reliably meaning relates to a variety of well-being variables. In this chapter, I will summarize research on meaning in relation to well-being. By the end of this chapter, I believe it will be apparent that many studies have found, and replicated, close ties between meaning and other variables that are used to indicate well-being. In fact, the weight of this research seems to make clear that asking whether meaning is related to well-being is no longer an interesting research question. Instead, a better question may be whether it is possible for people to experience well-being without meaning.

To help support this conclusion, this chapter will present the psychological approach to understanding meaning in life, including the most popular and recent theories and tools for measuring meaning in life. This chapter also will review empirical research on meaning in life, with a particular emphasis on results that have been found again and again, showing that many ties between meaning and wellbeing are reliably repeatable.

Meaning in Life in Psychology

Although there is evidence that people's concern for whether 'life, the universe, and everything' has any meaning is quite old, modern meaning in life scholarship does not draw its inspiration from ancient sources that touch on topics at the heart of meaning, such as the Judeo-Christian Bible or The Epic of Gilgamesh. Instead, in one form or another, most scholars trace the inspiration for studying our human attraction to meaning to Viktor Frankl. As we will see, Frankl really personalized the idea of meaning, rooting it in each individual's experience.

Earlier existentialist philosophers had argued that the failure of religion, governments, and other human institutional collectives to prove their authority over moral truth and righteousness led to the

inescapable conclusion that there really was no valid external entity that had dominion over these topics. There was no person, text, or tradition one could point to in life to say "OK, so *that's* what this is all about." Moral sources relied on an accumulation of authority and the weight of absolute conviction. Governmental sources relied on their ability to steward the needs of those they governed. Over centuries of war and exploitation, particularly the World Wars of the mid-20th Century, the capacity for these moral and governmental agents to represent moral truth and righteousness was in doubt. "Trust us" no longer seemed adequate to the task. Rational sources of moral authority did not fare any better. Brilliant and persuasive people could argue both sides of every issue from violence and human rights to the existence of God. The loss of these official sources of meaning left a vacuum, devoid of sense and direction. This realization struck many as alarming. Without being able to rely on millennia of teachings, dogmas, and laws to point a way toward how we are supposed to live our lives, we are forced to improvise. One person might determine that life is about helping others but another person might determine that life is about exploiting and dominating others, and our simple species couldn't say who was right because no one was right. The universe did not care. Life did not have moral rules. There was no absolute truth. Life and the universe were random, and in a meaningless universe, meaning is impossible.

Frankl had a different perspective. Frankl (1963) argued that there was, in fact, some kind of meaning out there for each of us, and that our primary job was to discover it and give it life. Meaning became a personal pursuit of purpose in Frankl's view, and the desire for meaning was put forward as essential to being human. Where earlier meaning was in the hands of an inert and uncaring universe, in the middle of the 20th Century meaning was positioned as a core part of who we are, manifested through our relationships, actions, and attitudes. This shift created the possibility that we could actually study something as abstract as meaning. We cannot test whether the universe has meaning, but we can test whether people have meaning, one person at a time. Thus, meaning in life—as a psychological variable—does not bother with what people think about where life came from, why bad things happen to good people, or whether there is a soul. None of their answers can be proven or disproven according to scientific methods. Such questions are about a different level of meaning. They are about the meaning *OF* life. In contrast, psychology cares about whether a person feels that there is meaning *IN* life, from her or his perspective.

From this critical pivot—from the vast universe to the lone individual—meaning in life became a human quality that psychologists could research. Not that they necessarily started to research meaning right away. About less than 100 papers were published per year in the 1970s, 1980s, and 1990s. However, beginning in 2006, interest in meaning took off. In 2015, 1,900 papers were published on the topic, and a large proportion of these papers presented empirical data, extending in small and large ways what we know about how people experience meaning in their lives and what that experience of meaning provides. Essentially, as many papers are published each and every year on this topic now as were published in the first 60 years of the field combined. This chapter draws on that large body of research to identify what we are confident we know about meaning in life as well as to identify key areas where we still do not know enough. We will begin by discussing definitions and theories concerning meaning.

Definition and Measurement of Meaning in Life

At a basic level, "meaning" itself is widely used to refer to how meaningful people perceive their lives to be. People who regard their lives to be very meaningful are said to "have meaning," or that their lives have the "presence of meaning." Meaning in this sense exists at a medium level of abstraction. At a more cosmic level is the meaning that the universe might or might not have (known as cosmic meaning). For example, people's belief or disbelief in religion are concerned with cosmic meaning. At a more specific level is the meaning any one of us might attribute or draw from a particular life event (known as situational meaning). Most interest in situational meaning concerns the way in which people interpret or try to make sense of trauma, tragedy, or adversity they encounter in life. For example, losing one's job can be interpreted as a rebuke or diminishment of worth, in which case the situational meaning is one of hardship and defeat. The meaning you perceive your life to have is more formally known as *personal meaning.* To some degree personal meaning includes the ways in which cosmic meaning and situational meaning are relevant to your life, but only insofar as they impact whether you feel your own individual life overall is meaningful. Throughout this chapter, and in most of the research people conduct, "meaning" is used in this manner.

A couple of additional distinctions are made in the field. First, although two people might both perceive similar levels of meaning in their lives, their *sources of meaning* may differ. Person A might get the most meaning from hard work, trying to achieve goals, and pursuing success, and Person B might get the most meaning from family time, being a good friend, and volunteering. Sources of meaning are those parts of life from which people draw meaning and in which they invest their energy. Generally, research

suggests that the most common sources of meaning are relationships and the types of activities we are engaged in (e.g., Steger et al., 2013). Not a lot of research has examined whether it makes a difference what sources of meaning people have, but studies often find that people who get their meaning from self-centered or materialistic sources are less happy and experience less meaning than people who get their meaning from self-transcendent and altruistic sources (Schnell, 2009).

Second, Person A and B might have very different orientations to meaning itself. Person A might go through life never thinking about meaning unless she or he is asked, whereas Person B might think about meaning much more, trying to get a deeper understanding of the nature of existence and being a good person, looking for more meaning all the time. Person B would be more likely to engage in the *search for meaning*. The search for meaning refers to how actively and intentionally people are oriented to meaning in terms of their interest to find more or deeper understandings of meaning in their lives. Research shows that people who are searching for meaning are a little more likely to be anxious and unhappy, but also are more likely to be open-minded and interested about the world around them (e.g., Steger, Kashdan, Sullivan, & Lorentz, 2008). The rest of this chapter is about the presence of personal meaning in a person's life, or, simply, *meaning*.

Theories of Meaning

Why should meaning be such an important part of well-being? Why should people experience meaning in the first place? There are few theories that tackle both of these questions. Frankl (1963) proposed that deep within humans is an innate need, or will, for meaning. In motivational need theories like this one, people experience well-being if they meet the need and distress if they do not. People successful at meeting needs are in their natural states, and look happy overall, particularly in contrast to people who are frustrated in their efforts to meet their needs. It still might be somewhat unclear as to why people would have a need for meaning. Frankl argues that humans are spiritual creatures, though not in any religious sense. As spiritual creatures, we need to address our built-in desire for living out our values in a meaningful way. In contrast to this spiritual explanation for why we might have an intrinsic orientation to meaning,

Klinger (1977) felt that as living creatures we have a natural inclination to set goals to attain those materials we need to stay alive. Klinger implies that this motivational drive transfers to meaning and purpose because we humans are able to conceive of big abstract notions about what our lives should be like. According to these two scholars, meaning is important as a motivational drive, perhaps rooted in our animalistic needs to seek out nutrition, warmth, water, and other life-giving resources, which then gets transferred to higher aspirations for having a life worth living. Battista and Almond (1973) suggested that people also need to have a mental framework they can use to understand what that life worth living might be like. In these theories, feeling the presence of meaning is the marker that we are doing a good job of pursuing good aspirations. Baumeister (1991) argued that meaning occurs when a specific set of needs are met: purpose (having big goals), self-worth (feeling good about one's self), value (having some way to justify decisions and actions), and efficacy (feeling competent to act effectively in the world). There are two studies that provide some evidence that these four needs are correlated to people's levels of meaning in the context of thinking about one's family (Lambert, Baumeister, Stillman, & Finchman, 2012) or under experimental ostracism conditions (Stillman et al., 2009). However, purpose has been viewed as central and even definitional to meaning since at least Frankl's work in the 1940s and 1950s, and self-worth, efficacy, and having a system of values or philosophies to guide one's actions are each part of models of general well-being in their own right. These close associations among meaning, well-being, and the proposed needs makes it difficult to tease apart whether they are needs, or whether those elements are part of meaning versus well-being. However, bridging these early theories of meaning's origin suggests that people have some level of primal motivational drive to act in the world that must be satisfied to create meaning in their lives.

A different account of where meaning comes from focuses more on the nature of our mental processes, rather than our motivational processes. Steger (2009, 2012, in press) argued that meaning is similar to other mental processes the people have, that making sense of important stimuli gave us an evolutionary competitive advantage. For example, making sense of the facial expressions of a new group of people you encounter helps you navigate possible conflict. Making sense of the landscape around where one lives helps identify dangers and resources. Making sense of the sounds and gestures produced by other members of your species helps preserve and spread knowledge. This information processing and integration capacity is very similar to the way in which meaning works. Meaning incorporates people knowledge about their selves, other people, and the world around them into maps or meaning systems, preserving and linking information, both concrete and abstract. People's meaning systems help them conceive of grand goals and aspirations for their lives, giving them a sense of purpose. Several other scholars have emphasized the cognitive sense-making nature of humans in relation to meaning (e.g., Heine,

Proulx, & Vohs, 2006).

Beyond motivation and cognition, some scholars have developed ideas about how people experience meaning through emotional means (e.g., Reker & Wong, 1988). People seem to decide whether their lives have meaning by using, in part, their gut feelings or emotions (Heintzelman & King, 2014). In fact, all else being equal, people rate their lives as more meaningful when they are in a positive mood (King, Hicks, Krull, & DelGaiso, 2006). That is, if I asked you how meaningful your life felt while you were watching a funny movie, you might rate it higher than if you were just sitting at home reading. However, some scholars feel that positive feelings are more important when they happen at a higher level of abstraction. While feeling good might make life seem more meaningful for a few minutes, it may be much more important to feel positively about your life as a whole, seeing that your life matters (George & Park, 2014). Thus, "meaning in life necessarily involves people feeling that their lives matter, making sense of their lives, and determining a broader purpose for their lives" (Steger, 2012, p. 177). More formally, *meaning emerges "from the web of connections, interpretations, aspirations, and evaluations that (1) make our experiences comprehensible, (2) direct our efforts toward desired futures, and (3) provide a sense that our lives matter and are worthwhile*" (Martela & Steger, 2016, p.538, italics added), which are known as comprehension (also known as coherence), purpose, and significance, respectively.

Tools for Measuring Meaning

Meaning research consists of two parts that are not very well connected. The first part, which we have just examined, is the background of theory that defines meaning to have three main parts. The second part is the empirical research tradition, which has established hundreds of links between meaning and living a life marked by happiness and well-being. This second part usually uses formal tools for measuring meaning, none of which really measure comprehension, purpose, and significance separately. Beginning in the 1960s, a series of measurement tools were developed. Early tools (i.e., Purpose in Life Test; Crumbaugh & Maholick, 1964; Life Regards Index, Battista & Almond, 1973), were criticized as having problems with their internal structure, item wording, and inclusion of unrelated content, among other issues (e.g., Dyck, 1987; Steger, 2006; 2007).

The two most widely used measurement tools today both benefitted from sophisticated statistical techniques that were not practical until somewhat recently, which produced psychometrically robust instruments. Ryff's (1989) Purpose subscale is a part of a larger measure of psychological well-being. This subscale assesses people's levels of energy, activity, worthwhile things to do, and goals that they can pursue. It is quite commonly used in health-related research. The Meaning in Life Questionnaire (Steger, Frazier, Oishi, & Kaler, 2006) is more of a generic measure of meaning, asking people directly if they feel their lives have meaning and purpose. It also measures how much people are searching for meaning. These two subscales are quite commonly used in psychological and educational research. New tools continue to be developed, usually with the aim of helping researchers understand the different dimensions and components of meaning in life (e.g., George & Park, 2014).

Review of Research Assessing Relationships between Meaning and Well-Being

Particularly within the last 10-15 years, many studies have been conducted providing extensive knowledge about the connections between meaning and well-being. As you might expect from the title of this chapter, the overwhelming conclusion is that meaning is closely tied to a vast array of well-being indicators. In this section, the most-replicated results will be reviewed, broken into three categories: subjective or hedonic well-being indicators, psychological or eudaimonic well-being indicators, and general quality of life indicators. Although the general pattern will be to report only a single citation for each finding, all of the results discussed here have been replicated. The importance of replication of results across multiple studies is a central foundation of science, and especially for a variable with its roots in philosophy and theology, knowing that different researchers have found the same phenomena several times gives solidity to meaning research. This is not a meta-analysis, however, so only one reference is provided for each finding, and it is not possible to provide an estimate of how many null findings it would take to outweigh the significant ones. In some cases, this chapter will highlight areas where singular results suggest an intriguing new angle that requires further research.

Subjective of Hedonic Well-Being Indicators

Subjective well-being (SWB) is a somewhat broad term for people's appraisals that their life is good with no particular boundaries or criteria imposed upon their responses. It is sometimes equated with hedonic well-being, which is an older philosophical idea that more or less boils down to the idea that if someone says she is happy, then she is happy, regardless of what information she uses to make that determination. SWB has been proposed to include variables such as happiness, life satisfaction, and

positive and negative emotions (Diener, 1984).

Meaning is positively correlated with experiencing positive affect and emotions (Chamberlain & Zika, 1988), such as love, joy, vitality (Steger et al., 2006), curiosity (Kashdan & Steger, 2007), and hope (Mascaro & Rosen, 2005). In fact, so much of this line of research has been published that a meta-analysis among older adults was feasible, identifying a near-large effect size between meaning and diverse measures of positive emotions (Pinquart, 2002). Further, experimental evidence from one set of studies shows that increasing positive emotional states raises people's perceptions of meaning (King et al., 2006). As one might expect, meaning is inversely correlated with negative affect and emotions (e.g., Steger et al., 2006).

Meaning also is positively related to broader indicators of SWB, such as happiness (Debats, van der Lubbe, & Wezeman, 1993), general well-being (Reker, 2002), psychological adjustment (O'Conner & Vallerand, 1998), and life satisfaction (Ryff, 1989). This latter finding includes one of the rare long-term longitudinal studies, demonstrating that meaning and life satisfaction are positively correlated over one year's time (Steger & Kashdan, 2007). However, many of these results have been demonstrated over shorter periods of time such as one month (e.g., Steger et al., 2006) or 2-3 weeks (Steger & Frazier, 2005).

Psychological or Eudaimonic Well-Being Indicators

Psychological well-being (PWB) is a more narrowly focused term for a specific set of variables that are deemed by some expert source as being necessary for human flourishing. It is generally associated with eudaimonic well-being, which draws inspiration from Aristotle's philosophy. PWB variables are often viewed as being critical for the full development of human potential, and do not always include the kinds of information someone might use to judge if she or he is happy. PWB variables focus on personal growth, persistence, virtue, morality, and so on. Meaning itself is often put forward as a PWB or eudaimonic well-being indicator (e.g., Ryff, 1989), although it certainly can be considered to be both hedonic and eudaimonic (Steger, 2016). Many characterizations of PWB suggest that people should have a positive view off their selves. Accordingly, meaning positively correlates with self-esteem (Ryff, 1989), self-worth (O'Conner & Vallerand, 1998), and self-actualization (Phillips, Watkins, & Noll, 1974). PWB also is associated with Self-Determination Theory (Deci & Ryan, 2000), which posits that humans must meet three needs in order to flourish psychologically: Autonomy, Positive Relationships, and Competence. Meaning has been positively correlated to these three needs in several studies and cultures (Church et al., 2014). Meaning also has been positively correlated with having a sense of personal control over one's life, or locus of control (Ryff, 1989), as well as positive perceptions of the world itself (Sharpe & Viney, 1973).

Quality of Life Indicators

The final category of well-being indicators is a diverse group of variables that can be lumped under the umbrella term, quality of life (QOL). QOL is most often associated with health and health research and includes factors such as whether people are free of illness or disease, physical impairments or symptoms, and mental health. It may bear recalling that the heritage of meaning research lies in clinical theory on how people develop and recover from disorders, like depression and anxiety. Although well-being often has been separated from research on disorders, several models of overall psychological flourishing argue that it is important to consider both distress and well-being (e.g., Keyes, 2002). Thus, this section includes indicators of positive QOL, such as health, as well as negative QOL, such as disorders.

Among the most common results in this area of research is the inverse relationship between meaning and depressive symptoms (Kleiman & Beaver, 2013). As with positive emotions, enough research has been done on this link that a meta-analysis was able to estimate a near-large effect size of -.46 among older adults (Pinquart, 2002). Although no meta-analysis has been conducted, inverse correlations between meaning and anxiety symptoms are of similar size and also are frequently reported (Steger, Mann, Michels, & Cooper, 2009). People who have high levels of meaning report lower levels of perceived stress (Flannery & Flannery, 1990) and fewer symptoms of stress-related disorders, such as PTSD (DeViva, Sheerin, Southwick, Roy, Pietrzak, & Harpaz-Rotem, 2016).

One idea of early existentialists like Frankl was that people who cannot find meaning may give up on life, and indeed research has found that those low in meaning report more hopelessness (Edwards & Holden, 2001), a higher degree of drug and alcohol-related problems (Nicholson et al., 1994), and even stronger tendencies to want to end their own lives through suicide, known as suicidality (Henry et al., 2014). On the flip side, those who do feel their lives have meaning report more effective coping (Debats, Drost, & Hansen, 1995) and are more likely to say that they not only have survived trauma and tragedy but even have grown psychologically, spiritually, or socially as a result of those experiences (Steger, Frazier, & Zacchanini, 2008).

Finally, those who report having more meaning not only feel they are in better health than others

according to their subjective health ratings (Battersby & Phillips, 2016), but they also live longer lives (Boyle, Barnes, Buchman, & Bennett, 2009).

Personality. Although not directly considered to be QOL variables, some personality traits consistently are linked to better health and well-being outcomes, so they are considered here. Meaning is positively related to extraversion (e.g., Pearson & Sheffield, 1974) and conscientiousness (e.g., Steger et al., 2008), and negatively related to neuroticism (e.g., DeViva et al., 2016). Finally, meaning has been positively linked to several ways of measuring a person's commitment to religious beliefs (e.g., Steger & Frazier, 2005), which, though not a dimension of personality often is related to dimensions of personality (e.g., conscientiousness) and well-being.

Discussion

Although there is appreciable breadth in the research that has been done on the many ties between meaning and well-being, there are several important areas where the field is reliant on one study (or less). Three areas in particular demand further study to clarify and expand upon tantalizing early research results. These areas are understanding mechanisms by which meaning helps create broader well-being, identifying how meaning impacts health, and exploring how meaning is construed or created in diverse cultural contexts.

How does meaning create well-being? While we may be at the point where we can assume that most people who have meaning also experience greater well-being, we do not know why that is so. One hypothesis is that meaning supports other parts of people's lives known to impact well-being. For example, positive relationships with other people are critical to people's psychological functioning and well-being, and as reviewed here people with meaning in their lives report better relationships. If meaning helps people establish better relationships, then that would provide one avenue for boosting well-being. There is evidence that people prefer to interact with those who have high levels of meaning, and even judge them to be more likeable, have greater potential as a friend, and even that this effect reduces the well-known impact of physical attractiveness on these markers of interpersonal appeal (Stillman, Lambert, Fincham, & Baumeister, 2011). There also is evidence that those high in meaning care more about helping and benefitting others (Martela, Ryan, & Steger, in press). Thus, the arrow seems to run both ways: better interactions and relationships foster meaning, and meaning creates better interactions and relationships.

A second hypothesis is that people with meaning engage in different activities, but very few studies have established these links. One of the only ones that has been conducted showed that levels of meaning were higher among people who tended relationships, did volunteer work, worked toward their goals, and persevered through challenge to a greater degree than other people (Steger, Kashdan, & Oishi, 2006). Both of these hypotheses require more research in order to identify what people with meaning seem to be doing differently than other people. It may simply be that meaning *is* part of well-being, but greater possibilities for improving people's lives are suggested if meaning additionally is viewed as a *path* to well-being.

How does meaning lead to health? Similar to the case of well-being, we know that meaning is linked to a longer, healthier life, but the number of studies implicating biological or behavioral mediators is still small. Studies have found that people high in meaning engage less often in behaviors such as smoking cigarettes, or abusing substances, which would reduce risks to their overall health, particularly over time (e.g., Nicholson et al., 1994; Steger, Fitch-Martin, Donnelly, & Rickard, 2015; Steger, Mann, Michels, & Cooper, 2009). Other research has targeted biological mediators between meaning and health, focusing on people's levels of stress-related hormones and immune cells. These studies find that people with greater meaning have less evidence of potentially toxic levels of stress and immune response, as marked by such things as inflammatory cytokines and killer T-cell levels (e.g., Bower, Kemeny, Taylor, & Fahey, 2003; Krause & Hayward, 2012). Thus, meaning seems to play a role in protecting people from the risk for physical harm, whether through their own behaviors or through the impacts of life and stress on their immune and hormone system functioning, but more research is needed to show that meaning really does predict these behavioral and biological precursors to health in longitudinal and experimental settings.

How is meaning construed in diverse cultures? Meaning, like much of the rest of psychology, draws its origins from Western European-influenced cultures. This limited cultural scope leaves open the possibility that meaning is to some degree a cultural artifact. Research strongly suggests that meaning and well-being are linked together in all of the couple of dozen countries where it has been studied (e.g., Church et al., 2014). The issue is that when cross-cultural research is conducted, what is learned is restricted to the questions that are asked. For meaning, we can say that when the MLQ is used, people say their lives have meaning regardless of which country they come from (at least in the countries studied so far). What we cannot say is whether we are asking the right questions about meaning. We are not able to estimate whether studying meaning requires asking totally different kinds of questions in New York versus New Guinea, New Zealand, or New Caledonia. Research is needed that builds from the ground up in many

different cultures and nations.

Meaning is somewhat unique among psychological variables because of the historic emphasis on sources of meaning. This interest in where people find meaning lends itself to more open-ended inquiries than do methods that require people to simply answer a list of validated survey items. It should be reasonably straight-forward to ask people from diverse cultures and backgrounds where meaning comes from in their lives. However, even studies that look at sources of meaning around the world favor Europe and North America and tend to aggregate results rather than explore possible differences (Fave, Brdar, Wissing, & Vella-Brodrick, 2013). One intriguing exception comes from a study of both Arab and Jewish residents of Israel, in which rankings of the importance of sources of meaning differed by respondent's ethnicity (Bar-Tur, Savaya, & Prager, 2001). While it is interesting to know that cultural context may affect how people prioritize sources of meaning, even better would be to conduct research in such a way as to enable each culture's unique assemblage of sources of meaning to be revealed.

Conclusion

From some of our species' earliest writings to large scale scientific research conducted around the world, meaning has presented a compelling set of questions. Some of these questions continue to evade the field, such as how meaning helps foster well-being and health, and how much of the richness of the human striving for meaning remains unexplored. Given the explosive pace of meaning research, these topics undoubtedly will be tackled in the near future. Until then, it is clear that a great deal of research links meaning with well-being, that these links generally represent large effects, and despite some gaps in research coverage, meaning in life is justified in its position as a cornerstone resource for human well-being and flourishing.

Abstract

This chapter uses the most recent version of Job Demands–Resources (JD-R) theory to explain how working conditions influence employees, and how employees influence their own working conditions. We show how employee self-undermining activates a loss cycle of job demands, strain, and negative behaviors over time, whereas employee job crafting activates a gain cycle of job resources, work engagement, and positive behaviors. Moreover, we argue that employee well-being and organizational behavior is a function of factors located at different levels (i.e. organization, team, individual level), which influence each other within and over time. We propose cross-level interaction effects of organization-level initiatives and leader/employee behaviors on team and individual well-being and performance. Although JD-R theory provides answers to many questions regarding employee well-being and performance, we discuss several issues that deserve research attention. The chapter closes with practical implications. We discuss how managers and supervisors can help employees to avoid health problems and flourish at work.

Keywords: JD-R theory; work engagement; multilevel; teams; HR practices

Occupational well-being is gaining momentum because managers, policy makers, and employees have started to realize that occupational well-being is a crucial determinant of human functioning and job performance (De Neve, Diener, Tay & Xuereb, 2013). Our knowledge about well-being at work comes from thousands of studies among the various stakeholders in organizational life: employees, their supervisors, HR managers, work teams, and clients. High-quality studies use multiple sources of information to investigate the predictors and outcomes of occupational well-being. In the past decades, we have created a rich knowledge base about the psychosocial factors in the work environment that are responsible for the experience of job stress or well-being, as well as organizational behavior. We know now which job demands and resources predict employee well-being and have an impact on performance (e.g., financial returns, absenteeism, client satisfaction) (e.g., Bakker, Demerouti, De Boer & Schaufeli, 2003; Xanthopoulou, Bakker, Demerouti & Schaufeli, 2009a). However, one important problem of the current literature is that the vast majority of studies in occupational well-being follow a relatively simplistic stimulus-response model; assuming that employees are passive and simply react to the working conditions they are exposed to.

In the present paper, we use the most recent version of Job Demands–Resources theory (Bakker & Demerouti, 2014; 2017) to explain how working conditions influence employees, and how employees actively influence their own working conditions. We argue that organizational life should be modeled at the various levels (organization, team, individual), which influence each other within and over time. In this way, we can start to understand the stable and dynamic properties of occupational well-being. Moreover, it is important to model the cross-level interaction effects of organization-level initiatives and leader/employee behaviors on team and individual well-being and performance. Using this multilevel approach, we can explain how managers and supervisors can help employees to avoid job stress, and enhance well-being and job performance.

Job Demands–Resources Theory

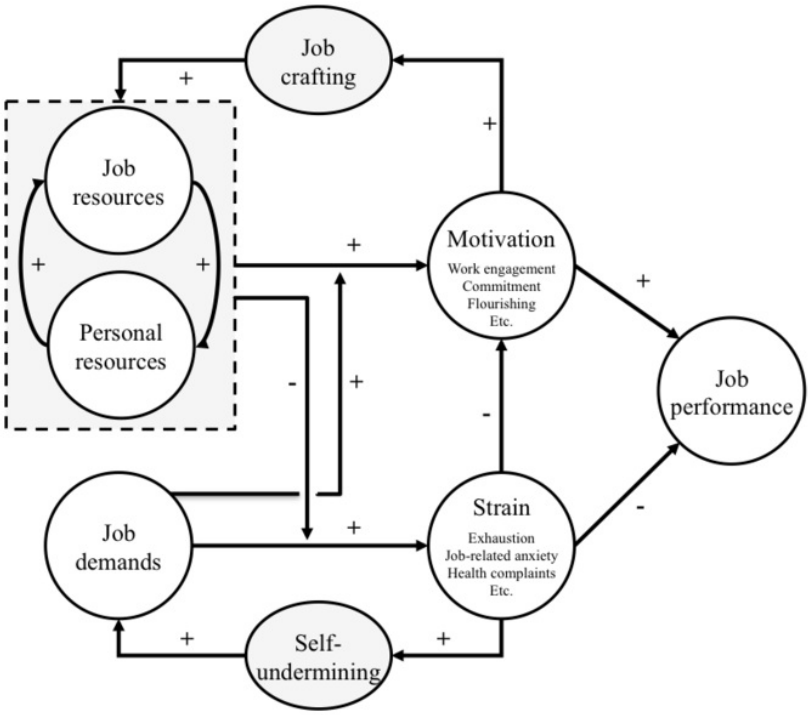
Since the end products of modern labor are so diverse that they range from the optimization of search engines to the provision of personal health care, it is obvious that working conditions can differ dramatically between organizations. Despite these differences, Job Demands–Resources theory (Bakker & Demerouti, 2014; 2017; Demerouti, Bakker, Nachreiner, & Schaufeli, 2001) proposes that all job characteristics can be classified in two main categories – namely job demands and job resources – that have unique properties and predictive value (*Proposition 1*). Job demands are the aspects of work that cost energy, like workload, complex tasks, and conflicts. Whereas workload and complexity can be qualified as challenge demands that help to perform well, conflicts are hindrance job demands that undermine performance (LePine, Podsakoff, & LePine, 2005). Job resources are the aspects of work that help

employees to deal with job demands and achieve their goals. For example, performance feedback, social support and skill variety are motivating job characteristics that provide meaning to employees, and satisfy employees' basic psychological needs, namely the needs for competence, relatedness, and autonomy (Deci & Ryan, 1985).

Job demands and resources have unique and independent effects on employee well-being (*Proposition 2*). As already proposed in the original version of the JD-R model (Demerouti et al., 2001), job demands may initiate a health-impairment process if exposure to daily workload transforms into chronic overload over a long time period. In this case, job demands lead to chronic exhaustion and may eventually result in physical health problems (including cardiovascular diseases). In contrast, job resources initiate a motivational process. Since job resources provide meaning and satisfy people's basic needs, job resources are motivating and contribute positively to work engagement (i.e. a fulfilling state of vigor, dedication, and absorption; Schaufeli & Bakker, 2004).

Proposition 3 of JD-R theory is that job resources can buffer the impact of job demands on negative strain. Thus, even though job demands and job resources have clear and independent main effects, they also work in concert (see Figure 1). Job resources are instrumental in that they arm employees with the means it takes to cope with the job demands. Whereas some scholars have argued that job resources should match the specific job demands – for example, that emotional job demands need to be matched with emotional job resources (De Jonge & Dormann, 2006), our research has shown that various job resources can buffer the impact of various job demands on negative strain (e.g., Bakker, Demerouti & Euwema, 2005; Bakker, Van Veldhoven & Xanthopoulou, 2010; Xanthopoulou et al., 2007).

Figure 1. The Job Demands–Resources model.



Proposition 4 brings the JD-R theory one step further as it suggests that job resources particularly influence motivation and work engagement when job demands are high. Thus, autonomy, skill variety, performance feedback, and task identity become particularly important when the job demands are very challenging. This idea is consistent with Hobfoll's (2001) notion that all types of tangible or psychological resources gain importance and become particularly useful when needed. Particularly when employees are confronted with a high workload and with emotionally demanding clients, they can use their autonomy, skills, and sense of prosocial impact to deal persistently with these demands and choose the right approach. Indeed, our research among Finnish teachers and dentists (Bakker, Hakanen, Demerouti & Xanthopoulou, 2007; Hakanen, Bakker & Demerouti, 2005) has shown that job resources such as appreciation, innovativeness, and skill variety are most predictive of work engagement when job demands (e.g., pupil misbehavior, unfavorable physical working environment) are high. Thus, job resources are particularly useful and motivating when needed.

Proposition 5 is that personal resources such as optimism and self-efficacy play a similar role as job resources (see Figure 1). Personal resources refer to the beliefs people hold regarding how much control they have over their (work) environment. Individuals who are high in optimism and self-efficacy believe that good things will happen to them, and that they are capable of handling unforeseen events. Such beliefs help employees to actively approach their job demands and deal with them in an effective way. For example, our research has shown that health care nurses who feel optimistic and self-efficacious can translate emotionally demanding interactions with their patients into challenges so that they feel engaged in their work (Bakker & Sanz-Vergel, 2013). Additionally, when nurses realize they have many personal resources, they are better able to deal with possible hindrance job demands, such as bureaucracy and conflicts.

JD-R theory puts employee well-being center stage, but an important goal of the theory is to predict employee behavior and organizational outcomes (absenteeism, productivity, organizational citizenship, client satisfaction). *Proposition 6* is that motivation has a positive impact on job performance, whereas job strain has a negative impact on job performance. Whereas motivation helps employees to be goal-directed and to focus all their energetic and cognitive resources on the tasks at hand, job strain impairs performance because it undermines the ability to focus. Employees who are exhausted or feel anxious at work are more likely to make mistakes, which have a negative impact on performance (Bakker, Van Emmerik, & Van Riet, 2008). In recent experimental studies (Hopstaken, Van der Linden, Bakker, & Kompier, 2015; Hopstaken, Van der Linden, Bakker, Kompier, & Leung, 2016), we have found that engaged individuals perform better on demanding tasks because they focus all their attention to the task, as indicated by pupil diameter data, brain activity, and self-report data. Furthermore, combining daily diary reports with objective financial data, Xanthopoulou et al. (2009a) showed that employees working in fast-food restaurants had better financial results on the days they were highly engaged in their work. =

Employees Influence their Own Job Design

As indicated in the opening paragraphs, most research in the domain of occupational health and well-being follows a stimulus-response model, thereby implicitly assuming that employees are passive and simply react to their working conditions. For example, the well-known demands-control model, effort-reward imbalance model, and job characteristics model (for a brief discussion, see Bakker & Demerouti, 2014) all assume that work characteristics influence employees, but do not explicate how employees may influence their own work environment. However, there is considerable evidence for the idea that employees play an active role in interpreting and modifying their working conditions. JD-R theory (Bakker & Demerouti, 2014, 2017) proposes that depending on their occupational health and well-being, employees may influence their own job design in one of two ways: (1) employees are stressed and influence their working environment in a negative way, inducing a loss cycle of job demands and strain; or (2) employees are engaged in their work and influence their working environment in a positive way, inducing a gain cycle of job resources and work engagement. These propositions are discussed in more detail below.

Loss Cycles in JD-R Theory

In his conservation of resources theory, Hobfoll (1989) proposes that people who lack various types of resources (e.g., a home, time, money, knowledge) are susceptible to losing even more resources. The assumption is that resources are related to each other in a 'web-like' nature, and that resource loss occurs in spirals. Loss spirals will follow initial losses, with each loss resulting in depletion of resources for confronting the next threat or loss (Hobfoll, 2001). For example, in a study on coping with traumatic stressors, Heath, Hall, Russ, Canetti, and Hobfoll (2012) found that exposure to political violence resulted in the loss of important personal and social resources. Resources loss predicted psychological distress, which predicted further resource loss. It is important to note that resource loss also prevents the switching of the situation into gain cycles, because there are not enough resources to invest in order to gain new resources. For example, in the context of work, one could invest knowledge, energy, and time to learn new skills in order to qualify for a new job. JD-R theory refers to loss *cycles*, because loss spirals eventually imply a complete depletion of resources. In most work organizations, people always have access to some resources. However, they may end up in a vicious cycle of resource loss in which one problem leads to another that aggravates the previous problem.

There is considerable evidence for loss cycles in an occupational context. Bakker, Schaufeli, Sixma, Bosveld, and Van Dierendonck (2000) found that general practitioners who had lost their enthusiasm and were more cynical towards their patients (cynicism) at the first wave of data collection faced more patient demands (complaints, threats) at the second wave five years later. In a similar vein, Ten Brummelhuis, Ter Hoeven, Bakker, and Peper (2011) found that financial consultants who had lost their enthusiasm and showed more burnout complaints reported a stronger increase in work overload, work hours, and work-home barriers over a period of two years. In a recent study, Frins, van Ruysseveldt, Van Dam, and Van den

Bossche (2016) found that older employees who lost their energy, felt exhausted and wished to retire at an earlier age reported more time pressure and more hectic work one year later.

Employees who experience high levels of job strain (e.g., chronic exhaustion) communicate poorly, make mistakes, and create conflicts, which add up to the already high job demands. Bakker and Costa (2014) have coined the term *self-undermining* to refer to "behavior that creates obstacles that may undermine performance" (p. 115). *Proposition 7* in JD-R theory is that negative job strain leads to self-undermining behaviors, which result in higher levels of job demands, and even higher levels of job strain. Bakker and Wang (2016) showed that employees who engaged in self-undermining behaviors (i.e., created stress, confusion, and conflict) reported higher levels of work pressure and emotional demands, were more exhausted, and scored lower on supervisor-ratings of job performance. Thus, self-undermining seems the consequence of high levels of job strain, and is the fuel of a loss cycle of high job demands and job strain (see Figure 1).

Gain Cycles in JD-R Theory

Longitudinal studies carried out in the past decade have also provided convincing evidence for gain cycles of job resources, well-being, and outcomes. For example, Hakanen, Perhoniemi and Toppinen-Tanner (2008) found that task-level job resources (craftsmanship, pride in the profession, and positive feedback from the results of work) predicted dentists' work engagement, and that work engagement predicted personal initiative over a period of three years. In addition, there was evidence for reversed causal effects. Among others, personal initiative positively influenced work engagement, and work engagement had a positive impact on future job resources, suggesting a gain cycle. Similarly, Reis, Hoppe and Schröder (2015) followed psychotherapists over a period of five months, and found that work engagement was a predictor and outcome of job resources such as autonomy, task variety, and learning opportunities. In addition, they found that the relationship between work engagement and mental health was reciprocal. Thus, those who felt generally cheerful, active, rested, and interested at time 1 (T1) were more likely to be engaged at work at T2, and those who were engaged at work at T1 were more likely to report a better general mental health at T2.

In their longitudinal study among engineers, Xanthopoulou, Bakker, Demerouti and Schaufeli (2009b) found that job resources predicted personal resources (self-efficacy, optimism, and self-esteem) and work engagement. They also found evidence for reversed causal effects from personal resources and work engagement to job resources – suggesting that those who were more self-efficacious, optimistic and enthusiastic at work gained more job resources over time. Finally, using a sophisticated study design with three waves of data collection, Weigl and his colleagues (2010) found that hospital physicians with higher levels of job control and active coping, and better work relationships at T1, felt more engaged at T2 (one year later). Work engagement, in turn, was a predictor of job control, active coping and high-quality work relationships at T3 (eighteen months later). Thus, T2 work engagement functioned as a mediator in the longitudinal relationship between T1 and T3 resources, suggesting a gain cycle of job resources. Taken together, these studies suggest that individuals who are engaged in their job are also motivated to stay engaged, and create their own resources (e.g., autonomy, feedback, support) over time. This idea is again consistent with conservation of resources theory (Hobfoll, 1989; 2001). Individuals are motivated to conserve their resources, and will try to expand these resources if possible. The question is how employees manage to optimize their own work environment.

JD-R theory acknowledges employees as active creators by modeling the loss and gain cycles employees initiate at work. We already saw that employees who are too strained by their job demands will become exhausted and initiate a loss cycle. Their exhaustion increases the likelihood of self-undermining behaviors, which further increase job demands and exhaustion. In contrast, employees who are engaged at work are motivated to stay engaged. We suggest that these employees will proactively search for challenges in their work and for the resources needed to perform well. The latter behavior is called job crafting.

Job crafting. According to Wrzesniewski and Dutton (2001), job crafting refers to the proactive changes employees make in their work tasks and their working relationships (e.g., with clients, colleagues, and their supervisor). The authors argue that job crafting may also refer to a cognitive process in which employees try to alter their view of work to make it more meaningful. In JD-R theory, we propose a behavioral approach, and argue that job crafting can take the form of proactively optimizing job demands and job resources (Tims, Bakker & Derks, 2012). More specifically, we propose that employees may increase their challenge job demands, increase their social and structural job resources, and decrease their hindrance job demands. A recent series of studies has indicated that job crafting can indeed lead to more job and personal resources and indirectly contribute to work engagement and job performance (see Figure 1; Demerouti, 2014, for an overview).

Proposition 8 in JD-R theory is that employees who are motivated by their work are likely to use job crafting behaviors, which lead to higher levels of job and personal resources, and even higher levels of motivation. Research of the past five years has provided convincing evidence for this process. For example, Tims, Bakker and Derks (2013) found that job crafting in the form of seeking challenges and resources predicted an increase in job resources, and indirectly related to increases in work engagement and job satisfaction. Vogt, Hakanen, Brauchli, Jenny and Bauer (2016) showed with a longitudinal study that employees who proactively built a resourceful and challenging work environment for themselves, increased their own psychological capital (hope, resilience, self-efficacy, and optimism) and work engagement.

Demerouti, Bakker, and Gevers (2015) showed that job crafting (particularly increasing job resources) was positively related to supervisor-ratings of contextual performance (i.e. helping others), through employee work engagement. In addition, job crafting was positively related to supervisor-ratings of creativity through work engagement and flourishing. Moreover, recent studies have shown that job crafting interventions in the form of training and self goal-setting can have favorable effects on employee well-being and job performance (Gordon et al., 2016; Van den Heuvel, Demerouti & Peeters, 2015; Van Wingerden, Bakker & Derks, 2016). Thus, employees can create their own 'gain cycle' of resources and work engagement by learning to craft their job. Unfortunately, however, most research seems to suggest that (self-initiated) job crafting in the form of reducing job demands is not an effective strategy to stop the loss cycle of high job demands and job strain (Demerouti, 2014).

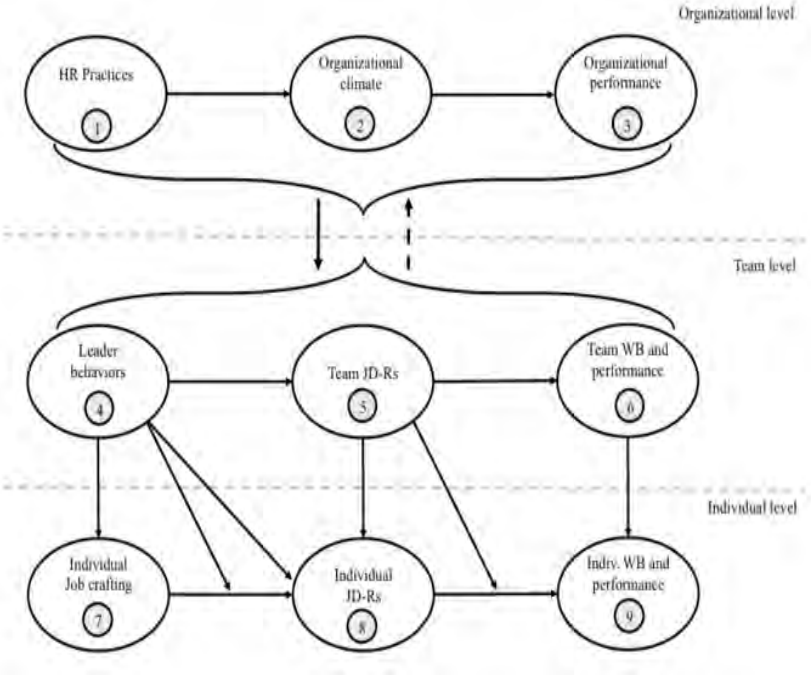
Multiple Levels in JD-R theory

JD-R theory outlines the processes through which job demands and resources influence occupational health, organizational behavior, and job performance. Most JD-R research has investigated these processes at the individual, employee level. Thus, employees are asked to report about their own job demands and resources and well-being, and this is then related to (self- or other-ratings of) individual performance. When managers know which specific job demands and resources need attention, they may take strategic and structural measures so that the work process is optimized for the employees in a top-down fashion which results in a better quality of working life. In addition, we have seen that employees influence their own working conditions. Employees can be reactive and undermine themselves by creating more job demands, or they can be proactive and optimize their own job demands and resources. This bottom-up perspective does not replace but rather complements existing top-down approaches. Acknowledging the active roles of various stakeholders raises the question how the various stakeholders interact. Therefore, it is essential that scientists distinguish between various levels, namely the level of the organization at large or management, the leader, the team, and the individual. In what follows, we illustrate how organizations, leaders and teams influence individual employees (*cross-level main and mediation effects*), and how the various levels interact to enhance employee well-being and organizational performance (*cross-level interaction effects*). Figure 2 gives an overview of the multilevel processes that may play a role here.

Organizational Level

In a recent paper, Albrecht, Bakker, Gruman, Macey and Saks (2015) have outlined how organizations may influence employee work engagement and performance through human resource (HR) practices. They argue that four key engagement-related HR practices (employee selection, socialization, performance management, and learning and development; see number 1 in Figure 2) influence the organizational climate (number 2) and the job demands and resources experienced by employees in their work roles (number 5 and 8), and indirectly influence work engagement and performance outcomes (number 6 and 9). Research has indeed provided evidence for this cross-level process. For example, Alfes, Shantz, Truss and Soane (2013) found that human resource practices such as employment security, extensive training, decentralization of decision-making, and sharing of financial and performance information (number 1) were positively related to individual organizational citizenship behaviors through work engagement (number 9). Dollard and Bakker (2010) found that when Australian teachers and administrators perceived a psychological climate in their organization signaling that management takes care of their employees (i.e., psychosocial safety climate; number 2), employees reported more job resources and endurable job demands (number 8) – which resulted in higher levels of work engagement (number 9). In a similar vein, Idris, Dollard, and Yulita (2014) found in their study in the Malaysian private sector that psychosocial safety climate (number 2) had cross-level effects on employee perceptions of job design (emotional job demands; number 8) and indirectly reduced psychological problems (exhaustion and depression; number 9).

Figure 2. Multiple levels in JD-R theory. ***Note.*** **WB = Well-being. Feedback loops are not included to avoid overly complex modeling.**



Furthermore, Van Wingerden et al. (2016) showed that job crafting training initiated by the HR department (number 1) had consistent positive effects on employee job crafting behaviors (number 7), and indirectly influenced job demands, resources (number 8) and work engagement (number 9). In a similar vein, Gordon et al. (2016) showed that job crafting training (number 1) influenced nurses' and surgeons' job crafting behaviors (number 7), and improved job demands and resources (number 8), as well as objective ratings of job performance (number 9). As a final example, in an impressive study among more than 15,000 employees from more than 1200 workplaces, Croon, Van Veldhoven, Peccei and Wood (2015) found that job enrichment HR practices (number 1) indirectly influenced organizational productivity (number 3) through employee perceptions of job resources (job control; number 8) and job satisfaction (number 9). These findings indicate that organizations can use HR practices to optimize the design of the jobs they offer. HR practices such as performance development and skills training create an abundance of challenging job demands and job resources that fuel employee well-being and performance.

Leader Level

How do leaders influence employees' job demands and resources? According to transformational leadership theory (Bass, 1985), effective leaders are able to inspire their followers to invest effort in common goals. By using inspirational motivation, individual consideration, and intellectual stimulation, leaders can motivate their followers to use their personal strengths. In a series of studies, Breevaart and her colleagues investigated how leaders may influence the working environment of their employees and in this way indirectly influence employee work engagement and job performance. In one study, Breevaart et al. (2014) followed naval cadets during their 34-day voyage from Northern Europe to North America by sail ship. The results showed that transformational leaders (number 4) had a positive influence on cadets' daily work engagement (number 9) because these leaders created abundant job resources for their followers (number 8). Naval cadets could use these resources to deal with the daily job challenges (e.g., hurricanes, complex exercises at sea).

In a follow-up study among a heterogeneous sample of white-collar workers, these findings were expanded. Breevaart, Bakker, Demerouti, Sleebos, and Maduro (2014) found that transformational leadership (number 4) contributed to followers' work engagement and leader-ratings of job performance (number 9) *through* job resources (autonomy, feedback, opportunities for growth; number 8). Similarly, Fernet, Trépanier, Austin, Gagné, and Forest (2015) investigated the impact of leadership on follower performance in their study among nurses and school principals. Consistent with JD-R theory, they found that transformational leadership (number 4) resulted in fewer job demands (cognitive, emotional and physical demands) and more job resources (e.g., participation in decision-making, job recognition, and quality of relationships; number 8), and indirectly contributed to more positive work attitudes and better job performance (number 9).

Team Level

In their study among Portuguese research teams, Costa, Passos and Bakker (2015) found that performance feedback, social support from co-workers, support from the supervisor, and information acted as team job resources (number 5) that predicted team work engagement (number 6) and objective research output (e.g., number of publications, number of oral presentations in conferences, organization of seminars/conferences, patents; number 6 and 9). Relationship conflict undermined the link between team resources and team work engagement, whereas task conflict aggravated the link between team work engagement and performance. These findings and the literature on teams clearly suggest that individual employees in work teams influence each other's engagement and performance.

There is indeed evidence for the crossover of work engagement between co-workers (e.g., Bakker, Van Emmerik & Euwema, 2006; Bakker & Xanthopoulou, 2009; link from number 5 to 8). Moreover, in their study among teams of occupational health professionals, Tims, Bakker, Derks, and Van Rhenen (2013) found that team work engagement (number 6) was related to individual performance through individual work engagement (number 9). Moreover, the latter study showed that employees were more likely to be proactive and improve their own job demands and resources, if they worked in teams where most others engaged in job crafting behaviors (see also Leana, Appelbaum, & Shevchuk, 2009). Bakker, Rodriguez Munoz and Sanz Vergel (2016) argue that employees imitate each other's job crafting behaviors and therefore influence each other's work engagement. The results of their study among dyads of employees from various companies showed indeed a reciprocal relationship between dyad members' job crafting behaviors. Moreover, employee's job crafting was related to colleague's work engagement through colleague's job crafting, suggesting a modeling process.

Interactions between Various Levels

As we saw in this review, it is important to differentiate between different organizational levels (organization, leader, team, individual), because the various stakeholders in organizations influence each other. Unfortunately, most research in organizational psychology is conducted at the individual level. Organizations are usually interested in average scores on job demands-resources, well-being, and performance at the team or departmental level. Therefore, researchers often aggregate individual scores to the group level. However, the aggregate of individual work engagement is phenomenologically different from team work engagement (Costa, Passos & Bakker, 2014). In addition, we have just seen that organizational life can better be explicitly modeled at various levels. This also offers the opportunity to investigate how the various levels statistically interact to produce occupational health and organizational performance (*cross-level interaction effects*).

Studies in the area of human resource management have investigated the cross-level interaction between HR practices and job demands/job resources. Boon and Kalshoven (2014) found that high-commitment HR practices (number 1) such as continuous training, high job security, empowerment, job rotation, a focus on learning and developmental feedback, variable pay, and an extensive benefits package were positively related to work engagement and organizational commitment (number 9), when task proficiency was low – that is, under the condition that employees lacked the resources to handle their tasks (number 8). This suggests that HR practices can help to overcome a lack of resources. However, Jensen, Patel, and Messersmith (2013) found that high-performance work systems, which are aimed at creating a competitive advantage for organizations, do so at the expense of workers. Using a multilevel sample of 1,592 government workers nested in 87 departments, they found that HPWS had several negative consequences when implemented with low levels of job control. Specifically, Jensen and colleagues showed that HPWS contributed positively to employee role overload (number 8) and anxiety (number 9) when job control (number 8) was low. These findings clearly indicate that if the implementation of HPWS practices is not coupled with an appropriate increase in autonomy among individual employees, simply instating a bundled set of integrated HR practices may have undesirable effects on employee job demands and well-being. These results point at the interplay between factors from different levels.

Using a general population sample of 2,343 Australian workers from a wide range of sectors, Hall, Dollard, Winefield, Dormann, and Bakker (2013) tested the buffering role of psychosocial safety climate as a macro-level resource in the health impairment process of the JD-R model. PSC refers to shared perceptions of organizational policies, practices, and procedures for the protection of worker psychological health and safety (Dollard & Bakker, 2010). When employees collectively believe that management takes good care of their health and safety, there is a high PSC. Hall and his colleagues found that PSC (number 2 in Figure 2) moderated the effects of (emotional and psychological) job demands (number 8) on depression (number 9), also after controlling for the impact of specific job resources (job control and social support). In a similar vein, Garrick et al. (2014) investigated the impact of general PSC in Australian schools on the link between teachers' daily job demands and well-being. They found that PSC (number 2) buffered the

impact of daily job demands (number 8) on fatigue (number 9), and boosted the impact of daily job demands (number 8) on work engagement (number 9). PSC also exerted a negative main effect on fatigue and a positive main effect on engagement. These findings suggest that organizations may be able to prevent worker depression and fatigue and foster work engagement when they focus on the development of a consistent PSC that signals a work environment conducive to worker psychological health and positive organizational behaviors.

Breevaart and Bakker (in press) hypothesized that daily transformational leadership behavior boosts employee work engagement on days characterized by high challenge job demands, and protects work engagement on days characterized by high hindrance job demands. Teachers filled out a short online questionnaire at the end of each workday during a two-week period. Results showed that teachers' daily challenge demands (workload and cognitive demands; number 8) had a positive relationship with work engagement (number 9) on the days transformational leadership (number 4) was high (vs. low). In addition, teachers' daily hindrance demands (role conflict; number 8) had a negative relationship with work engagement (number 9) on the days transformational leadership (number 4) was low (vs. high). These findings suggest that leaders use inspiration, intellectual stimulation and individual consideration to help followers to deal with their daily job demands.

Wang, Demerouti, LeBlanc, Bakker and Jiang (2017) investigated how Chinese leaders empower their followers so that they optimize their own working conditions and feel well (i.e. job crafting). They conducted a diary study among 106 leader-follower dyads (HR managers, consultants, engineers, and programmers) that had work contact on a daily basis. Wang and colleagues found that proactive leaders were most likely to show empowering behaviors, by consulting, delegating, enabling, and informing their followers. Further, the results showed that on the days leaders used more empowering behaviors (number 4), followers were more likely to engage in job crafting – i.e. to seek job challenges and resources, and to reduce hindrance demands (number 7). Moreover, daily empowering behaviors of leaders were particularly important for follower job crafting on the days followers had limited autonomy (number 8). These findings highlight that the interplay between leaders' behavior and individual job characteristics influences individual employee outcomes.

Future Outlook on JD-R Theory

Although JD-R theory provides answers to many issues regarding (occupational) well-being, there are several issues that need further attention. We will zoom in on three of these issues. First, although we know that job characteristics and well-being are related in the form of cycles or *spirals* (Salanova, Schaufeli, Xanthopoulou, & Bakker, 2010), we do not really know why this is the case. Why do individuals who are exhausted continue to find themselves in a negative cycle and not turn the negative cycle into a positive cycle? Similarly, how do individuals who are engaged in their job manage to remain in a positive cycle? Do such cycles lead to increases or decreases in the levels of well-being (i.e. higher levels of exhaustion or engagement), or do cycles generally keep the levels of well-being constant? We also do not know whether it is possible, and, if so, how individuals may change the progress of a negative cycle and turn it into a positive one. These questions not only require longitudinal data that allow testing cycles and spirals over time, but also advanced theory.

Second, we suggest in JD-R theory that well-being and performance are the outcomes of factors at the individual (job function) level but also at the team or even the organizational level. Several studies have provided evidence for such a claim. However, the empirical evidence is still scarce and scattered. We need more empirical evidence regarding whether a factor at the organizational level consistently acts as buffer or exacerbator of the effects on lower levels, or whether main effects are more important, for instance that a HRM policy directly influences the well-being of an individual. In addition, and in line with Bakker (2015), multilevel theories may differentiate between trait and state variables, integrate employee personality in the model, and outline how stable and dynamic variables interact. From a theoretical point of view, multi-level constructs result in a better understanding of psychological phenomena unfolding within organizations. From a practical point of view, knowledge gathered by following a multi-level approach can help guide the development of more effective interventions. We do not only need more systematic research on cross-level effects, but we also need better theoretical arguments explaining why and how factors at the higher level of the organization are important for processes occurring at the lower level.

Third, we have recently integrated employee behaviors in JD-R theory and have shown how employees may modify their job demands and resources through job crafting and self-undermining. In this chapter, we focused explicitly on self-undermining (involved in the negative cycle) and job crafting (involved in the positive cycle). Demerouti (2015) suggests that individuals may use various *strategies* – methods or plans that people choose to achieve a goal or solve a problem, which generally involve some planning or marshaling of resources for their most efficient and effective use. According to Demerouti,

examples of such strategies are coping, recovery from work-related effort, as well as selection, optimization, and compensation. Additionally, strength use (van Woerkom, Oerlemans, & Bakker, 2016) and proactive vitality management (Op den Kamp, Tims, Bakker, & Demerouti, 2017) may be important for the development of well-being. Integrating individual strategies into JD-R theory has both theoretical and practical implications and may uncover which behaviors help individuals to function well in a specific work context. These behaviors can then be stimulated or trained (see also, Bakker, 2017).

Implications for Practice

JD-R theory has been shown to be particularly influential in organizational practice as it helps practitioners and organizations to recognize the factors related to well-being (health and motivation) and to optimal functioning. Given the complexity of contemporary jobs, recognizing the demands and resources that may harm health or diminish motivation is one important but not sufficient step for improving well-being. Based on JD-R theory, we think that several steps are necessary in order to influence organizational life positively.

First, regular monitoring of the prevailing job demands and resources as well as of well-being is essential in order to recognize possible problems that require action. Second, as suggested, organizational level factors (HR practices, organizational climate) but also team-level factors (leaders' behavior, team demands and resources) may influence processes at the lower level. Therefore, constantly improving work processes and introducing employee friendly and high performance practices represent top-down interventions that can be beneficial for both the individual employee and organizational performance. In addition, training of supervisors to help them generate resources for their employees and teams to be resourceful to each other is a possible intervention at the middle level.

Third, we showed that in addition to managers also individual employees influence the conditions at work such that these conditions are optimized. Training employees to redesign their own jobs such that these jobs are better tailored to employees' preferences and abilities (through job crafting trainings; Van den Heuvel et al., 2015; Van Wingerden et al., 2016) may complement top-down approaches and make them even more effective. In order to achieve this, organizations need to enhance the relevant skills of their employees (through training or role modeling), and give employees the decision-authority to engage in job crafting.

Conclusion

In this chapter, we presented JD-R theory, which is appropriate to specify the factors that are related to the well-being of individual employees. Central in this theory are the prevailing job demands and job resources, which are responsible for health and motivational outcomes, respectively. However, we also provided evidence that the well-being of individuals triggers them to influence their job demands and resources (cf. job crafting and self-undermining), and these bottom-up influences operate next to the top-down changes initiated by the organization or its leaders. Moreover, we discussed that these processes occur over time in the form of positive or negative cycles, and that factors from different levels of the organization are involved in these processes. Although further research is needed to test its propositions, JD-R theory has clear implications for practice. We hope that JD-R theory will continue to inspire researchers and practitioners in organizations who aim to improve employee well-being and effective organizational functioning.

Wisdom and Well-Being

By Hannes Zacher, Leipzig University, & Ursula M. Staudinger, Columbia Aging Center, Columbia University

Citation
Zacher, H., & Staudinger, U. M. (2018). Wisdom and well-being. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

The literature that has investigated the association between wisdom and well-being has yielded conflicting results ranging from positive associations through zero to even negative associations. After defining and explaining the central constructs, the chapter will provide a review of this literature. While it seems intuitively right that wisdom should be positively associated with well-being, researchers have argued that the association depends on the type of definition and measurement of wisdom and well-being. The chapter will review and discuss the association between wisdom and well-being as a function of the notion and assessment of these constructs and will interpret the seemingly contradictory findings accordingly. Furthermore, the distinction between two types of positive personality development, that is, adjustment and growth, is used to help clarify the relationship between wisdom and subjective and psychological well-being. We conclude with a discussion of directions for future research on wisdom and well-being.

Keywords: Wisdom, Well-Being, Adjustment, Growth

Wisdom, "the pinnacle of insight into the human condition and about the means and ends of a good life" (Baltes & Staudinger, 2000, p. 122), has been a topic of rapidly growing interest among psychological scientists studying human development, potential, and well-being (Bangen, Meeks, & Jeste, 2013; Karelitz, Jarvin, & Sternberg, 2010; Staudinger & Glück, 2011). The goal of this chapter is to review and discuss the relationship between wisdom and subjective well-being (SWB) and psychological well-being (PWB). To this end, we first outline different definitions and operationalizations of wisdom. Importantly, in this chapter we focus on what has been called explicit theories of wisdom (i.e., how to conceptualize and measure wisdom of individuals based on psychological theorizing) and not on implicit theories of wisdom (i.e., how ordinary people perceive and define wisdom and wise people; cf. Staudinger & Glück, 2011). Next, we describe important indicators of SWB and PWB, the distinction between these constructs, as well as two types of positive personality development (i.e., adjustment and growth; Staudinger & Kunzmann, 2005). Third, we present the results of a review of empirical studies on wisdom, SWB, and PWB published over the past two decades. We conclude the chapter by integrating the findings of our review with the concepts of adjustment and growth, and we outline directions for future research.

Wisdom

Psychological scientists have investigated the ancient notion of wisdom for nearly 40 years (e.g., Baltes & Staudinger, 1993; Clayton & Birren, 1980; Sternberg, 1990). In their comprehensive review of the psychological wisdom literature, Staudinger and Glück (2011) broadly distinguished between general and personal wisdom. While general wisdom entails insights into life in general, without personal concern, personal wisdom involves people's insights into their own lives, including personal problems (Staudinger, 2013; Staudinger, Dörner, & Mickler, 2005).

General Wisdom

Research on general wisdom is based on cognitive research on expertise (i.e., expert knowledge and judgment), and adopts a performance-based view on wisdom in that wise people are assumed to possess and demonstrate greater knowledge and better judgment about fundamental life matters compared to less wise people. The most prominent approach to general wisdom is the Berlin wisdom paradigm. The Berlin wisdom paradigm defines wisdom as expertise in the fundamental pragmatics of life, that is, exceptional knowledge and judgment about the human conditions as well as life planning, management, and understanding (Baltes & Smith, 1990; Baltes & Staudinger, 2000, see Staudinger & Glück, 2011, for a review of other approaches to general wisdom). With regard to well-being, Baltes and Staudinger (2000) argued that wisdom "involves good intentions. It is used for the well-being of oneself and others" (p. 123). The paradigm proposes five wisdom criteria, including rich factual knowledge, rich procedural knowledge, lifespan contextualism, relativism of values and life priorities, and recognition and management of uncertainty. Wisdom is assessed by scoring participants' responses to difficult and existential life problems, such as the potential suicide of a friend. The validity of the Berlin wisdom paradigm has been demonstrated

in numerous studies (e.g., Baltes, Staudinger, Maercker, & Smith, 1995; Staudinger, Lopez, & Baltes, 1997; Staudinger, Maciel, Smith, & Baltes, 1998; Staudinger, Smith, & Baltes, 1992). These studies have shown that performance-based wisdom is typically normally distributed, with mean values below the mid-point of the measurement scale. With regard to the association with well-being, the paradigm predicts that SWB is a necessary but not sufficient condition in terms of predicting general wisdom-related performance.

Personal Wisdom

Research on personal wisdom is typically based on scholarship in the fields of personality psychology and personality development, and both performance-based and self-report measures have been developed to assess personal wisdom (see Staudinger & Glück, 2011, for a review of different approaches). Mickler and Staudinger (2008) define personal wisdom as the realization of one's own potential while considering the well-being of others and society. Based on the Berlin wisdom paradigm, they developed and validated a performance-based measure of personal wisdom that involves scoring participants' answers to a difficult personal problem according to five criteria (i.e., self-knowledge, growth and self-regulation, interrelating the self, self-relativism, and tolerance of ambiguity). With regard to well-being, Mickler and Staudinger (2008) proposed that SWB is a necessary but not sufficient precondition with regard to predicting personal wisdom.

The most prominent self-report measures of personal wisdom were developed by Ardelt (2003) and Webster (2003). Ardelt (2004) defines wisdom as the combination of cognitive (e.g., desire to understand the truth), reflective (e.g., taking multiple perspectives), and affective (e.g., an empathetic attitude) personality characteristics. She developed a self-report scale, the Three Dimensional Wisdom Scale (3D-WS) to measure these wisdom dimensions. Webster (2007) defines wisdom as "the competence in, intention to, and application of critical life experiences to facilitate the optimal development of self and others" (p. 164). He developed the Self-Assessed Wisdom Scale (SAWS) to measure five dimensions of wisdom (i.e., experience, emotion regulation, reminiscence and reflectiveness, openness, and humor). As personal wisdom is a socially desirable characteristic, scores on these scales are typically highly skewed toward the positive end of the measurement scales. Theoretically, both Ardelt (2004) and Webster (2007) predict that their measures of self-reported wisdom are positively associated with indicators of SWB. Consistently, both measures have demonstrated a substantial association with measures of SWB. A common criticism of self-report scales of wisdom concerns their validity, in that wisdom involves critical self-reflection and, therefore, wise people may not rate themselves higher on these scales than less wise people (Staudinger & Glück, 2011). Moreover, when the same individuals are asked to rate both their personal wisdom and their SWB, common method bias (or single source bias) is likely to be a problem, as this approach can lead to artificially inflated correlations between self-reported constructs (Podsakoff, MacKenzie, & Podsakoff, 2012).

Subjective and Psychological Well-Being

SWB (also sometimes referred to as "happiness") involves individuals' cognitive judgments and affective reactions when they think about and evaluate the quality of their lives (Diener, 1984, 2000; Diener, Suh, Lucas, & Smith, 1999). In empirical studies, the cognitive component of SWB is typically operationalized as life satisfaction (Diener, Emmons, Larsen, & Griffin, 1985), and the affective component of SWB is operationalized as the balance between experiences of positive and negative affect (Watson, Clark, & Tellegen, 1988). Life satisfaction and affective balance SWB have been distinguished from psychological well-being (PWB), which involves feelings of autonomy, growth, environmental mastery, positive social relations, self-acceptance, personal growth, and purpose in life (Keyes, Shmotkin, & Ryff, 2002; Ryff, 1989). This distinction is very similar to that the one between hedonic and eudaimonic well-being (Ryan & Deci, 2001). Ryff and Keyes (1995) developed a self-report inventory of PWB to measure the six dimensions of PWB just mentioned.

Building on research on personality development and well-being, Staudinger and Kunzmann (2005) proposed two dimensions of positive personality development across the lifespan (see also Staudinger & Kessler, 2009). In this approach, personality development toward adjustment entails increases in life satisfaction, affect balance, as well as increases in the big five personality characteristics of conscientiousness, agreeableness, and emotional stability (see Digman, 1990). Moreover, the PWB dimensions of environmental mastery, positive relations, and self-acceptance are part of a broader personality adjustment factor (Wink & Staudinger, 2015). Personality adjustment is conceived as the result of individuals coping with normative developmental tasks and it enables individuals to function effectively within societies. The second dimension, that is, personality development toward personality growth, involves increases in openness to experience and the PWB dimensions of autonomy, personal growth, and purpose in life (Wink & Staudinger, 2015). Personality growth involves experiences that go beyond societal requirements, expectations, and structures. According to Staudinger and Kunzmann (2005), a certain level

of adjustment is necessary, but not sufficient for growth to occur.

Researchers have argued that wisdom is conceptually closer to the notions of psychological/eudaimonic well-being and personality growth than to subjective/hedonic well-being and personality adjustment (Staudinger & Glück, 2011). Next, we review the empirical literature on wisdom and well-being, with particular attention to specific operationalizations of both wisdom and well-being across studies.

Review of the Empirical Literature

We conducted a literature review to identify empirical studies on wisdom and well-being. We searched four common databases (i.e., Ebscohost, Google Scholar, PsycInfo, Web of Science) using the following keywords in different combinations: wisdom, wise, well-being, wellbeing, psychosocial, satisfaction, affect, and happiness. We screened out irrelevant studies based on the title and abstract (e.g., abstract that simply referred to "established wisdom in the field"). We also excluded non-empirical book chapters and review articles (e.g., Ardelt, 2011; Ardelt & Ferrari, 2014; Baltes, Glück, & Kunzmann, 2002; Knight & Laidlaw, 2009; Kramer, 2000). Overall, our search resulted in 28 relevant empirical studies. These studies and their most important findings regarding wisdom and well-being are summarized in Table 1.

Table 1

Empirical Studies on Wisdom and Subjective Well-being (in the Same Order as Reviewed in the Text)

Authors and Year	Sample and Design	Operationalization of Wisdom	Indicators of Subjective Well-Being	Main Results
Performance-Based Wisdom and Well-Being				
1. Staudinger et al. (1997)	125 adults between 19 and 87 years (mean age = 45.4 years); cross-sectional design	Performance-based general wisdom (Berlin wisdom paradigm)	Psychological well-being (Ryff & Keyes, 1995)	Wisdom was associated with personal growth, but not the other indicators of psychological well-being.
2. Kunzmann and Baltes (2003)	293 participants from three age groups (93 young adults, 93 middle-age adults, and 107 older adults); cross-sectional design	Performance-based general wisdom (Berlin wisdom paradigm)	Positive and negative affect, positive affective involvement	Wisdom was negatively related to both positive and negative affect, and positively related to positive affective involvement.
3. Mickler and Staudinger (2008)	83 younger adults (ages 20–40) and 78 older adults (ages 60–80); cross-sectional design	Performance-based personal wisdom (Berlin wisdom paradigm)	Life satisfaction, positive and negative affect, agreeableness, conscientiousness, psychological well-being (composite of autonomy, mastery, and self-acceptance)	Personal wisdom was unrelated to indicators of subjective well-being.

4. Glück et al. (2013)	47 wisdom nominees and 123 control participants between 26 and 92 years; cross-sectional design	Self-reported wisdom (3D-WS and SAWS) and performance-based general wisdom (Berlin wisdom paradigm)	Psychological well-being (Ryff & Keyes, 1995): personal growth and self-acceptance	Both measures of self-reported wisdom were positively related to both indicators of well-being; performance-based wisdom was not significantly related to well-being.
5. Wink and Staudinger (2015)	163 participants between 68–77 years of age; cross-sectional design	Performance-based general (Berlin wisdom paradigm)	Personality growth and adjustment	Wisdom was positively related to personality growth, personality adjustment, and generativity. The association between wisdom and adjustment/generativity were mediated by growth.
6. Wink and Helson (1997)	94 adults at age 54; cross-sectional design	Self-reported wisdom (practical wisdom scale based on adjective check list) and observer ratings of transcendent wisdom	Life satisfaction	Wisdom measures were not significantly associated with life satisfaction.
7. Helson and Srivastava (2002)	92 participants at ages 21 and 61, and 201 participants at age 60; longitudinal design	Wisdom composite consisting of self-reported practical wisdom, as well as observer ratings of transcendent wisdom and a wisdom task based on the Berlin Wisdom paradigm	Well-being/adjustment (feeling optimistic and in good health), psychological well-being (Ryff & Keyes, 1995)	Wisdom was not significantly related to well-being/adjustment, and positively related to personal growth and positive relations with others.
8. Grossmann et al. (2013)	241 adults from three age groups (25-40, 41-59, 60-90 years); cross-sectional design	Performance-based general wisdom (wise reasoning)	Positive and negative affect, life and relationship satisfaction, rumination, longevity, emotional discourse patterns	Wise reasoning was associated with greater life satisfaction, less negative affect, better social relationships, less depressive rumination, more positive vs. negative words used in speech, and greater longevity.Wise reasoning mediated age-related differences in well-being.

9. Shi, Ardelt, & Orwoll (2016)	66 wisdom nominees, 84 creativity nominees, and 92 controls (age range = 53-92 years, mean age = 71.3 years); cross-sectional design	Nominations	Life satisfaction	Wise and creative nominees reported higher life satisfaction than controls, even after controlling for subjective health.
Self-Reported Wisdom and Well-Being				
10. Ardelt (1997)	120 older women and men from the 1968/69 Berkeley Guidance Study; cross-sectional design	Self-reported wisdom (3D-WS)	Life satisfaction	Wisdom was associated with life satisfaction above and beyond objective conditions.
11. Ardelt (2000)	82 older women from the 1968/69 Berkeley Guidance Study; cross-sectional design; same sample as [10]	Self-reported wisdom (3D-WS)	Life satisfaction	Wisdom was associated with life satisfaction above and beyond objective conditions.
12. Le (2011)	123 community-dwelling adults (age range = 39-96 years, mean age = 64 years); cross-sectional design	Self-reported wisdom (3D-WS)	Life satisfaction	Wisdom was positively related to life satisfaction.
13. Bergsma and Ardelt (2012)	7,037 respondents who participated in an internet survey; cross-sectional design	Self-reported wisdom (3D-WS)	Hedonic happiness	Wisdom, particularly reflective wisdom, was positively related to hedonic happiness (especially among people with lower levels of education).
14. Mansfield et al. (2010)	85 community members (age range = 18-71 years, mean age = 39.8 years); cross-sectional design	Self-reported wisdom (3D-WS)	Psychological well-being (Ryff & Keyes, 1995)	Wisdom was not significantly related to psychological well-being.
15. Taylor et al. (2011)	176 participants ranging in age from 18-68 years (M = 36.60); cross-sectional design	Self-reported wisdom (3D-WS; SAWS)	Life satisfaction, forgiveness	Both wisdom scales were positively related to life satisfaction and forgiveness.
16. Ardelt et al. (2013)	144 community residents, nursing home residents, and hospice patients between 56-98 years; cross-sectional design	Self-reported wisdom (3D-WS)	Life satisfaction, cheerfulness, absence of depressive symptoms, death fear	Wisdom was combined with measures of mastery and purpose in life. This psychosocial strengths measure predicted SWB above and beyond objective life conditions.
17. Ardelt and Edwards (2015)	156 older community residents (mean age = 71 years) and 41 older hospice patients and nursing home residents (mean age = 77 years); cross-sectional design; sample overlap with [16]	Self-reported wisdom (3D-WS)	Life satisfaction, cheerfulness, absence of depressive symptoms	Wisdom was positively related to SWB, especially in the nursing home and hospice sample; the relationship was partially mediated by purpose in life, both directly and via a sense of mastery.

18. Ardelt (2016)	123 older community residents (mean age = 72 years); two-wave study over 10 months	Self-reported wisdom (3D-WS)	Subjective well-being, mastery, purpose in life, and physical well-being	Wisdom was positively related to subjective well-being, mastery, purpose in life, and physical well-being at Time 2.
19. Ardelt and Jeste (2016)	994 adults aged 51–99 years (M = 77) from the Successful AGing Evaluation (SAGE) study; cross-sectional design	Self-reported wisdom (3D-WS)	Positive mental health, happiness, and life satisfaction	Wisdom, in particular reflective wisdom, was positively related to subjective well-being and buffered the negative relationship between adverse life events during the previous year and current well-being.
20. Etezadi and Pushkar (2013)	360 retired older adults (mean age = 61 years, range = 45–79 years); cross-sectional design	Self-reported wisdom (3D-WS)	Positive and negative affect	Coping strategies, perceived control, and life engagement mediate the positive relationships of wisdom with positive and negative affect.
21. Zacher et al. (2013)	175 university students (age range = 17-41 years, mean age = 21 years) and 400 online workers (age range: 16-74 years, mean age = 31.6 years); cross-sectional designs	Self-reported wisdom (3D-WS)	Life satisfaction, positive and negative affect	Positive relationships of wisdom with life satisfaction and positive affect (but not negative affect) became weaker and non-significant when emotional intelligence was controlled.
22. Webster et al. (2012)	512 adults (age range = 17-92 years; mean age = 46.46 years); cross-sectional design	Self-reported wisdom (SAWS)	Mental health (emotional, psychological, and social well-being)	Wisdom was positively related to mental health, above and beyond certain demographic and personality characteristics.
23. Webster et al. (2014)	512 adults (age range = 17-92 years, mean age = 46.46 years); cross-sectional design; same sample as [22]	Self-reported wisdom (SAWS)	Mental health (emotional, psychological, and social well-being)	Wisdom was positively related to mental health.
24. Proctor et al. (2011)	135 undergraduate university students; cross-sectional design	Self-reported wisdom (Values-In-Action strengths classification system)	Life satisfaction, positive and negative affect	General strengths use is positively associated with subjective well-being, but wisdom is one of the least-endorsed strengths.
25. Moraitou and Efklides (2012)	446 adults (age range = 20-80 years); cross-sectional design	Self-reported wisdom (Wise Thinking & Acting Questionnaire)	Positive and negative affect	Wisdom was positively related to positive affect and not significantly related to negative affect.

26. Krause and Hayward (2015a)	1,535 older adults who participated in a nationwide survey (mean age = 63.3 years); cross-sectional design	Self-reported practical wisdom (newly developed 7-item scale)	Life satisfaction	Practical wisdom was positively related to life satisfaction.
27. Krause and Hayward (2015b)	1,535 older adults who participated in a nationwide survey (mean age = 63.3 years); cross-sectional design; same sample as [26]	Self-reported practical wisdom (newly developed 7-item scale)	Self-esteem, hope	Practical wisdom is positively related to self-esteem and hope.
28. Krause (2016)	1,535 older adults who participated in a nationwide survey (mean age = 63.3 years); cross-sectional design; same sample as [26, 27]	Self-reported practical wisdom (newly developed 7-item scale)	Life satisfaction	Wisdom and humility relate positively to life satisfaction; the relationship between humility and life satisfaction is stronger for wise people.

Note. 3D-WS = Three-Dimensional Wisdom Scale (Ardelt, 2003); SAWS = Self-Assessed Wisdom Scale (Webster, 2003).

Performance-Based Wisdom and Well-Being

We identified five studies based on the Berlin wisdom paradigm that investigated relationships between performance-based wisdom and indicators of well-being (Table 1). First, Staudinger et al. (1997) recruited a diverse sample of 125 participants that were assessed using measures of general wisdom-related performance, fluid and crystallized intelligence, personality (including the big five and Ryff's six indicators of PWB), and constructs at the intelligence-personality interface (e.g., creativity, cognitive style). Results showed that of the six PWB indicators, only personal growth was positively related to general wisdom-related performance at the bivariate level. Using backward regression analysis, openness to experience and psychological mindedness, but none of the PWB indicators remained significant predictors of wisdom.

Second, using a sample of nearly 300 participants from three age groups, Kunzmann and Baltes (2003) found that people scoring high in general wisdom-related performance experience both positive and negative affect less frequently than people scoring lower. These researchers suggested that wise people have a more realistic and less positively biased views on life, and that they also possess greater emotion-regulation skills. Furthermore, Kunzmann and Baltes (2003) also reported that people with high levels of wisdom-related performance had a higher degree of affective involvement, which involves experiences such as being interested and feeling inspired, as well as values related to greater personal growth, life insight, societal engagement, others' well-being, and ecological protection.

Third, using a sample of 83 younger and 78 older adults, Mickler and Staudinger (2008) examined associations of performance-based personal and general wisdom with several indicators of SWB. They found non-significant relationships between personal wisdom-related performance and life satisfaction, positive and negative affect, and personality adjustment (i.e., conscientiousness, agreeableness, environmental mastery, self-acceptance, and autonomy). General wisdom-related performance was also not significantly related to the SWB indicators, with the exception of a moderate positive relationship with life satisfaction (with and without controlling for age). Mickler and Staudinger (2008) concluded that SWB is not a sufficient condition to attain personal wisdom. In contrast, they suggested that critical self-reflection and coping with negative events and emotional states which often are linked with lowering subjective well-being are more important for achieving personal wisdom.

Fourth, Glück et al. (2013) included 47 wisdom nominees and 123 control participants in their study on relationships between different well-established measures of wisdom including both self-report and performance measures. Their analysis showed that performance-based general wisdom as measured with the Berlin Wisdom paradigm was not significantly related to Ryff's PWB indicators of personal growth and self-acceptance.

Fifth, Wink and Staudinger (2015) investigated the relationship of performance-based general wisdom with personality adjustment and growth as well as generativity (i.e., the concern for establishing

and guiding the next generation; Erikson, 1950) in a sample of 163 older men and women. They found positive correlations between wisdom and personality growth, personality adjustment, and generativity. Personality growth was operationalized as a composite including openness to experience, psychological mindedness, and a sense of well-being derived from growth, purpose in life, and autonomy. Personality adjustment was a composite of life satisfaction, high agreeableness and conscientiousness, low neuroticism, and a sense of well-being derived from positive relations with others, self-acceptance, and environmental mastery. Using latent path analysis, Wink and Staudinger (2015) further showed that the associations between personality adjustment and wisdom and between generativity and wisdom were mediated by personality growth. According to the authors, these findings suggest that wise people are capable of balancing different personal strengths and interests, and that this integration takes place by pursuing personality growth via personality adjustment.

We identified four additional studies that used interview ratings by trained observers and a nomination procedure to measure wisdom. In an early study, Wink and Helson (1997) found no significant relationship of life satisfaction with self-reported practical wisdom and transcendent wisdom ratings by trained observers. A later longitudinal study by Helson and Srivastava (2002) examined how wisdom related to well-being at ages 21 and 60, and to change in well-being from age 21 to age 61. The researchers created a wisdom composite by averaging scores on self-reported practical wisdom, as well as observer ratings of transcendent wisdom and responses to a wisdom task based on the Berlin Wisdom paradigm. SWB was measured in terms of adjustment (i.e., feeling optimistic and in good physical and mental health) with the California Psychological Inventory, and PWB was measured with the Ryff scales. Results showed that wisdom was unrelated to SWB at age 21 and change in SWB between ages 21 and 61. In contrast, wisdom was positively associated with Ryff's PWB indicators of personal growth and positive relations with others at age 60.

A study by Grossmann, Na, Varnum, Kitayama, and Nisbett (2013) with 241 adults from different age groups measured performance-based wisdom as the extent to which people use pragmatic reasoning to solve social conflicts. The researchers found that wise reasoning was positively related to life and social relationship satisfaction, the use of more positive vs. negative words in speech, and longevity, and negatively related to negative affect and depressive rumination (correlations ranged from .17 to .33). The pattern of relationships remained the same when socioeconomic factors, verbal abilities, and personality traits were statistically controlled. Wise reasoning further mediated age-related differences in participants' well-being, particularly among older adults. Finally, a recent study by Shi, Ardelt, and Orwoll (2016) examined personal wisdom and creativity using nominations by others. These researchers included 66 wisdom nominees, 84 creativity nominees, and 92 control participants in their study. Results showed that people nominated as wise and creative reported higher life satisfaction than control participants, even after controlling for subjective health.

In summary, performance-based general as well as personal wisdom do either show none or only weak associations with SWB in the sense of a necessary but not sufficient condition for wisdom. The same holds true for the adjustment-related component of PWB. In contrast, the growth-related component of PWB shows substantial associations with performance-based wisdom measures.

Self-Reported Wisdom and Well-Being

The vast majority studies in our literature review examined associations between wisdom and well-being using self-report scales of wisdom (see Table 1). This outcome is likely due to the ease and practicability of administering self-report wisdom scales (Staudinger & Glück, 2011). Of the 22 studies using self-report scales, 13 studies used Ardelt's (2003) 3D-WS, four studies used Webster's (2003) SAWS (note that one study included both the 3D-WS and the SAWS; Glück et al., 2013), and six studies using other self-report scales (e.g., practical wisdom scale, the values-in-action strengths classification system, wise thinking and acting questionnaire).

Ardelt's 3D-WS and well-being. In two early studies, Ardelt (1997, 2000) used the 3D-WS to examine the relationship between self-reported wisdom and life satisfaction in samples drawn from the 1968/69 Berkeley Guidance Study. Both studies showed that self-reported wisdom was positively associated with life satisfaction, above and beyond other factors such as age, self-reported physical health, socioeconomic status, financial situation, physical environment, and social involvement. Subsequent studies using the 3D-WS have largely reported consistent results for life satisfaction. Specifically, using a sample of 123 community-dwelling adults, Le (2011) found that self-reported wisdom was positively related to life satisfaction. Similarly, Bergsma and Ardelt (2012) reported that self-reported wisdom was positively related to a measure of "hedonic happiness" in a large sample of over 7,000 adults who completed an online survey (9.2% explained variance). Contrary to the authors' expectations, a study with 85 community members by Mansfield, Mclean, and Lilgendahl (2010) did not find a significant relationship between self-

reported wisdom and a composite of the PWB scales by Ryff and Keyes (1995). This finding may be due to the PWB scales measuring both personality adjustment and growth (cf. Wink & Staudinger, 2015), and an aggregate score does not take this important distinction in to account. However, a study by Taylor, Bates, and Webster (2011) with 176 adults found positive associations between the 3D-WS and both PWB and a measure of forgiveness.

Glück and colleagues (2013) found positive and moderate relationships between self-reported wisdom measured with the 3D-WS and Ryff's PWB indicators of personal growth and self-acceptance. In a study with 144 community residents, nursing home residents, and hospice patients, Ardelt, Landes, Gerlach, and Fox (2013) found that a psychosocial strengths measure (including self-reported wisdom, mastery, and purpose in life) predicted various indicators of SWB (i.e., life satisfaction, cheerfulness, absence of depressive symptoms, and low fear of death), above and beyond demographic variables (i.e., age, gender, race, and marital status) and objective life conditions (i.e., physical health, socioeconomic status, financial situation, social involvement). In a later article using a similar sample, Ardelt and Edwards (2015) reported that self-reported wisdom (3D-WS) was positively associated with the same composite of SWB, and that this relationship was partially mediated by purpose in life, both directly and via a sense of mastery.

Ardelt (2016) conducted the only longitudinal study on self-reported wisdom and SWB to-date. Using a sample of 123 community residents who provided data at two measurement points separated by 10 months, she found that self-reported wisdom measured at Time 1 was positively related to SWB, mastery, purpose in life, and physical well-being measured at Time 2. In another recent study, Ardelt and Jeste (2016) found that self-reported wisdom, and especially the reflective component, was positively related to SWB (i.e., life satisfaction, happiness, and positive mental health). Moreover, high levels self-reported wisdom buffered the negative association between adverse life events during the previous year and current SWB.

Two studies examined variables that may account for positive relationships between self-reported wisdom (as assessed by the 3D-WS) and SWB. In a sample of 360 older adults, Etezadi and Pushkar (2013) found that coping strategies, perceived control, and life engagement mediated the positive relationship between self-reported wisdom and positive affect, and perceived control and life engagement mediated the negative relationship between self-reported wisdom and negative affect (controlling for social desirability, health, and sociodemographic variables). Zacher, McKenna, and Rooney (2013) examined self-reported wisdom, emotional intelligence (i.e., the perceived ability to perceive and regulate emotions in oneself and others; Law, Wong, & Song, 2004) in two samples of 175 university students and 400 online workers. They reported that the positive associations of self-reported wisdom with life satisfaction and positive affect (but not negative affect) became weaker and non-significant when controlling for emotional intelligence in the analyses.

In summary, research using the 3D-WS has generally found positive associations between self-reported wisdom and various indicators of well-being. Taking into account, however, that self-reported wisdom, as measured by the 3D-WS, do not differentiate wisdom nominees from matched controls (Glück et al., 2013), limits the meaning of this finding for improving our understanding of the association between wisdom and well-being. Also, research on the potential explanations for these relationships (e.g., coping, emotional intelligence) is still in its infancy, and the vast majority of studies are based on cross-sectional instead of longitudinal designs.

Webster's SAWS and well-being . Four articles using Webster's (2003) SAWS found positive associations between self-reported wisdom and well-being. Specifically, Taylor et al. (2011) found that the SAWS was positively related to both PWB and forgiveness. In two articles using the same large sample of 512 adults, Webster, Westerhof, and Bohlmeijer (2012) and Webster, Bohlmeijer, and Westerhof (2014) reported that the SAWS was positively related to mental health (operationalized as emotional, psychological, and social well-being), above and beyond several demographic (i.e., age, gender, education) and personality characteristics (i.e., neuroticism, extraversion, and openness to experience). Finally, Glück and colleagues (2013) found small positive relationships between the SAWS and Ryff's PWB indicators of personal growth and self-acceptance.

Wisdom as values-in-action and well-being. Research using self-report measures of wisdom other than the 3D-WS has also generally found support for positive associations between self-reported wisdom and indicators of well-being. First, using the values-in-action strengths classification system (Peterson & Seligman, 2004), Proctor, Maltby, and Linley (2011) examined the association between endorsement of strengths, including wisdom, and SWB indicators in a sample of undergraduate students. While more endorsement of strengths was positively associated with life satisfaction and positive affect, and negatively associated with negative affect, wisdom was one of the least-endorsed strengths and,

therefore, its unique association with SWB was not assessed. Second, Moraitou and Efklides (2012) assessed self-reported wisdom with the "wise thinking and acting questionnaire," which they developed for their study. The items of the questionnaire ask participants to rate their practical wisdom, integrated dialectical thinking, and awareness of uncertainty in life. Using a sample of 446 adults, the authors found a positive relationship with positive affect, but no significant relationship with negative affect.

Practical wisdom and well-being. In a series of articles based on the same sample of 1,535 middle-aged and older adults, Krause and Hayward examined relationships between a newly developed self-report measure of practical wisdom and various indicators of well-being. Practical wisdom was conceptualized as a higher-order factor comprising self-beliefs regarding learning from mistakes, understanding others, forgiveness, helping others, tolerance of ambiguity, and perspective taking. Krause and Hayward (2015a) found that frequency of church attendance was associated with greater self-reported practical wisdom which, in turn, was positively associated with life satisfaction, experienced awe of god, sense of connectedness with others, and life satisfaction. Krause and Hayward (2015b) reported that self-reported practical wisdom was positively associated with self-esteem and hope. Krause (2016) showed that self-reported wisdom is positively associated with humility values and life satisfaction, and that the relationship between humility and life satisfaction is boosted by greater levels of self-reported wisdom.

In summary, most research on self-reported wisdom and well-being has found positive relationships, independent of the specific operationalizations of self-reported wisdom and SWB. With regard to PWB the findings are mixed as some studies use an average across the six scales and other studies use individual subscales. It seems that personal growth and self-acceptance, indicators of personality maturation towards growth, show moderately positive associations with self-reported wisdom.

Discussion

We reviewed empirical research on the association between wisdom and well-being as a function of the wisdom and the well-being measures under study. In this section, we discuss the five main conclusions of our review. First, performance-based measures of wisdom show a small but significant association with SWB. More specifically, it is general wisdom scores that demonstrate this relationship whereas personal wisdom does not seem to be related with SWB. This pattern of results may highlight the fact that while being better able to provide advice to others may be associated with better SWB, higher levels in self-related insight and wisdom seem to come at a cost in terms of SWB. This interpretation is supported by the finding that the maturity aspects of psychological wellbeing are more strongly linked with personal than general wisdom (Mickler & Staudinger, 2008).

Second, self-reported wisdom measures show a substantial positive relation with well-being. While research using performance-based measures of wisdom found no significant or only weak associations with SWB, most research using self-report questionnaires to assess wisdom found moderate to strong positive relationships with SWB. There appear to be some differences between self-report measures of wisdom with regard to their associations with well-being (cf. Glück et al., 2013). However, further research using reports from multiple sources (e.g., friends, coworkers) as well as a broad variety of well-being indicators is needed to better understand the reasons for these initial results. The same applies to the association between wisdom and PWB. In particular, it seems that the scales of self-acceptance and personal growth show a positive association.

Third, the distinction between personality maturation toward adjustment and/or growth (Staudinger & Kunzmann, 2005) may be useful to clarify the seemingly contradictory findings on wisdom and SWB. As noted earlier, personality adjustment includes not only personality characteristics such as conscientiousness and agreeableness, but also common indicators of SWB (i.e., life satisfaction and affective balance). In contrast, personality growth includes openness to experience and certain dimensions of psychological well-being (i.e., autonomy, personal growth, and purpose in life; Ryff & Keyes, 1995). Wisdom researchers have argued that valid measures of wisdom should be more strongly related to personality growth than to personality adjustment, and that personality adjustment may be only a necessary but not sufficient precondition for the development of wisdom (Staudinger & Glück, 2011; Sternberg & Jordan, 2005; Wink & Staudinger, 2015). Indeed, consistent with this assumption, Wink and Staudinger (2015) found that personality growth mediated the association between personality adjustment and performance-based general wisdom.

Fourth, the validity of self-report measures of wisdom may be problematic, as truly wise individuals may not rate themselves particularly high on these instruments (Staudinger & Glück, 2011). And indeed, in a nomination study of wisdom, the self-report measures were not able to differentiate the wisdom nominees from matched controls (Glück et al., 2013). Instead, individuals scoring high on self-reported wisdom may be those who respond in a socially desirable way, which is consistent with personality adjustment. This may explain why most studies reported positive relationships between self-

reported wisdom and various indicators of SWB, whereas relationships between self-reported wisdom and PWB, and particularly the growth-oriented dimensions of Ryff and Keyes' (1995) PWB measure, where mixed. Future research assessing performance-based wisdom, self-reported wisdom, personality maturation towards adjustment and towards growth is needed to verify these assumptions.

Finally, our review of the literature showed that most studies relied on cross-sectional designs. Thus, it is important that researchers conduct more longitudinal studies to examine the causal direction of relationships, as well as the (co-)development of wisdom and well-being over time.

In conclusion, researchers have argued for a long time that wisdom does not necessarily come with happiness, but is an indicator of personality growth and a meaningful life (Staudinger & Glück, 2011; Weststrate & Glück, in press). Indeed, gains in wisdom, in particular personal wisdom, may result from overcoming negative challenging life events (Mickler & Staudinger, 2008; Staudinger et al., 2005). Our review showed that performance-based measures of general wisdom are weakly related to indicators of SWB and this association is fully mediated by personality maturation towards growth. Thus, in future research on wisdom and well-being, it will be important to distinguish, both conceptually and empirically, between self-report and performance measures of wisdom as well as between general and personal wisdom. The distinction between personality maturation toward growth (represented by performance-based wisdom measures) and personality maturation toward adjustment (which is represented by most of the self-report wisdom scales) seems to be helpful in understanding some of the seemingly conflicting evidence in the literature.

What's Love Got to Do With it? Romantic Relationships and Well-Being

By Jessica Kansky, University of Virginia

Citation
Kansky, J. (2018). What's love got to do with it?: Romantic relationships and well-being. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

Social relationships are one of the most important facets of well-being and one of the strongest links with both physical and psychological health. Romantic relationships specifically may have a particularly intense impact on well-being due to heightened emotions and cognitions within these close relationships. Prior research has identified the importance of romantic relationships and relationship status for well-being and psychological adjustment, yet less has considered the specific qualities that play a role in this link. I will consider the specific relationship qualities that may particularly benefit or damage well-being. Intimate relationships become increasingly important as individuals transition from dating in adolescence, cohabitating in emerging adulthood, and ultimately marriage in adulthood. I review the extensive literature on the benefits of healthy romantic relationships on well-being, highlighting how each influences the other during different developmental stages of relationships from initiation to dissolution adjustment. I also point to the increasing diversity of understudied romantic experiences (i.e., online, casual, polyamory, arranged versus self-selecting marriages, sexual minority) and highlight important unanswered questions this proliferation leaves open. Future directions for further understanding the unique role of romantic experiences in its association with well-being will be discussed.

Keywords: Romantic relationships, relationship quality, well-being

One of the strongest links to subjective well-being is the quality of one's social relationships (Frisch, 2005; Oishi, Diener, & Lucas, 2007). The happiest people report having the most satisfying social lives. Specifically, people with high positive affect and life satisfaction are more likely to engage in more social activities including spending more time talking to others, have more friends, and feel closer to their friends (Diener & Seligman, 2002; Mehl, Cazire, Holleran, & Clark, 2010). Those with strong social ties reap myriad benefits beyond its critical link to well-being. For example, those with healthy social relationships tend to live longer and have better physical health (House, Landis, & Umberson, 1988; Umberson & Karas Montez, 2010), have greater job satisfaction and work performance, academic competence (Resnick et al., 1997; Chambel & Curral, 2005; Cotton, Dollard, & de Jonge, 2002), and are more creative (Perry-Smith, 2006). Psychological health including depression, anxiety, substance use, and feelings of self worth and self esteem has been strongly tied to social relationships (Cutrona & Russell, 1987; Diener & Seligman, 2002; Kawachi & Berkman, 2001; Richards, Hardy, & Wadsworth, 1997; Taylor, Doane, & Eisenberg, 2013).

There are several theories as to *why* happy individuals benefit from having strong ties with others. Developing social resources has evolutionarily been beneficial for survival (Buss, 2000). Those in a supportive group have been able to live longer and provide for their offspring in ways that living in solitude could not provide. Humans at their core have needs to belong and to develop close social relationships (Baumeister & Leary, 1995). Therefore, it is unsurprising that meeting these needs and having close social ties is linked to well-being. An alternate perspective is that happy people attract social resources and can also build relationships with others when in positive moods. This is most similar to Fredrickson's broaden-and-build model (1998, 2001), which proposes that positivity allows one to expand resources including one's social network and relationships because they already have a strong foundation of met needs (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008). Being in a positive mood allows individuals the flexibility and freedom to explore and invest in social relationships because they do not have concern over immediate or imminent survival. Happy individuals can devote more time towards building close social relationships increasing their social capital that is especially useful in future times of stress.

Yet another perspective lies in a functional account of emotions, which proposes that affect guides behaviors through a series of rewards and punishments, and that social relationships and interactions can be especially important influences in generating informative and evocative functions (Keltner & Haidt, 2001; Keltner & Kring, 1998). Positive emotions indicate that a particular interaction or behavior is going well and sends a reward signal to the individual to reinforce that behavior. This in turn leads to a greater

likelihood of repeating the behavior in the future. Rather than simply providing feedback as information, positive feelings can also evoke positive feedback from others through pleasant conversations, activities, or games which all serve to continue building healthy relationships.

Rather than simply having a large social network, social relationship *quality* may contribute to well-being in important ways. Social support specifically refers to the sense of being taken cared of, listened to, loved, and appreciated. Social support has been identified as a critical driver of both physical and mental health benefits (Cohen, 2004). Not only is the presence of social relationships important for well-being, but the quality, especially the perceived satisfaction and level of support, from these relationships influences our psychological health as well.

Romantic Relationships:
Similarities and Differences with Other Relationships

While social relationships in general have been extensively studied and linked to well-being, the focus for this chapter will be on one specific type of relationship. In particular, *romantic relationships* may be uniquely and powerfully related to subjective well-being. Romantic relationships differ from general social relationships in important ways, yet researchers have acknowledged the difficulty in defining a romantic relationship. One primary feature distinct between friendships and romantic relationships is a marked difference in intimacy (Moss & Schwebel, 1993). While close friends share intimate details of their lives, the role of intimacy involved in romantic relationships is typically deeper and more pervasive. Combined with intimacy, passion and commitment are two additional features central to romantic relationships (Sternberg, 1986). Ultimately, Sternberg proposes that the total amount of love depends on the overall sum of the three components, and the *type* of love depends on the strength of each component relative to each other. Depending on the relative strength of each feature, a relationship may be classified by different types of love including romantic, companionate, empty, infatuation, and consummate.

Further, all three components (i.e., intimacy, passion, and commitment) are associated with relationship satisfaction and their links to satisfaction vary over time as relationships evolve. All three components increase over time as couples transition from casual dating to monogamous dating to engagement (Gao, 2001). However, passion and intimacy tend to decline while commitment increases for married couples over time (Acker & Davis, 1992). Although all three components are associated with relationship satisfaction, commitment has the strongest association (Acker & Davis, 1992). Greater mismatches among the three qualities within couples are associated with greater relationship dissatisfaction (Sternberg, 1986; 1988; Sternberg & Barnes, 1985).

In addition to Sternberg's triangular theory of love, many other researchers have attempted to define and conceptualize love in order to empirically study this important relational quality. Many theorists have identified two major types of love: passionate and companionate (Fehr, 1988; Fischer, Shaver, & Carnochan, 1990; Hatfield & Rapson, 1993; Hatfield, Rapson, & Martel, 2007). Passionate love is often referred to as infatuation, erotic love, or romantic love. It is usually characterized by sexual feelings and intense emotions such as jealousy, passion, and anxiety. Alternatively, companionate love typically involves less intense emotions and is characterized by attachment, intimacy, trust, closeness, and commitment. Companionate love has also been referred to as storgic love (Lee, 1988). While theorists have proposed that passionate love declines over time and companionate love remains stable, empirical work has generally found a small decline in both types over time for married couples (Sprecher, 1999; Hatfield, Pillemer, O'Brien, & Le, 2008). Each type of love has an important role in a successful marriage and may account for different relationship and well-being qualities. For example, passionate love more strongly predicts positive and negative affect, while companionate love more strongly predicts life satisfaction (Kim & Hatfield, 2004). Hendrick, Dicke, and Hendrick (1988) found that passionate and companionate love are both positively related to relationship satisfaction.

In addition to the two main types of love, Lee (1977) defined six types of love *styles*. The three main love styles are eros (i.e., rooted in strong physical attraction), ludus (i.e., viewing love as a game, noncommittal), and storge (i.e., friendship evolving into a romantic relationship). The next three styles are combinations of the three main love styles including mania (i.e., possessive, jealous, anxious attachment to a partner reflected via the combination of eros and ludus), pragma (i.e., practical approach reflected via the combination of ludus and storge), and agape (altruistic love reflected via the combination of eros and storge). Hendrick and Hendrick (1986) developed a 42-item Love Attitude Scale that categorizes individuals into one of these six love styles. Subsequent analyses have linked the eros and agape styles to higher commitment and relationship satisfaction, while ludus is negatively associated with satisfaction and commitment (Frazier & Esterly, 1990; Hendrick, Hendrick & Adler, 1988; Morrow, Clark, & Brock, 1995). Individuals within couples who have different love styles tend to report lower quality relationships and satisfaction (Davis & Latty-Mann, 1987). In a cross-cultural study, the storge love style predicted

subjective well-being in the United States and Portugal while eros and mania predicted well-being in the Mozambican sample (Galinha, Oishi, Pereira, Wirtz, & Esteves, 2014). Cross-cultural interpretations of love styles and their impact on well-being remain a vastly understudied area, but early findings point to important potential differences. Overall finding suggest that although there are many different types of love for romantic partners, those with eros and agape styles and those who have similar love styles tend to report better relationship quality and higher satisfaction.

The many different definitions and conceptualizations of love complicate attempts to assess the role of love in romantic relationship stability, quality, and satisfaction. Yet, the intimacy and intense feelings of love continue to be cited as qualities that make romantic relationships from other types of social relationships. In addition to these potentially unique aspects, romantic relationships typically include a sexual component as well, which set this type of relationship apart from others. Indeed, romantic love includes passion, exclusiveness, sexual intimacy and physical attraction, all of which are typically absent in other forms of love such as platonic or companionate (Gooch, 1989, Kaplan & Keys, 1997; Monsour, Betty, & Kurzweil, 1993). Although sexual attraction may be present in platonic love, it is typically not acted upon compared to the frequent utility of sexual attraction and intimacy in romantic love (Davis & Todd, 1982; Monsour et al., 1993). However, more recently there has been a rise of nonromantic sexual relationships (i.e., hookups; friends with benefits) especially common among emerging adults, complicating attempts to define a romantic relationship (see Garcia, Reiber, Massey, & Merriwether, 2012 for a review; Furman & Shaffer, 2011; Paul, McManus, & Hayes, 2000).

A primary framework for understanding romantic relationships comes from attachment theory (Bowlby, 1973; 1980). A crucial extension of Bowlby's attachment theory, which originally was proposed to explain parent-child relationships, is that adults may develop analogous attachment patterns to romantic partners. Similar to a mother being seen as the primary attachment figure in childhood, a romantic partner may be seen as the primary attachment figure in adulthood (Hazan & Shaver, 1987; Prager, 1995). The quality of interactions with an attachment figure when in distress helps shape the attachment style one is likely to adapt. A secure base, proximity seeking, and safe haven, which are characteristics of a strong and secure attachment figure, are transferred from parents to romantic partners. Eventually, a romantic partner will replace a parental figure as the primary attachment figure (Hazan & Shaver, 1994). When an attachment figure is perceived as emotionally unavailable or unreliable, one may be more prone to feel insecure and have doubts about the relationship; when a close other is perceived as available, reliable, trustworthy, and willing to provide support when needed, one is more likely to feel a sense of secure attachment, intimacy, support, and nurturance (Cassidy, 2000; Hazan & Shaver, 1994; Mikulincer, Shaver, & Pereg, 2003). Thus, adults in romantic relationships form a unique attachment to their romantic partner as compared to their level of commitment and engagement with other social partners.

Beyond attachment style, romantic love, intimacy, and passion, there are myriad other characteristics that might define a romantic relationship. Researchers have disagreed about what constitutes a romantic relationship, especially for unmarried couples. This is in part due to the changing norms of how people are defining their own relationships in the gray area of dating prior to a committed marriage during an era of proliferation of dating terms. I also want to acknowledge that this chapter will mainly focus on heteronormative relationships – mainly heterosexual populations that hold the Westernized view of relationship development towards self-selecting marriages. This is partially due to a lack of well-being research on alternate forms of relationships as well as due to lack of space to consider all relationship forms in the scope of this chapter. I will very briefly describe an overview of the research, and lack thereof, on "nontraditional romantic relationships" such as polyamory, online dating, arranged marriages, and sexual minority groups. Therefore, for the purposes of *this chapter*, a romantic relationship will be considered to be one, monogamous, self-selecting, committed relationship between two individuals. In the sections that follow, I will expand on the idea of attachment, intimacy, commitment, passion, and others as important characteristics of romantic relationships and how they may relate to individual well-being and relationship satisfaction.

The Basics: Are Romantic Relationships Linked to Well-Being?

In general, research has identified romantic relationships specifically as being uniquely related to subjective well-being. Marriage has been cited as one of the leading sources of both support and stress for adults (Walen & Lachman, 2000). Specifically, marriage has been linked to lower psychological distress and higher well-being in adulthood as well (Diener, Gohm, Suh, & Oishi, 2000; Efklides, Kalaitzidou, & Chankin, 2003; Glenn & Weaver, 1979; Holder, 2012; Wu & Hart, 2002). Even prior to marriage, romantic relationships are linked to one's overall sense of subjective well-being (Campbell, Simpson, Boldry, & Kashy, 2005; Dush & Amato, 2005; Keyes & Waterman, 2003). It is not simply the involvement in a romantic relationship that may account for the link to well-being, but the quality of that relationship as well (Myers, 2000).

In late adolescence, teens report feeling the greatest levels of support but also perceiving the greatest amount of conflict from their romantic partners as compared to from their peers or parents (Furman & Shomaker, 2008). While social relationships across the lifespan are important for well-being, romantic relationships gain in importance and salience as a major aspect of one's identity steadily throughout late adolescence, young adulthood, and eventually adulthood (Giordano, Longmore, & Manning, 2001; Seiffge-Krenke, 2003; Umberson & Karas Montez, 2010). It will be critical to discuss how romantic experiences influence well-being and vice versa as individuals' needs, goals, and values in a relationship developmentally change over time. Additionally, there are developmental differences in romantic relationships across the lifespan, which can also change the strength of the link between intimate relationships and well-being. The developmental differences of romantic experiences and their association with well-being will be discussed.

Given the developmental perspective of the centrality of maintaining intimacy within a romantic relationship in young adulthood, it is not surprising that one's relationship status and quality of their romantic partnership are linked to physical and mental health. Prior findings consistently point to the marriage benefit in terms of less mental illness, distress, substance abuse, physical health complaints, mortality, and morbidity (Gove, 1972; Horwitz, White, & Howell-White, 1996; Umberson, 1987; Waite, 1995). Romantic relationships generally are sources of high well-being, intimacy, companionship, and happiness for emerging adults prior to marriage as well (Berry & Willingham, 1997; Demir, 2010; Diener et al., 2000; Johnson, Kent, & Yale, 2012).

Let's Get Specific: What Qualities are Linked to Well-Being?

We see growing evidence that it is not simply relationship status that accounts for the benefits for well-being. The *quality* of a romantic relationship as well as how *satisfied* one is with their relationship and partner are both essential to assess as well. Subjective well-being encompasses affect and global life satisfaction judgments; however, it can also include subjective evaluations of specific life domains including social relationships, work performance, or citizenship. Prior findings suggest that global subjective well-being and domain-specific relationship satisfaction are highly correlated, which one would expect given the strong link between well-being and relationships. Relationship quality has been found to positively correlate with well-being in terms of more satisfied individuals reporting higher levels of happiness, life satisfaction, and positive affect and lower levels of negative affect (Dush & Amato, 2005; Dyrdal, Roysamb, Nes, & Vitterso 2011; Love & Holder, 2015). Importantly, relationship satisfaction is associated with higher levels of subjective well-being regardless of relationship status (Dush & Amato, 2005). Indeed, feeling satisfied with one's relationship status, regardless of what that relationship status is, predicts higher life satisfaction but is less tied to emotional and psychological well-being (Adamczyk, 2017). Interestingly, relationship satisfaction has been linked to idealistic, rather than realistic, views of a romantic partner (Murray, Holmes, & Griffin, 1996) pointing to a potential positivity bias towards partners among those high in relationship satisfaction.

Relatedly, sexual satisfaction has been another relationship domain that is linked to relationship quality, satisfaction, and well-being. In a review, Sprecher and Cate (2004) found that sexual satisfaction is significantly related to relationship stability and quality. Prior findings also indicate that changes in sexual satisfaction are linked to changes in relationship satisfaction, love, and commitment to a partner in unmarried couples (Sprecher, 2002). Key components of the link between sexual and relationship satisfaction is likely communication and sexual expression (Sprecher, Metts, Burleson, Hatfield, & Thompson, 1995). Given the importance of intimacy that is a hallmark and defining feature of romantic relationships compared to its role in other social relationships, it is not surprising that sexual satisfaction is an important characteristic. Being able to communicate with a partner about sexual needs and to receive what one desires are both important aspects of high levels of sexual and relationship satisfaction, and this communication is likely highly linked to overall intimacy.

Many other important qualities beyond intimacy emerge as essential factors for overall well-being. Poor marital quality has been linked to poor immune and endocrine functioning, depression, anxiety, and problem behaviors (Kiecolt-Glaser & Newton, 2001; Sampson, Laub, & Wimer, 2006; Umberson & Williams, 1999). High conflict and hostile relationships are linked to poor mental health reflected in greater rates of depression, anxiety, aggression, and substance abuse (Hawkins & Booth, 2005; Horwitz, McLaughlin, & White, 1998; Umberson, Williams, Powers, Liu, & Needham, 2006; Whisman, 2007). Demir (2008) found that for emerging adult couples, emotional security and companionship were the strongest predictors of happiness and when combined with the qualities of reliable alliance, help, self-validation, and intimacy, accounted for 13% of the variance in happiness. In adulthood, commitment, trust, and intimacy in romantic relationships emerge as being especially highly related to subjective well-being

(Drigotas, Rusbult, & Verette, 1999; Mehta, Walls, Scherer, Feldman, & Shrier, 2016; Uysal, Lin, Knee, & Bush, 2012). We begin to see that while there are common qualities that are beneficial across developmental stages, it is worthwhile to assess which qualities may be more influential and important than others for unmarried versus married couples.

Another key mechanism that acts as a moderator between many relationship qualities and overall well-being is attachment style. A secure attachment style is strongly linked to high quality romantic relationships (Banse, 2004; Simpson, 1990) and securely attached individuals report relationships with greater commitment, trust, and satisfaction (Simpson, 1990) which are qualities that have previously been identified as critical to relationship satisfaction and well-being. Secure attachment has been linked to higher levels of subjective well-being, while insecure attachment styles (i.e., avoidant and anxious) are negatively related to well-being (La Guardia, Ryan, Couchman, & Deci, 2000; Li & Fung, 2014; Schiffrin, 2014; Van Buren & Cooley, 2002). Attachment security can also predict relationship stability, or whether unmarried couples tend to remain together or break up (Duemmler & Kobak, 2001) as well as whether one chooses to enter into a committed relationship (Schindler, Eagundes, & Murdock, 2010). Specifically, attachment anxiety is associated with a strong desire to commit while attachment avoidance is related to lower levels of commitment and willingness to enter a committed relationship (Morgan & Shaver, 1999; Schindler et al., 2010).

Those with secure attachment styles may feel most comfortable and confident in themselves and the relationship which allows the healthy qualities of trust, communication, intimacy, and others to foster more naturally and to a greater extent compared to individuals who are avoidant or anxious in their attachment styles. Indeed, Leak and Cooney (2001) found that secure attachment was positively related to self determination and that together they both related to higher well-being and mental health. Further, the link between secure attachment and satisfaction was mediated by commitment and intimacy, again pointing to a strong link between attachment styles and other romantic qualities (Madey & Rodgers, 2009). Following from above, insecure attachment styles were related to lower levels of sexual satisfaction (Butzer & Campbell, 2008).

Finally, what many people may consider to be crucial in romantic relationships, in addition to support, sexual intimacy, and healthy conflict management, love is also a component of relationship and individual well-being and satisfaction. Married couples tend to identify love as being the most important quality that makes them feel close, connected, and committed to their spouse (Riehl-Emde, Thomas, & Willi, 2003). Even in unmarried couples, love emerges as strongly linked to satisfaction (Hendrick et al., 1988). Love, romance, and intimacy are all positively associated with well-being but this link may be stronger for females than males (Love & Holder, 2015). While beyond the scope of this chapter, gender differences in romantic experiences are important to consider in relationship research, which I will highlight in the concluding section on future directions.

Overall, it is clear that intimate partnerships greatly impact one's physical and emotional health in both positive and negative ways depending on relationship status and quality. It is also evident that many of these relationships are bidirectional – higher quality relationships can benefit well-being while higher levels of well-being foster qualities that can enhance relationship satisfaction and functioning. Although many couples report love as being the most important aspect of their relationship satisfaction, findings also point to the qualities of attachment, support, intimacy, companionship, and sexual satisfaction as being critical to relationship satisfaction and well-being as well.

The Mechanism: Why are Romantic Relationships Linked to Well-Being?

Romantic relationships may uniquely contribute to well-being for several reasons. First, successfully navigating romantic relationships is identified as a primary developmental task of emerging adulthood (Arnett, 2000; Roisman, Masten, Coatsworth, & Tellegen, 2004). Happiness has been associated with success in different life domains, especially the domains that are most pertinent to the appropriate developmental stage (Lyubomirsky, King, & Diener, 2005). Thus, failure to meet the goal of maintaining intimacy with a romantic partner during early adulthood may be linked to poorer well-being, self-esteem, and psychological health. Indeed, abstaining from dating until early adulthood has been linked to a host of negative outcomes including poor psychosocial functioning (Lehnart, Neyer, & Eccles, 2010; Rauer, Pettit, Lansford, Bates, & Dodge, 2013).

One possible mechanism for the link between relationship status and well-being is that maintaining a romantic relationship is seen as a socially appealing marker of success during early adulthood. Those unable to form close relationships with others by adulthood in the form of a committed, monogamous relationship may be more likely to experience lower well-being and greater levels of mental distress. Evidence for this mechanism is suggested by cultural findings on the link between marriage and well-

being. Diener and colleagues (2000) found that the benefit of being married was smaller in collectivist nations and in nations where there was a high tolerance of divorce. They argue that in cultures where divorce is considered taboo, unmarried individuals' well-being may be impacted in a greater magnitude as compared to nations where divorce is more common and acceptable (Gibbs, 1969; Glenn & Weaver, 1988; Stack, 1990). Thus, in societies where committed romantic relationships are valued as a cultural norm, failing to meet this goal may lead to poor psychological health and well-being. Related to developmental goals, one's well-being may be more impacted by failing to meet the intimacy goal during young adulthood as compared to earlier in adolescence. Thus, the context and cultural expectations for romantic relationships are likely powerful influences on the link between intimate relationships and well-being.

Beyond the socially constructed need to find one committed romantic partner in adulthood, marriage may serve a more general and universal human need: social support. Recall that evolutionarily, developing social support and resources is beneficial for survival (Baumeister & Leary, 1995; Buss, 2000). Prior researchers have suggested that marriage can fulfill this need via providing companionship and thus fighting against loneliness (Glenn, 1975; Glenn & Weaver, 1979; Rook, 1984). Indeed, Fromm (1956) suggested that the concept of love developed over time as a way to combat loneliness and emotional and social isolation. Thus, the evolutionary benefit of general social support may naturally extend to the positive outcomes associated with having a strong, supportive marital partner (for a review see Eastwick, 2016). Happy people may be more likely to attract and maintain a healthy romantic relationship while unhappy individuals struggle to find a suitable partner or to maintain a stable relationship over time (Diener & Diener McGavran, 2008). Further, mate selection theorists have identified a preference for pleasant personality characteristics (Buss & Barnes, 1986) indicating those with high well-being may be more desirable mates. Successful romantic relationships may have also provided the financial, emotional, and social support associated with greater likelihood of successful reproduction as well. Married individuals benefit from having a partner to share life's burdens, problems, and struggles with which can help boost trust and intimacy between partners and decrease the distress linked to life's hardships (Gove, Style, & Hughes, 1990; Williams, 1988). Not only are partners beneficial for providing support when one is undergoing stress, but they also provide the opportunity to reciprocate with support as well. Providing care, love, and support for a spouse may boost one's self-esteem, provide greater purpose in one's life, and increase sense of mastery over a salient developmental task (Gove et al., 1990).

Providing instrumental support via division of labor in the home may also be beneficial for individuals as they share the burden of everyday tasks rather than solely providing everything for themselves. Blumstein and Schwartz (1983) found couples who agree on a suitable division of labor for financial and household responsibilities report the highest relationship satisfaction. Further, marital happiness and conflict were both related to satisfaction with division of labor (Suitor, 1991). One's own hours and perception of partner's hours spent on housework and paid work all seem to influence marital satisfaction (Stevens, Kiger, & Riley, 2001). Sharing of household and work tasks is an ongoing discussion and negotiation for many couples, highlighting the importance of communication. The perception of *why* partners provide help is also linked to well-being and satisfaction. For example, sacrifices and helping with approach motives (i.e., focusing on increasing positive outcomes) is associated with greater well-being and higher relationship quality, while those with avoidance motives (i.e., focusing on decreasing negative outcomes) is linked to lower well-being, relationship quality, and relationship stability (Gable & Reis, 2001; Impett, Gable, & Peplau, 2005). Thus, agreeing on division of labor and interpretation of partner's motives are important for relationship and individual well-being. With more dual-income families becoming the common family dynamic, more research regarding division of labor and subsequent satisfaction for relationship and individual well-being is warranted.

Beyond the role of a romantic partner in providing social support when conflict, distress, or other negative events arise, the utility of sharing positive news and confiding in a romantic partner may also help explain the link between relationship status and well-being. While friends can also provide social outlets to share good news, a romantic partner is often someone of greater trust, intimacy, emotional connection, and importance. Thus, romantic partners may particularly benefit from sharing and responding to positive news. Gable, Gonzaga, and Strachman (2006) found that how partners respond to good news is more closely related to relationship stability and well-being than how they respond to bad news. In particular, responding in an active-constructive manner as compared to passive-constructive, passive-destructive, or active-destructive, is important for individual and relationship well-being and satisfaction (Gable, Reis, Impett, & Asher, 2004). Thus, capitalizing on the positive experiences and events a romantic partner discloses may boost relationship functioning and well-being.

Yet another potential mechanism that explains the well-being and romantic relationship link is felt understanding. Feeling understood by others generally is associated with higher well-being (Reis, Clark, & Holmes, 2004; Reis, Lemay, & Finkenauer, 2017). Related to capitalizing on sharing positive news with a

romantic partner, perhaps feeling heard and understood also helps boost well-being between individuals in a relationship. The impact of feeling understood by a romantic partner may be particularly salient for well-being, relationship satisfaction, and conflict management between partners (Gordon & Chen, 2016). In general, knowing a partner well is linked to greater intimacy and relationship satisfaction (Gottman, 1994; Gottman, Coan, Carrere, & Swanson, 1998; Swann, De la Ronde, & Hixon, 1994). Knowing a partners' attitudes and well-being is associated with greater relationship satisfaction, perceived support from partner, and life satisfaction and lower negative affect and depression (Moore & Diener, in press; Moore, Uchino, Baucom, Behrends, & Sanbonmatsu, 2017). Thus, feeling understood by a partner may provide greater emotional support, intimacy, and other important mental health and relationship benefits that lead to greater well-being overall. A romantic partner may be the closest, most intimate relationship someone has in his or her adult life. The felt understanding one perceives from this romantic partner may thus especially impact well-being, as feeling understood by the person one is closest too seems to carry more weight than felt understanding from strangers, friends, or other social relationships. A successful, healthy romantic relationship in which both partners perceive great understanding and familiarity with each other is likely to have psychological and relationship benefits.

Alternative explanations exist that may account for the link between romantic involvement and well-being that focus on the quality of these partnerships. Happy individuals may be able to provide for their partner in terms of support, intimacy, and emotional expressivity compared to individuals lower in well-being. Positive affect has been linked to greater feelings of intimacy and warmth toward a partner while negative affect is linked to decreased feelings of intimacy (Berry, Willingham, & Thayer, 2000; Demir, 2008; Gleason, Iida, Shrout, & Bolger, 2008; Prager, 1995; Sprecher, 1999; Williams, Connolly, & Segal, 2001). While intimacy is one example, it is likely that affect may play a role in the development of trust, sexual satisfaction, support, communication, and companionship which have all been identified as important relationship qualities linked to well-being.

Romantic Developmental Differences: Adolescence, Emerging Adulthood, and Adulthood

Adolescence

Although research on romantic relationships and well-being have largely focused on marriage in adulthood, it is widely recognized that romantic experiences come online much earlier and that these experiences are influential to concurrent well-being and romantic development over time. Adolescents begin experimenting with dating as early as 12 years old when about 25% report involvement in some type of romantic relationship with an average relationship duration of 5 months (Carver, Joyner, & Udry, 2003). Nearly half of adolescents report being involved in a romantic relationship by the age of 15; by age 18, more than three quarters of adolescents report engaging in romantic involvement and on average, these relationships last much longer – on average 20 months (Carver et al., 2003).

Per a review of romantic development theories by Meier and Allen (2014), normative romantic exploration begins in early adolescence, which typically involves group dating and is relatively short in duration. In mid-adolescence, multiple short-term relationships with an increased emphasis on sexual and emotional intimacy become common. By late adolescence and into adulthood, one exclusive, sexual, committed relationship becomes the normative experience. Early adolescent romantic experiences are characterized as being more affiliative and companionate as compared to late adolescent romantic relationships which tend to be more committed, supportive, and loving (Shulman & Kipnis, 2001; Shulman & Scharf, 2000).

While maintaining intimacy within romantic relationships is not considered a primary developmental goal until emerging adulthood, teens personally consider navigating intimate relationships as important for their psychosocial lives. The majority of teenagers report at least one exclusive relationship experience by the end of adolescence and the prevalence and importance of engaging in intimate relationships increases during the transition into young adulthood (Carver et al., 2003; Furman & Shomaker, 2008; Giordano, Manning, Longmore, & Flanigan, 2012; Reis, Lin, Bennett, & Nezlek, 1993). Romantic relationships have been linked to both negative behaviors and poor psychological health and well-being (Davies & Windle, 2000; Furman & Collins, 2009; Neemann, Hubbard, & Masten, 1995; Thomas & Hsiu, 1993; van Dulmen, Goncy, Haydon, & Collins, 2008; Zimmer-Gembeck, Siebenbruner, & Collins, 2004).

However, romantic exploration is common and normative among adolescents, and thus teen dating also been linked to positive developmental outcomes as well in terms of later well-being and future romantic relationships. Evidence suggests that while romantic experiences in *early* adolescence are more strongly linked to problematic behaviors, the link decreases in magnitude for romantic experiences that occur in late adolescence (Neemann et al., 1995). Instead, adolescents who were involved in romantic

relationships by the end of high school were more likely to marry and cohabitate in early adulthood (Raley, Crissey, & Muller, 2007). High quality adolescent romantic relationships have been linked to positive relationships and a range of psychosocial benefits including positive commitment in relationships in early adulthood, fewer externalizing problems, higher levels of social support, and greater social competence, self-worth, and self-esteem (Collibee & Furman, 2015; Collins, 2003; Connolly, Craig, Goldberg, & Pepler, 1999; Connolly & Konarski, 1994; Furman, Low, & Ho, 2009; Masten et al., 1995; Raley et al., 2007; Seiffge-Krenke, 2003; van Dulmen et al., 2008). Specifically, support and self-disclosure have been identified as essential predictors of successful adolescent relationships (Hansen, Christopher, & Nangle, 1992). Overall, we see that romantic relationships begin during adolescence and that these early experiences can have important links to well-being and romantic trajectories over time.

Emerging Adulthood

Successfully navigating intimate relationships is recognized as a primary developmental task of early and emerging adulthood (Barry, Madsen, Nelson, Carroll, & Badger, 2009; Clark & Beck, 2010; Erikson, 1982; Roisman et al., 2004). Indeed, recent societal changes have delayed the age of first marriage for young adults, which has led to the relatively new conceptualization of emerging adulthood as a distinct developmental stage ranging from ages 18 through 29 (Arnett, 1998, 2000). Especially common during this time is a period of exploration as individuals aim to blend romantic, personal, and career lives together which partially accounts for the delayed entrance into long-term stable relationships (Shulman & Connolly, 2013). Thus, emerging adulthood can be characterized by a series of romantic relationships that vary in the extent of commitment, intensity, and intimacy (Cohen, Kasen, Chen, Hartmark, & Gordon, 2003).

However, the trend for emerging adults to explore several romantic options during the 20-something years does not necessarily mean that these romantic experiences are not as important or influential for development and well-being. Remaining single or engaging in a series of various types of non-committal romantic relationships (i.e., hooking up, friends with benefits, casual dating) is often a conscious, intentional decision for these young adults (Katz & Schneider, 2013; Paul, McManus, & Hayes, 2000**;** Puentes, Knox, & Zusman, 2008; Shulman & Connolly, 2013). Emerging adults may place career, travel, or friendship priorities ahead of finding "the one" and as such the characteristic romantic exploration is a choice rather than due to a deficit in connecting with a partner for a monogamous relationship. Shulman and Connolly (2013) argue that young adults may deliberately choose to pursue work or school goals rather than continue or initiate a long-term, monogamous, committed romantic relationship. Other researchers have an optimistic view of this romantic exploratory period. For example, Marcia (2002) suggests that it is healthy to explore available options prior to making a decision and this can extend to romantic exploration for a marriage partner as well.

Perhaps paradoxically, emerging adults are still placing a high value on romantic relationships during this time frame. Schulenberg, Bryant, and O'Malley (2004) found that emerging adults report stronger ties between their well-being and successfully meeting the goal of romantic exploration and intimacy, than between well-being and progress in reaching other developmentally-salient goals such as avoiding substance use, maintaining close friendships, reaching educational achievements, or achieving financial independence. For those in a romantic relationship, their partner is often identified as a greater influence on well-being compared to parents or friends (Demir, 2010; Meeus, Branie, van der Valk, & De Wied, 2007). Compared to in adolescence, high quality romantic relationships in emerging adulthood are more strongly linked to well-being and relationship satisfaction, indicating a developmental shift in centrality of intimate relationships to well-being (Collibee & Furman, 2015; Meeus et al., 2007). There is some evidence suggesting that college students who are in committed relationships report higher levels of well-being compared to their single peers (Braithwaite, Delevi, & Fincham, 2010) and that those young adults who get and stay married report higher levels of well-being compared to their single peers (Horwitz, White, & Howell-White, 1996). Further, college students often report their romantic relationship as the closest and most meaningful type of relationship they have (Snyder, Berscheid, & Omoto, 1989). However, others have found little to no difference in long-term impacts on well-being between those who have casual hook up relationships and those in committed romantic relationships (Furman & Collibee, 2014; Vrangalova, 2014).

Given that emerging adulthood is a relatively new developmental stage, it is not surprising that we see mixed findings for whether and to what extent the characteristic romantic exploration is related to concurrent or long-term well-being. One particularly interesting area of open research will be to further assess whether different types of romantic relationships (casual relationships, open relationships, friends with benefits, hooking up) impact individual and interpersonal development and well-being to different degrees.

Adulthood

Historically, research on romantic relationships has focused on married couples. As outlined above, prior findings consistently point to what may be referred to as the marriage benefit. Namely, that being married serves a positive function in general such that those who are married tend to reap benefits in terms of both physical and mental health (Dush & Amato, 2005; Wu & Hart, 2002). However, even in adulthood, we see varying relationship stages and transitions taking place that are each related to well-being in different ways. Those who are married are happier than those who are cohabitating, casually dating, monogamously dating, or rarely date (Dush & Amato, 2005). Even after controlling for relationship satisfaction, relationship status in adulthood was found to remain linked to well-being. Further, with each increase in relationship commitment level, there was an increase in subjective well-being. It is hypothesized that it is this growing level of commitment and stability that accounts for the differences in well-being (Brown, 2000; Dush & Amato, 2005)

In addition, married adults report greater levels of happiness compared to those who are single, divorced, separated, or cohabitating (Dush, Taylor, & Kroeger, 2008; Glenn & Weaver, 1979; Gove et al., 1990; Mastekaasa, 1994; Myers, 2000; Proulx, Helms, & Buehler, 2007; Stack & Eshleman 1998). Helliwell (2003) found that being married is associated with the highest subjective well-being while being separated is linked to the lowest ratings of well-being with the divorced and widowed falling in between. In a meta-analysis, Proulx and colleagues (2007) found a moderate link (r = .37) between marital quality and well-being.

The relationship between high quality romantic relationships and well-being becomes stronger with age (Segrin, Powell, Givertz, & Brackin, 2003; Simon & Barrett, 2010). Interestingly, married couples tend to experience a decrease in life satisfaction over the course of their marriage; however those couples with high marital happiness reported the smallest declines (Dush et al., 2008). Whether individuals report high general life satisfaction and happiness was strongly linked to whether the marriage was classified as high, middle, or low in marital happiness indicating that individuals who have a high baseline well-being carry over their happiness into their marriage with potential lasting effects. While it was well documented that married individuals are happier, more recent research calls for attention to be shifted from relationship status to relationship quality in explaining the potential for a marriage benefit to exist.

Romantic Dissolution and Divorce: Implications on Well-Being

Thus far, I have presented research suggesting the benefits of having a healthy marriage, yet there are many societal changes that complicate the "simple," Westernized notion of choosing a marriage partner for life and assuming that this choice would relate to high levels of well-being. In emerging adulthood, romantic exploration is key, which brings along a series of relationships including breakups. In adulthood, the divorce rate is steadily climbing adding to the challenge of redefining romantic relationships in mid to late adulthood as well. Therefore, it is worthwhile to consider the opposing situation and its impact on well-being. It seems obvious that divorce or a breakup would be stressful, but how much of an impact does dissolution have on well-being?

A romantic breakup has been cited as one of the worst types of traumatic experiences (Frazier & Hurliman, 2001). Yet, it is relatively common during emerging adulthood such that nearly 40% of young adults report at least one breakup over a 20-month period (Rhoades, Dush, Atkins, Stanley, & Markman, 2011). Romantic dissolutions have been linked to serious negative outcomes including anxiety, depression, posttraumatic stress, substance abuse, self esteem, poor physical health, and finally low life satisfaction (Chung et al., 2002; Fine & Harvey, 2006; Fleming, White, Oesterle, Haggerty, & Catalano, 2010; Lewandowski, Aron, Bassis, & Kunak, 2006; Monroe, Rohde, Seeley, & Lewinsohn, 1999; Rhoades et al., 2011). Given the normative process of romantic exploration during young adulthood, researchers have begun exploring the possible benefits of nonmarital dissolutions. The scarce findings begin supporting the idea that individuals can experience post-traumatic growth, personal growth, and positive emotions following a breakup (Lewandowski & Bizzoco, 2007; Tashiro & Frazier, 2003). Further, they may report increased satisfaction and higher relationship quality in their next romantic relationship (Kansky & Allen, 2017).

While in emerging adulthood, dissolutions are considered to be common and there are mixed findings regarding their detriment to psychological well-being, breakups in adulthood in the form of divorce may have more significant negative impacts. Indeed, adults cite divorce as one of the most stressful events they may encounter in their lifetime (Kitson & Morgan, 1990). Compared to those married, individuals who are divorced or separated report lower levels of psychological well-being, greater alcohol abuse, and greater use of psychological treatment (Fine & Harvey, 2006; Gove & Shin, 1989; Kitson & Morgan, 1990; Waite, 1995). Further, individuals who had previously divorced report lower levels of well-being even if they remarry indicating the potential for long-term negative impacts on psychological health (Richards et al., 1997). Interestingly, individuals report similar decreases in well-being following

dissolution whether they were married or only cohabitating in adulthood (Wu & Hart, 2002). This indicates that dissolution of adult committed relationships even outside the context of marriage may impact well-being similarly, even though the benefits of being in a marriage compared to cohabitating have differential impacts on well-being.

However, other findings indicate that divorce may not alone account for the lower reports of well-being. Rather, individuals tend to report greater distress and lower well-being over several years *prior* to the divorce compared to those in happy, stable relationships (Mastekaasa, 1995). This indicates that prior to filing for divorce, there may be a difference between those who stay married and those who part ways in terms of their pre-transition stress and well-being levels. Rather than individuals suffering from divorce or separation, their well-being may be negatively impacted from conflict, poor communication, and distress related to a low quality relationship prior to the actual event of a divorce.

Attachment is an important moderator of many relationship qualities and satisfaction, and again we see evidence for its role as a moderator in post divorce adjustment. Divorced individuals report greater distress compared to their married counterparts, but only if the divorced report insecure attachment styles (Birnbaum, Orr, Mikulincer, & Florian, 1997). Another dimension that moderates the relationship between divorce status and well-being may be how quickly one finds a new, fulfilling, committed relationship. For example, those who cohabitate with a new partner during the first year following the initial separation report higher well-being compared to those who choose to live alone (Mastekaasa, 1994). Yet another moderator may be cultural acceptance of divorce. As mentioned earlier, the impact of being unmarried or divorced on well-being may be greater in cultures where divorce is less socially acceptable (Diener et al., 2000; Glenn & Weaver, 1988). While in general it has been accepted that married individuals are happier than divorced adults, many qualities and adjustment behaviors may paint a more complex picture.

The New Normal? Diverse Romantic Relationships and Well-Being

As indicated previously, most research on romantic relationships and well-being has focused on Western, heteronormative relationships. In particular, adult married populations are often the focus of research in this realm. However, romantic experiences exist in many alternate forms, and recent empirical attention has attempted to capture the range of romantic relationships and how it relates to well-being.

Sexual Minority Status

For example, sexual minority relationships have increasingly gained empirical support to understand their similarities and differences with heterosexual romantic relationships. Given the finding of a marriage benefit for heterosexual couples, it is important to consider whether this exists for sexual minority couples as well. Because legal recognition of homosexual couples is not uniform, whether relationship status (i.e., committed versus married) for homosexual, as compared to heterosexual, individuals impacts well-being differently is important to consider.

In a study of lesbian, gay, and bisexual individuals, those in committed or legally recognized relationships reported higher well-being and less psychological distress as compared to single participants (Riggle, Rostosky, & Horne, 2010). Further, those in legally-recognized relationships reported higher well-being compared to those in committed relationships pointing to a possible marriage benefit for non-heterosexual couples as well. Lesbians, gay men, and bisexuals experience a higher prevalence of mental disorders and distress compared to heterosexuals (Gilman et al., 2001; Meyer, 2003; Sandfort, de Graaf, Bijl, & Schnabel, 2001). Findings also suggest that sexual minority youth report greater negative affect and concern over romantic relationships and friendships compared to their heterosexual peers (Diamon & Lucas, 2004).

Nonmonogamy and Polyamory

Beyond sexual orientation as a defining feature of "nontraditional" relationships, we are seeing an increasing diversity of types of relationships based on other features as well. Individuals are increasingly engaging in alternative relationship categories such as polyamory or open relationships. In a recent review of nonmonogamous relationships and well-being, Rubel and Bogaert (2014) found little evidence for differences in well-being based on monogamist or nonmonogamist status. Relationship qualities, not overall well-being, based on this status may differ. For example, polyamorous individuals reported greater levels of intimacy compared to monoamorous participants (Morrison, Beaulieu, Brockman, & O'Beaglaoich, 2013). Because polyamorous relationships are characterized by emotional intimacy, openness, and honesty rather than sexual intimacy, it is not surprising that higher levels of general intimacy are reported (Barker, 2005; Fierman & Poulsen, 2014; Klesse, 2006). Overall, there is still little research identifying how nonmonogamous, compared to monogamous, relationships may differentially relate to well-being, and whether these unique relationship types differ in terms of qualities or experiences from the

traditional, committed marital relationship that has been the focus of romantic relationship research historically.

Online Dating

Now that the Internet is almost constantly at one's fingertips, the invention of online dating websites and mobile dating applications together are an increasingly important facet of romantic experiences that has yet to be fully tapped by researchers. A Pew Research Center study found that 38% of "single and looking" American adults have used online dating sites themselves and almost 50% report knowing someone who has been an online user (Smith & Duggan, 2016). One recent study found that one-third of marriages from 2005 to 2012 began online such as through online dating websites (45%), social networking platforms (21%), chat rooms (10%), online community forums (6%), and other avenues as compared to meeting offline through work (22%), friends (19%), school (11%), social gatherings (10%), bars (9%), family (7%) or other conventional means (Cacioppo, Caccioppo, Gonzaga, Ogburn, & VanderWeele, 2013). There is also some evidence suggesting that those couples who begin their relationship online report higher relationship quality, higher marital satisfaction, and were less likely to experience a marital breakup as compared to those who met offline (Cacioppo et al., 2013; Rosenfeld & Thomas, 2012), yet other studies find few differences (see Finkel, Eastwick, Karney, Reis, & Sprecher, 2012 for a review). Thus, there is continued debate as to whether online dating is beneficial or detrimental to relationship formation, stability, and satisfaction.

Research identifying who may be more likely to use online avenues to find a romantic partner is also limited but begins pointing to older adults and sexual minority individuals as being especially likely candidates to take their dating efforts online (Rosenfeld & Thomas, 2012; Stephure, Boon, MacKinnon, & Deveau, 2009). Yet, other studies identified the mid-20s through mid 40's group as being most likely to use online dating tools (Smith & Duggan, 2016). Given the proliferation of online dating avenues (i.e., general and niche dating websites, mobile dating applications, chat rooms, gaming websites), lumping online dating into one single category may neglect the heterogeneity of this recent trend. For example, older adults are more likely to use email to meet potential spouses online while younger adults prefer mobile applications and social networking sites (Caccioppo et al., 2013). The increased utility of online means for individuals looking to connect with potential partners who may otherwise not form romantic relationships through more conventional means highlights the significant potential impact online avenues may have for boosting well-being. Despite the challenges the quickly changing online dating scene poses for researchers, evidence begins pointing to similarities and differences between online versus offline relationships especially how the access point of individuals meeting may influence relationship satisfaction and stability. Given the continued increase in reported online dating use (Smith & Anderson, 2016), it is essential to more clearly understand how romantic relationship quality, satisfaction, and well-being may be affected by this virtual trend.

Arranged Marriages

Yet another category of relationships that we did not extensively review thus far is that of non-Western traditional forms of marriage. In non-Western cultures, such as India and areas of China, marriages of choice are considered risky and frowned upon as they may detract from family obligations (Medora, Larson, Hortacsu, & Dave, 2002). Instead, an estimated 90% of all Indian marriages are arranged (Gautam, 2002). Even within westernized societies, subcultures exist that favor arranged marriages. For example, in orthodox Judaism, it is relatively common to use a matchmaker, a Shadchan, to assist in bringing couples together (Rockman, 1994). The traditionalist view on marriage suggests that free choice marriages start off with high satisfaction which decreases over time, while arranged marriages have the opposite pattern in which initial satisfaction is low but increases with time (see Xiaohe & Whyte, 1990 for a discussion). However, in a pivotal study Blood and Wolfe (1960) found that for both self-selecting and arranged marriages in Tokyo, satisfaction and love expression decreased over time. Husbands in arranged marriages showed a more gradual decline than self-selecting husbands, while wives in arranged marriages reported more dissatisfaction and lower love expression compared to self-selecting wives. In a partial replication study in Chengdu, China, Xiaohu and Whyte (1990) found that wives in self-selecting marriages reported greater relationship satisfaction compared to women in arranged marriages.

More research on these diverse marriage typologies has compared arranged marriages in Indian cultures to self-selecting, or love, marriages in the United States. Findings suggest that there are differences in the importance that arranged versus love or self-selecting married individuals place on relationship characteristics that may ultimately influence marital satisfaction. For example, Yelsma and Athappilly (1988) found that communication was less tied to marital satisfaction for arranged marriages as compared to love marriages; yet those in arranged marriages reported higher marital satisfaction than those in self-selecting marriages. Others have found differences in importance of qualities such as love and loyalty

between arranged versus love marriages but failed to find that this ultimately led to differences in relationship satisfaction (Myers, Madathil, & Tingle, 2005). In a recent comparison, Madathil and Benshoff (2008) found that arranged Indian married individuals place greater importance on finance and shared values, while self-selecting American married individuals consider loyalty to be more important and tend to report higher satisfaction overall.

Where Do We Go From Here?

Future Research Directions and Literature Gaps

In this chapter, I have reviewed the broad physical and mental health benefits stemming from social relationships and highlighted how romantic relationships specifically are related to well-being. I want to again acknowledge that the chapter focuses on heteronormative relationships – mainly heterosexual populations that hold the Western traditional view of relationship development and marriage. As noted previously, the choice to focus on this working definition of relationships was partially due to the majority of relationship research focusing on this traditional relationship type. In addition, space limitations for this chapter prevented discussion of *all* relationship forms, many of which accordingly fall outside the scope of this chapter.

Again, most research on romantic relationships and well-being has focused on Western, heteronormative relationships, especially adult married couples. Thus, more research should consider the unique influences of diverse romantic relationships on psychological well-being and mental health. In recent years, there has been an increase in research on sexual minority relationships, but this is still a relatively open area for future research as it relates to well-being. More research regarding the unique stressors for sexual minority individuals on their relationship satisfaction and experiences as well as their well-being is needed.

Beyond sexual orientation, the diversity in romantic experiences based on commitment (polyamory and nonmonogamy versus monogamy), avenue of meeting potential partners (online versus offline), and freedom in selecting a marriage partner (arranged versus self-selecting) provides a plethora of alternative relationships that may relate to well-being differently as compared to the link between well-being and Western, monogamous, self-selecting married relationships. In particular, long-term outcomes for psychological health and well-being associated with nonmonogamous relationships is needed, as only recently have these alternative lifestyles been the subject of empirical attention. Further research on whether well-being and other individual characteristics are related to the use of technology-assisted dating will add to our limited understanding of this societal trend. In addition, whether online versus offline dating differentially impacts relationship satisfaction and well-being is a challenging open area of research yet to discover. The quickly changing online dating scene complicates efforts to assess long-term outcomes linked to this relatively recent trend. Further, longitudinal studies of couples who met online compared to offline, or who engage in online-only romantic relationships are needed to more clearly understand the unique impacts of these alternative relationships on well-being. Finally, just as there is heterogeneity within committed, self-selecting marriages that leads to different impacts on well-being, there also exists a broad range of arranged marriages in which many factors influence a couple's marriage decision and trajectory including family and cultural influences or perceived input on the decision making process. Given such discrepant and scarce findings of well-being and love versus arranged marriages, future research on the differences between marriage types for relationship satisfaction and well-being is needed.

While I discussed love as an important characteristic of Western romantic relationships, this may not apply cross-culturally, especially in societies in which traditional, arranged marriages are more common. Indeed, college students in Western nations report love as being more important to a successful marriage compared to students in Eastern nations (Levin, Sato, Hashimoto, & Verma, 1995). Further, love may be defined or expressed differently in various cultures (de Munck, Korotayev, de Munck, & Khaltourina, 2011; Karandashev, 2015; Nadal, 2012). Different qualities may be tied to relationship investment and satisfaction cross-culturally as well (Karandashev, 2015; Madathil & Benshoff, 2008; Schmitt, 2006; Schmitt et al., 2009; Yelsma & Athappilly, 1988). I reviewed evidence suggesting that there are cultural differences regarding which love styles are related to well-being and satisfaction, yet this remains a relatively understudied area. Because the concept and definition of love may vary cross-culturally, more research on universal and culture-specific relationship qualities (including love) for well-being is warranted.

Another complication for assessing romantic relationships and well-being is that the definition of what constitutes a romantic relationship is ever changing. While there is a wealth of research of marital relationships, there is a societal trend in creating different categories of a relationship based on commitment and intimacy levels. This is especially common among emerging adults who are exploring romantically and delaying making "the one" decision for much longer than in the past. In addition to an

increase in nonmonogamous relationship subtypes in Western society, sociosexuality is another relationship dimension that has recently received empirical attention. Sociosexuality is defined as one's willingness to engage in sexual encounters and experiences with others without the commitment, intimacy, emotional connection, and closeness that traditionally accompanied sexual engagement (Gangestad & Simpson, 1990; Simpson & Gangestad, 1991). Sociosexuality exists on a continuum ranging from restricted (sex is accompanied by commitment and closeness) to unrestricted (sex in the absence of emotional connection or commitment). Because up to 80% of college students report casual sexual experiences and hooking up may replace traditional dating development (Garcia & Reiber, 2008; Bogle, 2008), assessing whether unrestricted sociosexuality impacts well-being or romantic satisfaction is warranted. Research regarding hook up culture and positive versus negative impacts on well-being has thus far been mixed (Fielder & Carey, 2010, Grello, Welsh, & Harper, 2006; Grello, Welsh, Harper, & Dickson, 2003; Owen, Quirk, & Fincham, 2013; Vrangalova, 2015). Thus, considering how sociosexuality and each distinct category of nonmarital dating (casual, monogamous, cohabitating, hooking up, friends with benefits, etc.) relates to well-being is an important area of future study.

Another area lacking in sufficient research is identifying the beneficial aspects of early teen dating and the possible benefits associated with the normal process of romantic exploration during adolescence and emerging adulthood. Historically, research on adolescent romantic relationships has focused on its negative correlates and risky behavior. More recently, researchers have begun to identify its utility for overall mental health and successful future relationships, but there is much more that can be uncovered. While there has been an uptick in research that looks at teen and young adult romantic involvement, this is an area that deserves more attention especially given how potentially formative our early relationships can be for future individual and interpersonal functioning.

Relatedly, I reviewed potential mechanisms that account for the strong link between romantic relationships and well-being. Specifically, the social, emotional, and instrumental support a romantic partner can offer in healthy relationships has been commonly cited as a key mechanism of this link. Providing and receiving support in both distressing and positive events with a romantic partner may be a crucial factor in predicting overall well-being. Beyond the general support hypothesis, others have attempted to identify additional explanations for the relationship benefit. Feeling understood by others, and in particular by romantic partners, is linked to higher well-being and relationship satisfaction (Gordon & Chen, 2016; Reis, Lemay, & Finkenauer, 2017). Open communication to convey what one needs from a partner and, in turn, understanding a partner's needs and perspective may boost relationship benefits for well-being. The familiarity, trust, understanding, and support romantic partners can provide all seem to benefit individual well-being. Research on qualities unique to romantic relationships as compared to social relationships and their impact on well-being continues to be limited. Further, more research on the specific mechanisms that account for the link between romantic experiences and overall well-being is needed.

Finally, gender differences are often considered when discussing romantic relationships. Prior research concerning the impact of romantic relationship transitions and experiences suggest that there may be different implications for men and women. Early research on potential gender differences found that males tend to benefit more from marriage and suffer more from divorce compared to women (Bloom, White, & Asher, 1979; Gove, 1972). However, more recent findings suggest relatively few to no gender differences in the marriage benefit for physical health or well-being (Kiecolt-Glaser & Newton, 2001; Simon, 2002; Strohschein, McDonough, Monette, & Shao, 2005; Umberson, Chen, House, Hopkins, & Slaten, 1996; Williams, 2003). Future research that addresses the conflicting findings regarding potential gender differences would be beneficial.

Overall, there has been a wealth of research considering the link between romantic relationships and well-being, but the vast majority has focused on the idea of identifying the marriage benefit and its mechanisms. Many prior findings also linked well-being solely to relationship status without considering more discrete qualities of those relationships. Moving forward, it will be critical to assess the characteristics of romantic relationships that are most closely linked to well-being and relationship satisfaction. It is evident that there are many more relationship qualities that impact well-being in addition to love and that the concept of love varies across cultures, time, and development. Given the changing definition of a romantic relationship and importance of different relationship qualities over time, more research focusing on a greater variety of relationship types – whether it be varying degrees of commitment, number of partners, or gender – and their link to well-being and relationship satisfaction is warranted.

Abstract

In this chapter we provide an overview of how resilience has been defined and measured with a particular emphasis on the relationship between resilience and well-being. Specifically, we distinguish between resilience defined as a trait and resilience defined as a pattern of psychological well-being over time. We provide a review of the developmental origins of resilience and summarize recent research regarding interventions designed to increase resilience in adults. We also differentiate resilience from closely related constructs such as hardiness, grit, character strengths, and psychological capital. Finally, we provide guidance on potential future directions for the study of resilience.

Keywords: Resilience, Well-being, Stress, Development

An observer taking a look through an airport bookstore or even the business leadership section of the local book shop could be forgiven for thinking that "resilience" is just another big fad being pushed by self-help gurus and consultants. And although there may be some truth in this assessment, the actual science of resilience, its antecedents, and its effects are fairly well-established. In fact, the question as to what makes an individual resilient in the face of trauma goes back many thousands of years.

That said, the boom in popular press books has largely reflected a similar explosion in research about resilience itself over the past two decades and there are many excellent reviews of the topic in the clinical, education, workplace, and social psychological literatures (e.g. Bonanno, Westphal, & Mancini, 2011; Britt, Shen, Sinclair, Grossman, & Klieger, 2016; Luthar, Cicchetti, & Becker, 2000; Windle, 2011; Vanhove, Herian, Harms, & Luthans, 2015). Estimates of how many people are resilient range from 25-84% (Vanderbilt-Adriance & Shaw, 2008). But what exactly does that mean? In the following sections, we will define resilience, describe how it is modeled and measured, explain its relationship with well-being, delineate how it is developed, and review closely related constructs. At the end, we will discuss some major remaining issues for research and practice in the study of resilience.

Models of Resilience

Defining Resilience

One persistent problem in the resilience literature is understanding its meaning. Specifically, resilience tends to have two somewhat distinct meanings. On one hand, resilience can mean the ability to resist being damaged or deformed by traumas or destructive forces. On the other hand, resilience can also mean readily "bouncing back" or recovering from those traumas or destructive forces. The first definition perceives resilience as a trait an individual needs to survive. The second definition instead emphasizes resilience as a means of thriving. This distinction is important, as an individual facing adversity can go further than merely coping by finding meaning in the trauma-inducing events and utilizing this meaning to enhance their well-being. Such an individual experiences post-traumatic growth, a process in which one cognitively associates benefits with the situations or events that have generated the experienced trauma (Elder, 1998; Feeney & Collins, 2014; Jayawickreme & Blackie, 2014).

These dueling definitions have resulted in the development of two somewhat independent streams of research, each of which claims to be studying resilience. One on side, there are researchers who look at resilience as something that an individual possesses. On the other side are those who believe that resilience can only be demonstrated through one's reactions to adverse events.

Resilience as a trait or capacity. There are several models and measures of resilience that treat the construct as something that an individual has *and* can report on based on prior experience (Britt et al., 2016). These models approach resilience either as a single construct (e.g. Brief Resilience Scale, Smith et al., 2008) or a composite of several distinct traits or capacities. Across measures, a wide variety of candidate traits have been suggested for inclusion in resilience measures as either antecedents or components of resilience. For example, the Connor-Davidson Resilience Scale (CD-RISC, Connor & Davidson, 2003), widely considered the "gold standard" of resilience measures, is a 25-item measure of resilience assessing acceptance of change, control, personal competence, spiritual influences, and trust in

one's instincts. The more recently developed Five-by-Five scale (DeSimone, Harms, Vanhove, & Herian, 2016) is also a 25-item measure with five dimensions, but it assesses adaptability, emotion regulation, optimism, self-efficacy, and social support. A more extreme version of this approach is the Global Assessment Tool or GAT (Peterson, Park & Castro, 2011; see also Lester, Harms, Herian, & Sowden, 2015), a 105-item, multidimensional instrument used by the U.S. military in order to provide developmental feedback for soldiers and reservists participating in resilience development programs. The GAT assesses resilience in terms of four "fitness" dimensions (Emotional, Social, Family, and Spiritual). Each higher-order dimension can in turn be broken down into subdimensions. For example, Emotional Fitness consists of adaptability, good and bad coping, catastrophizing, character, depression, positive and negative affect, and optimism. The GAT consists of a mixture of antecedents and outcomes of well-being, leading to some concerns surrounding whether scores for the higher-order dimensions themselves are interpretable (Harms, Wood, & Spain, 2016). That said, the instrument does not provide an overall "resilience" score since the intention is to encourage soldiers to think of resilience in a multi-faceted manner.

Protective Factors

In general, it is accepted that resilience is inherently related to the resources that an individual can draw on to overcome adversity (e.g. Richardson, 2002; Werner, 1995). These protective factors come in a wide variety of forms that combine to *make* a person resilient. Various researchers tend to focus on the study of resilience at one level of analysis, often with the goal of developing resilience interventions targeted at that level.

Individual factors. It is with this level that psychologists are typically concerned. It involves the psychological and neurobiological factors that can play a role in maintaining and recovering well-being after traumatic events or setbacks. This level of resilience typically involves investigations of personality and coping styles described in the preceding section that mediate the relationship between adversity and well-being (Luthar et al., 2000; Masten, 2007), but it can extend to include investigations of physical and cognitive abilities as well as neurocognitive structures and neural responses to stressors (Feder, Nestler, & Charney, 2009; Reinelt et al., 2015).

Social factors. These factors concern the social relationships one has and whether an individual can call on and expect support in times of crisis. These can involve family, friends, coworkers, or really anyone in one's social network who could provide social, emotional, and even financial support to the individual. Research has demonstrated that having such relationships can be an important determinant of whether an individual can cope with major stressors such as the loss of a job, the dissolution of a marriage, or chronic physical illness. Social support is widely construed to contain both affective and instrumental components. Adams, King, and King et al. (1996; p. 412) note that "there is a growing consensus that social support can come from both work and non-work sources and that this support is primarily in the form of either emotional support (e.g., listening and providing empathy) or instrumental support (e.g., tangible assistance aimed at solving a problem)."

Community factors. The discussion of resilience has even moved beyond the realm of individual-focused psychology to include resilience at the community or national level. This type of resilience goes beyond individual capacities and takes into account economic, institutional, ecological, and infrastructure capacities when evaluating which communities are most likely to be resilient in the face of tragedies such as terrorist attacks, natural disasters, or even economic downturns (Cutter et al., 2008; Norris, Stevens, Pfefferbaum, Wyche, & Pfefferbaum, 2008; Murphy, 2007). For instance, it might not only be necessary to know whether or not a given area has emergency services, but also how well integrated the services are in terms of communication and coordination. Importantly, community resilience need not be limited to government institutions. For example, in the aftermath of Hurricane Katrina, Wal-Mart famously was able to reach beleaguered areas with supplies before the federal and state governments because they had contingency plans in place for just such an event and adapted their plans as events unfolded.

Resilience as a process. Simply put, the process approach to studying resilience looks more at *how* individuals cope with hardship and, in particular, is often associated with assessing patterns of well-being over time to determine who is resilient in periods of stress (Luthar, Cicchetti, & Becker, 2000; Windle, 2011; Becker & Ferry, 2016). It has been suggested that there are three general patterns that reflect resilience: 1) functioning well under adverse conditions; 2) a relatively quick recovery to normal functioning after facing adverse conditions; and 3) developing in the face of adversity (Bonanno, 2004, 2005; Masten, Best, & Garmezy, 1990).

Figure 1. Patterns of Recovery from Trauma

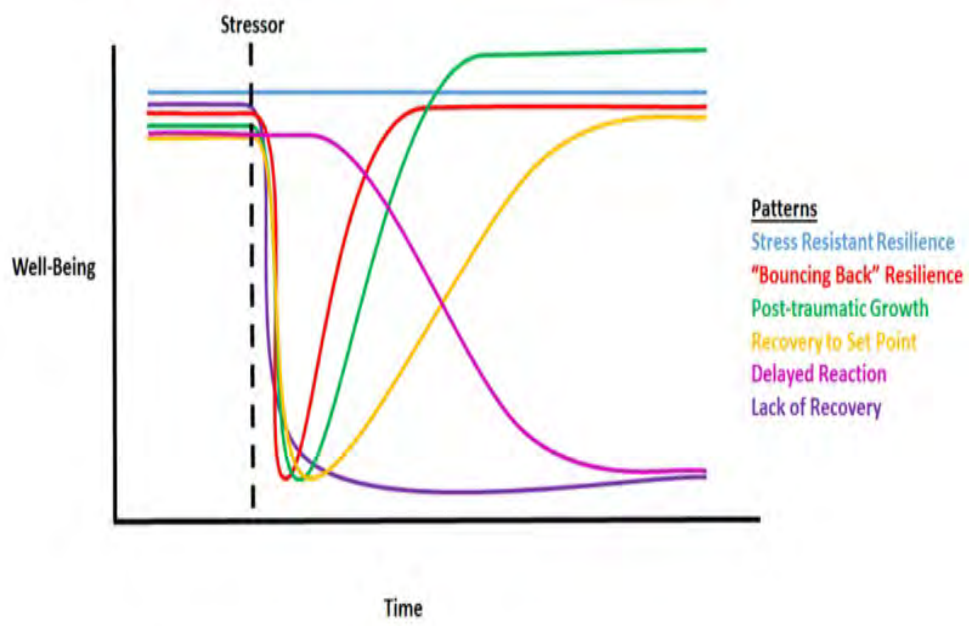

Figure 1 provides an overview of these different patterns. In this figure, the first three patterns all represent a form of resilience. The first two patterns, which have been labeled *stress resistant resilience* and *"bouncing back" resilience*, reflect the most common forms of resilience (Bonanno, 2005). In the case of stress resistance (blue), individuals do not appear to display any adverse reaction to the stressor or negative event. Rather, they continue on with their lives in spite of it. In the case of the "bouncing back" pattern (red), the individuals experience a loss but quickly adapt to it. The *post-traumatic growth* pattern (green) largely parallels the 'bouncing back' pattern, but additionally reflects the idea that positive development can occur after stressors – and importantly, *because* of exposure to these stressors – although this does not necessarily occur quickly. The final three patterns all reflect individuals who are not considered high in resilience. The basic *recovery to set point* pattern is meant to indicate that some individuals will eventually return to levels of well-being similar to those that they experienced pre-trauma, but that it will take an extended period of time to recover. The *delayed reaction* pattern (pink) represents individuals who initially appear to be healthy, but eventually begin to display signs of distress. The final pattern, *lack of recovery* (purple), reflects an individual who displays chronic problems caused by the stressor or trauma that are never fully dealt with or resolved.

Developing Resilience

Life History

There is an extensive literature showing that resilience in adulthood can be traced to childhood experiences (e.g. Masten, 2001; Masten & Tellegen, 2012; Obradovic et al., 2009; but see also Ong, Bergeman, & Boker (2009) for a review of later life events impacting resilience). Specifically, a history of poverty, disease, or abuse is typically associated with lower levels of resilience later in life (Schibli, Wong, Hedayati, & D'Angiulli, 2017; Windle, 2011). At the same time, there are those who argue that harsh environments can help individuals develop resilience since these early experiences provide the opportunity to develop the skills necessary to overcome setbacks (e.g. Crane & Searle, 2016; Duckworth, 2016; Goldstein, 2008; Rutter, 1999). In other words, experiences of stress and hardship can, for some people, be an opportunity to learn and grow and become more ready to meet the next challenge. Individuals who never experience challenges may experience high well-being on a regular basis, but they may also be more likely to fall apart when they finally do face adversity (Davydov, Stewart, Ritchie, & Chaudieu, 2010). That said, it has also been pointed out that individuals may also develop strategies for overcoming hardship that could be grossly inappropriate in non-threat environments (Schibli et al., 2017). For example, upon becoming a parent, an individual who had developed a detachment strategy for dealing with interpersonal conflict is likely to discover that this strategy is inappropriate for dealing with infants.

Resilience-Training Programs

Resilience-training programs have utilized several different approaches to increasing individual levels of resilience (Yost, 2016). These include encouraging a growth mindset, deliberative practice, meditation, teaching coping strategies, and providing social support.

One of the most famous developmental interventions for children is the Penn Resiliency Program (Gillham, Reivich, Jaycox, & Seligman, 1995). This program is based on cognitive behavioral therapy approaches and is usually implemented in school or group settings. At its core, the program attempts to help participants develop cognitive and emotional skills that they can utilize when encountering setbacks. For example, one cognitive skill that is taught is decatastrophizing or "putting things in perspective". That is, participants are instructed to step back and evaluate how important a failure event or embarrassing situation may be. Such a response is a form of cognitive reappraisal, widely considered the most effective form of emotion regulation (Gross, 2015). Cognitive reappraisal is an antecedent-focused strategy that occurs when an individual changes his or her subjective evaluation of the situation or event that has stimulated the emotion in order to change the emotion that they feel (Fisher, Minbashian, Beckmann, & Wood, 2013). As such, cognitive reappraisal allows the individual to avoid overreacting to negative events.

One of the most popular resilience interventions in the research literature is the Penn Resiliency Program. While meta-analytic work has shown the program produced some positive effects, its results were highly variable and, in general, it was not more effective than other active control conditions or other interventions designed to improve mental health and well-being (Brunwasser, Gillham, & Kim, 2009).

Beyond classroom settings, resilience-training initiatives are now becoming more popular in corporate and government environments. Although it is believed that almost anyone can benefit from such programs, there is also a consensus that resilience may be most important for occupations such as first-responders (i.e. police, firefighters, etc.) or medical personnel where high levels of stress are common and exposure to secondary trauma—which is concerned with the intrapersonal emotive responses a person can experience during or following an interaction(s) with another individual who shares their personal stories of disempowerment, trauma, or abuse (Williams, Helm, & Clemens, 2012)—is frequent (Britt et al., 2016). Consequently, military organizations have been on the forefront of developing resilience-building programs (Harms, Krasikova, Vanhove, Herian, & Lester, 2013). Of particular note has been the Comprehensive Soldier and Family Fitness (CSF2) program by the U.S. Army, which is based on the Penn Resiliency Program and has been implemented at every level of the Army. CSF2 entails not just regular self-assessments of resilience, but also includes online modules to address particular concerns of the soldiers and embeds Master Resilience Trainers (MRTs) in units across the force to implement group-based training of cognitive and behavioral skills that are associated with higher levels of resilience and well-being. The CSF2 program proved to be more effective at developing resilience in younger soldiers than in older soldiers (Lester, Harms, Herian, Krasikova, & Beal, 2011) and has also been shown to be related to lower levels of substance abuse in units which receive the training (Harms, Herian, Krasikova, Vanhove, & Lester, 2013).

A recent meta-analysis of organizational resilience interventions (Vanhove, Herian, Perez, Harms, & Lester, 2016) has shown that not all resilience programs are created equal and not all people respond in the same way to such programs. For example, although the benefits of resilience-development programs tend to wear off for most people over time, there was evidence that for the most at-risk populations, the benefits tended to accrue over time. Analyses also revealed that computer-based interventions were the least effective medium for resilience training while one-on-one training was the most effective. Overall, the results of these studies have suggested that social factors that promote resilience can interact with individual factors and that well-designed interventions should target resilience development across levels in order to achieve the best results.

The Relationship Between Resilience and Well-Being

Resilience and well-being are fundamentally related and, as noted above, in some instances resilience is even measured using well-being instruments (Davydov et al., 2010; Windle, 2011). This conflation creates problems with where to position resilience in models of well-being. First, it should be pointed out that although meta-analyses have demonstrated that there are robust relationships between measures of resilience and measures of well-being (Hu, Zhang, & Wang, 2015; Lee et al., 2013), there is evidence that self-report measures of resilience are not simply redundant with indices of well-being (Burns & Antsey, 2010; Martínez-Marti & Ruch, 2017). At the same time, the relationship between resilience and well-being is not straightforward.

Some researchers have argued that higher levels of well-being serve as an antecedent of resilience (e.g. Kuntz, Näswall, & Malinen, 2016). In particular, there has been extensive work showing that positive emotions facilitate resilience (e.g. Fredrickson, Tugade, Waugh, & Larkin, 2003; Ong, Bergeman, Bisconti, & Wallace, 2006; Ong, Zautra, & Reid, 2010; Tugade & Fredrickson, 2004). Research suggests that positive emotions can promote greater resilience because they promote flexible thinking (Isen, Daubman, & Nowicki, 1987) and facilitate both adaptive coping (Folkman & Moskowitz, 2000) and the maintenance of social relationships (Keltner & Bonanno, 1997).

Others have suggested that the relationship between well-being and resilience can also work in the opposite direction. For example, several researchers have used resilience to directly predict a number of well-being outcomes including depression (Loh, Schutte, & Thorsteinsson, 2014), job satisfaction (Luthans, Avolio, Avey, & Norman, 2007), and subjective well-being (Cohn, Fredrickson, Brown, Mikels, & Conway, 2009; Liu, Wang, Zhou, & Li, 2014). Still others have argued that resilience and related constructs can serve as moderators between stressors and well-being outcomes (e.g. Flinchbaugh, Luth, & Li, 2015; Min, Kim, & Lee, 2015).

That said, there is nothing inherently wrong with acknowledging that all of these theoretical positions are potentially true. Positive individuals may ultimately be more resilient because they approach situations expecting better outcomes and tend to elicit more positive responses (Wood, Harms, & Vazire, 2010). And although it is probably correct to position resilience indicators (the individual, social, and community factors mentioned earlier) as moderators between stressors and well-being, that does not mean that studies showing a direct path cannot infer that resilience is moderating several unmeasured stress events over a long period of time and that the direct path simply captures the general trend across events.

A challenge, however, to conflating resilience and well-being is that the abilities honed by resilient individuals may be more generative of self-efficacy, and in fact may actually hinder well-being. For example, an individual cast away by his or her only family at a young age may learn how to navigate very challenging environments to succeed. An individual's resilience may lead to high self-efficacy and a successful approach to his or her career, yet may also produce an "it's all about me and getting what I deserve" attitude that can undermine well-being. Considering that longitudinal research has found that receiving social support is an antecedent of well-being (Elder, 1974, 1998), such an individual may isolate him or herself from sources of such support.

Additionally, some individuals who experience high levels of well-being may lack the focus that produces resilience. The positive emotions associated with well-being, such as joy and calmness, tend to generate a diffuse contentment rather than the sharp, vivid focus on challenges associated with resilience (Fredrickson, 1998; Silard, 2016). In fact, the action tendencies produced by positive emotions—such as inactivity from contentment and free activation from joy—are often less specific (in terms of goal orientation) and lacking in autonomic reactivity (Fredrickson & Branigan, 2005). It may be possible that some antecedents of well-being and resilience diminish the attainment of the other. Future research might better uncover these potential disparities.

Other Related Constructs

As noted above, a lack of strong theory surrounding resilience has meant that its position in the nomological network can often be confusing and seemingly contradictory. The same issue applies to other closely related personality characteristics. Recent reviews of resilience have suggested a number of constructs that conceptually appear very similar to resilience (e.g. King, Newman, & Luthans, 2016; January, 2016). The following section identifies some major constructs that are closely related to resilience.

Psychological Capital

Psychological capital (PsyCap) is argued to be a set of four psychological factors associated with overcoming obstacles that together form a higher-order construct (Luthans et al., 2007; Youssef & Luthans, 2007). Specifically, these psychological factors are self-efficacy, optimism, hope, and resilience. Resilience in this model is often simply described as the capacity to adapt in the face of adversity. Because of the self-report nature of the instrument and the limited number of questions typically asked, PsyCap assessment tools generally have to assume that the resilience component is unidimensional, that respondents have experienced appropriate setbacks in order to make informed judgments, and that they are able to meaningfully average across the responses to multiple adverse events. Because of these potential issues, there have been recent efforts made to create implicit measures of PsyCap that better reflect the individual's actual levels of resiliency (Harms & Luthans, 2012). Both the explicit and the implicit instruments have been shown to predict health and well-being across multiple domains (Avey, Reichard, Luthans, & Mhatre, 2011; Harms, Vanhove, & Luthans, 2017; Luthans, Youssef, Sweetman, & Harms, 2013). For example, one recent study found that PsyCap was predictive of both mental health and substance abuse in a large sample of U.S. soldiers (Krasikova, Lester, & Harms, 2015). That said, although there has been a great deal of research using PsyCap measures to predict important outcomes both in and out of the workplace, there is still an ongoing debate as to whether combining the components of PsyCap into a single score is appropriate or whether they are best considered independent of one another. In particular, it could be argued that resilience should not be included in the set of PsyCap factors because it is theoretically positioned as an outcome of the other three.

Character Strengths

Character strengths are conceived of as "naturally recurring patterns of thought, feeling, or behavior that can be productively applied" (Hodges & Clifton, 2004, p. 257). In other words, they are a broad array of personality characteristics distinguishable from other traits because they are associated with high levels of functioning both behaviorally and psychologically (Peterson & Seligman, 2004). In practice though, they tend to be assessed as efficacies or self-appraisals of ability to function well on particular activities or in specific domains. High levels of character strengths have been suggested to be key antecedents of resilience (Martínez-Marti & Ruch, 2017; Peterson, Park, & Castro, 2011; Peterson & Seligman, 2004) or as potential indicators of resilience itself (Goodman, Disabato, Kashdan, & Machell, 2017). However, the empirical evidence of this assertion is somewhat mixed in terms of which strengths are associated with well-being (Goodman et al., 2017; Park, Peterson, & Seligman, 2004). That said, there is fairly good evidence that self-assessments of character strengths are useful predictors of mental health outcomes (e.g. suicide and substance abuse; Lester, Harms, Bulling, Herian, & Spain, 2011). There are, however, numerous criticisms of strengths measures in terms of their construct definitions, their theoretical structure, the way they are scored, and their interpretation (Kaiser & Overfield, 2011; Kaplan & Kaiser, 2013). Consequently, although the relationship between strengths and resilience looks promising, further refinement of character strengths instruments is needed before it can be determined whether strengths are antecedents of resilience or whether "resilience" as a trait should simply be considered redundant with specific characteristics already contained in existing strengths measures.

Grit

Popularized by Duckworth (Duckworth, Peterson, Matthews, & Kelly, 2007), grit is conceived of as perseverance in the face of challenges and experiencing passion in the pursuit of long-term goals. The relationship with resilience is immediately apparent based on this definition in that one component of grit, perseverance, seems to reflect a resilient personality and even the "passion" component might be considered a possible antecedent of resilient behavioral patterns. However, meta-analytic evidence suggests there is a trivial relationship between measures of resilience and grit even though grit appears to be related to well-being outcomes such as depression and life satisfaction (Credé, Tynan, & Harms, 2017). That said, once again measurement issues limit the degree to which firm conclusions can be drawn about grit. First, the combination of the two factors of grit is not supported by either theory or empirical evidence. Moreover, the current measures of grit have been demonstrated to largely overlap with existing measures of trait conscientiousness (Credé et al., 2017). Consequently, little can be meaningfully said about overall "grit" at this point and further scale refinement is necessary before any firm conclusions can be drawn.

Hardiness

Of the closely-related constructs, hardiness probably comes closest in terms of conceptual similarity to resilience. Individuals high in hardiness are described as being "unshakeable," and they tend to attack problems directly and willingly (Kobasa, 1979). Specifically, hardiness itself is conceived of as a cognitively-based personality trait consisting of three characteristics that shape how hardy individuals view events in their lives: control, commitment, and challenge (Bartone, 2006; Maddi, Kahn, & Maddi, 1998). Control reflects the degree to which one believes that they have a high level of influence over their lives. Commitment refers to the tendency or ability to find purpose in one's life or to attach meaning to one's efforts. Challenge reflects a tendency to see difficult circumstances as an opportunity for growth as opposed to nuisances or threats. Further, meta-analytic evidence shows that individuals with high trait hardiness tend to have higher levels of psychological well-being, better coping skills, higher levels of health, and more well-developed social support networks (Eschleman, Bowling, & Alarcon, 2010). The primary difference between resilience and hardiness at the measurement level is that hardiness has a very concrete theoretical model both in terms of structure and rationale. Resilience models have not yet arrived at a consensus as to what should be included in the measures and what the specific antecedents are.

Future Directions

Not to belabor the point, but there is a real need for construct clean-up in the domain of resilience. Not only are there several related constructs that need to be differentiated from resilience, but it is unclear as to whether many measures of resilience are even measuring the same construct (Britt et al., 2016). Further, as noted in the above sections, one important future direction for resilience and related measures is to further refine their theories and measurement tools. Too often, resilience measures combine antecedents and outcomes of resilience along with overall assessments in their measures and then try to infer a trait based on structuralist logic that because variables are correlated, they must necessarily go together. Particularly problematic is the inclusion of items that refer to well-being outcomes in the resilience measures themselves as this tendency tends to create spuriously high correlations between constructs (Wood & Harms, 2016). Instead, it would be preferable to embrace a functionalist approach to assessing

resilience (see Harms & Wood, 2016; Wood, Gardner & Harms, 2015), that is, to tease out the antecedent psychological components of resilience and investigate how they interact to produce behavioral and emotional resilience. Another fruitful approach may be to move away from questionnaire-based approaches altogether and attempt to develop assessments of resilience based on neurological measurements (e.g. Quisenberry, 2015), implicit measures (e.g. Harms & Luthans, 2012), or situational tests (e.g., Kirschbaum, Pirke, & Hellhammer, 1993).

At the same time, it may not be necessary to completely eschew self-report measures if the goal is to assess resilience as process or pattern. There have been many calls for more longitudinal research to investigate resilience as patterns of well-being rather than the cross-sectional, retrospective studies which tend to dominate in the literature (Britt et al., 2016; King et al., 2016). Recent work by Welbourne (2014) has shown that even asking a single question concerning well-being repeatedly over several days can produce enlightening results in terms of determining an individual's overall resilience. Taking this logic a step further is recent research by Sotak (2015), who has demonstrated that daily and weekly patterns in emotions and well-being can be removed from such assessments in order to garner a more accurate view of fluctuations in response to stressors.

Hand-in-hand with the development of new instruments and techniques is the need to validate those instruments and techniques. A recent review of resilience measures showed that almost none of them had gone through rigorous validation procedures and the overall validity of most resilience measures was questionable at best (Windle, Bennett, & Noyes, 2011). Without appropriate tools, it is hard to see how we can put much faith into much past research or how we are to move the field forward.

Beyond the need for new measures is a real need for theoretical development in the field of resilience. In particular, it is reasonable to expect a little more precision in predictions than simply that resilience should be positively correlated with good outcomes and negatively correlated with bad outcomes. Clinical psychologists are fairly clear about what they expect in terms of outcomes of resilience. When bad things happen, resilience is established by how one recovers from stress. However, researchers in the positive psychology movement have been inconsistent in terms of what to expect from resilience interventions. For them, the goal is or should be to see if they can promote individual flourishing. At the same time, it is acknowledged that the degree to which programs based on positive psychology are deemed effective is the extent to which they reduce mental illness (Seligman & Fowler, 2011). Likewise, industrial psychologists attempt to tie resilience to all manner of work outcomes with little regard for theory (Britt et al., 2016). Having more clearly defined constructs and models would help prevent this shotgun approach to science and save precious resources and time.

Conclusions

Resilience is more than just a buzz word used to sell books in airports. It is a valuable framework for understanding how individuals cope with stress and maintain their levels of well-being. The past few decades of research have revealed a great deal in terms of what factors are most important for driving resilience and how interventions can be designed to facilitate growth and recovery in the face of adverse events. Nonetheless, challenges remain in terms of the theory surrounding resilience, its measurement, and its meaning. However, new approaches to assessing resilience show great promise for the study of resilience in the future.

Abstract

To fully understand how psychological functioning is related to health and longevity, it is important to not only consider psychological distress, but also subjective well-being (i.e., the presence of positive thoughts and feelings). This chapter reviews the most recent and highest quality evidence for whether and how subjective well-being is linked with living healthier and longer lives. Accumulating evidence has begun to suggest that initially healthy individuals with higher versus lower levels of subjective well-being are less likely to be diagnosed with incident disease including coronary heart disease, stroke, diabetes, arthritis, and, to a lesser extent, cancer. The reoccurrence of disease in individuals who have already been diagnosed shows a similar although less robust pattern. Associations are comparable for mortality, with fairly persuasive evidence demonstrating that higher levels of subjective well-being in initially healthy individuals are associated with longevity, but a somewhat less compelling body of work supporting the association among cohorts of patients. Underlying pathways for these associations are discussed – including mechanisms related to stress buffering and physiological and behavioral processes – and suggestions for future research are provided.

Keywords: health, longevity, morbidity, mortality, subjective well-being, life satisfaction, positive emotions

The notion that psychological states and physical states are connected has endured across the ages. Most empirical research on this topic has focused on how psychological distress is related to poor health outcomes. For example, compared to people with low levels of depression, anxiety, and stress, people with high levels have an increased risk of incident coronary heart disease and mortality (Nicholson, Kuper, & Hemingway, 2006; Pratt, Druss, Manderscheid, & Walker, 2016; Richardson et al., 2012; Roest, Martens, de Jonge, & Denollet, 2010; Rugulies, 2002; Steptoe & Kivimaki, 2013). However, most people are not psychologically distressed. In fact, most people report feeling happy most of the time (Diener & Diener, 1996; Diener, Kanazawa, Suh, & Oishi, 2015). Thus, to understand how the full range of psychological functioning is related to health and longevity, it is important to not only consider psychological distress, but also the presence of positive thoughts and feelings.

The frequent experience of positive thoughts (like satisfaction with life) and feelings (like positive emotions) comprise the construct of subjective well-being (Diener, Suh, Lucas, & Smith, 1999). Subjective well-being – which is colloquially known as happiness – inherently feels good. Moreover, evidence suggests that subjective well-being is also associated with beneficial outcomes in a variety of life domains such as in the workplace and in social relationships (Boehm & Lyubomirsky, 2008; Lyubomirsky, King, & Diener, 2005). In the last decade or so, an explosion of research has explored whether the benefits of subjective well-being are apparent with regards to health and longevity as well. Thus, this chapter reviews the most recent and highest quality evidence for whether and how positive thoughts and feelings are linked with living longer and healthier lives.

The strongest evidence for associations between subjective well-being and health-related outcomes come from studies that are methodologically rigorous, as indicated by the following characteristics: 1) prospective longitudinal design that takes baseline health into account and follows individuals across many years; 2) assessment of subjective well-being with a well-validated and multi-item questionnaire or an objective measure; 3) objective assessment of a health outcome (e.g., via medical records); 4) analyses that control for confounding variables (e.g., socioeconomic status); 5) analyses that consider possible underlying pathways (e.g., health behaviors); and 6) analyses that test whether subjective well-being's associations are independent from psychological distress (e.g., depression, anxiety). The selective review that follows describes studies that are characterized by most or all of these criteria. I first describe evidence linking subjective well-being with a variety of disease outcomes, then I describe evidence linking subjective well-being with mortality. Because correlates and underlying processes may differ for people who are initially free from disease and those who have been diagnosed with a medical condition, I review evidence

for both groups separately. This chapter ends with a discussion of the mechanisms by which subjective well-being may be linked with better health and longevity, as well as considerations for future research.

Note that although evidence also exists regarding how other indicators of positive psychological functioning are associated with health outcomes – such as purpose in life or optimism (e.g., Cohen, Bavishi, & Rozanski, 2015; Rasmussen, Scheier, & Greenhouse, 2009) – here I focus exclusively on the positive indicators that comprise subjective well-being (i.e., life satisfaction and positive affect) to maintain a manageable scope. In addition, low levels of negative emotions are sometimes included as part of subjective well-being's conceptualization, but I do not consider negative emotions here because there is a very large and separate literature that has focused on the relationship between various negative emotions and poor health (see selected references above).

Morbidity

In Initially Healthy People

Evidence is accumulating to suggest that happy and satisfied people have lower risk for being diagnosed with a variety of medical conditions. Cardiovascular disease has been the most frequently studied outcome, in part because it is a well-defined disease with objective indicators (Boehm & Kubzansky, 2012). For example, 1,700 Canadian men and women over 18 years old had their positive affect assessed via the facial expressions they displayed during a clinical interview (Davidson, Mostofsky, & Whang, 2010). Relative to people showing fewer positive emotions in their faces, people showing more positive emotions had a 22% reduced risk of being diagnosed with coronary heart disease across 10 years. These findings were robust to adjustment for a variety of confounders and possible behavioral mechanisms, as well as to adjustment for hostility and symptoms of depression and anxiety. Another study reported similar findings based on a cohort of nearly 8,000 British civil servants. Individuals with greater initial life satisfaction across a variety of domains (including satisfaction with work, family, and one's sex life) tended to have a reduced risk of incident coronary heart disease (Boehm, Peterson, Kivimaki, & Kubzansky, 2011). This study had a follow-up period of approximately 5 years and controlled for a range of variables including sociodemographic characteristics, health behaviors, blood pressure, lipids, body mass index, diabetes, and psychological ill-being.

However, positive affect was not related to incident coronary heart disease in the same cohort of British civil servants followed across a mean of 12 years (Nabi, Kivimaki, De Vogli, Marmot, & Singh-Manoux, 2008). The null association between positive affect and heart disease was evident regardless of which covariates were included in the models. With nearly 9,000 participants and more than 600 cases of heart disease, statistical analyses were adequately powered to detect associations. Yet, there has been some criticism of the Affect Balance Scale (Bradburn, 1969), which was used to assess baseline positive affect. Reliability is relatively low (e.g., alpha less than .70), some of the items may be outdated or otherwise problematic (e.g., feeling "on top of the world"), and there is a focus on personal accomplishment rather than pure positive feelings (McDowell, 2006). Thus, null findings could have been due to a relatively poor assessment of positive affect.

Other work has also reported a null association between subjective well-being and coronary heart disease though (Feller, Teucher, Kaaks, Boeing, & Vigl, 2013). In one prospective study that followed more than 6,000 Dutch men and women over age 55 for a dozen years, neither positive affect nor negative affect were significantly associated with incident cardiovascular disease in minimally-adjusted models and fully-adjusted models (Freak-Poli et al., 2015). Null associations persisted when stroke, heart failure, and coronary heart disease were investigated separately, as well as after stratification by age and gender. One possible explanation for the null findings in both the British and Dutch studies was the relatively homogenous cohort of participants. In both cases, socioeconomic status did not vary much and participants were relatively well off. Notably, however, the study with British civil servants found an association between negative affect and heart disease whereas the Dutch study did not. The null findings for negative affect are inconsistent with other work (e.g., Kubzansky, 2007).

Another possibility in the latter study is that the measure of positive affect – a 4-item composite of positive emotions derived from the Center for Epidemiologic Studies-Depression [CESD] scale (Radloff, 1977) – did not adequately capture positive emotional experience. Although deriving indicators of subjective well-being from measures originally designed to assess psychological distress is not ideal (Boehm & Kubzansky, 2012), other studies have used this approach and found evidence for an association between positive affect and cardiovascular disease. For example, positive affect derived from the CESD scale was related to reduced risk of incident stroke among nearly 2,500 people over the age of 65 (Ostir, Markides, Peek, & Goodwin, 2001). These participants were followed for 6 years, and associations were evident for men and women and blacks and whites. Moreover, the inverse association between positive affect and stroke risk held after accounting for sociodemographic characteristics, body mass index,

smoking status, and other health conditions (all participants were free from stroke at baseline). (For other stroke-related findings, see also Feller et al., 2013; Lambiase, Kubzansky, & Thurston, 2015). Another study using the positive affect items from the CESD scale also reported inverse associations with hypertension in a cohort of older Mexican Americans (Ostir, Berges, Markides, & Ottenbacher, 2006). For individuals who were not on antihypertensive medication, every unit increase in positive affect was associated with 9% reduced odds of belonging to a higher blood pressure category, controlling for sociodemographic factors, health behaviors, diabetes, and even negative affect. The association between well-being (specifically, emotional vitality) and hypertension has since been replicated in a British cohort (Trudel-Fitzgerald, Boehm, Kivimaki, & Kubzansky, 2014).

Apart from cardiovascular-related outcomes, other health conditions have been investigated in relation to subjective well-being. For example, one review of the literature has suggested that well-being is tied with diabetes (Celano, Beale, Moore, Wexler, & Huffman, 2013). A study of almost 100 older women who were initially free from diabetes demonstrates this. Women with higher levels of baseline positive affect tended to have healthier levels of glycosylated hemoglobin – a marker of glycemic control in recent months – two years later, controlling for negative affect and depression diagnosis (Tsenkova, Love, Singer, & Ryff, 2007). More recently, a prospective study of nearly 8,000 British civil servants showed that higher levels of both life satisfaction and emotional vitality were associated with reduced odds of self-reporting a physician diagnosis of diabetes (Boehm, Trudel-Fitzgerald, Kivimaki, & Kubzansky, 2015). These findings held after adjusting for demographic characteristics, health behaviors, blood pressure, and body mass index, but were attenuated for emotional vitality after adjusting for depressive symptoms (findings were maintained for life satisfaction when adjusting for depressive symptoms). No gender differences were reported in the study, although a separate study of more than 50,000 German participants followed across 8 years found an association between life satisfaction and incident diabetes among women but not men (Feller et al., 2013). More specifically, women who were unsatisfied with their lives had a 17% increased risk of developing Type II diabetes compared with their very satisfied counterparts.

In addition to examining incident diabetes in the very large German cohort, incident cancer was also considered. Cancer outcomes are less frequently investigated in connection with psychological predictors because of the numerous different types of cancer and somewhat less precise way to define diagnoses. However, in this case, an association was apparent between life satisfaction and cancer across 8 years. Unsatisfied women had a 45% increased chance of incident cancer relative to satisfied women (Feller et al., 2013). These findings held when controlling for sociodemographic factors and health behaviors, but not when controlling an indicator of psychological distress. Moreover, there was no association between life satisfaction and incident cancer in men. In a different study of approximately 12,000 Finnish women, the relationship between life satisfaction and breast cancer was investigated. No relationship existed between life satisfaction and incident breast cancer across 21 years in age-adjusted and multivariable-adjusted models (Lillberg et al., 2002). Such null findings for cancer have been reported in other studies as well (Bai et al., 2016; Okely & Gale, 2016).

Nonetheless, subjective well-being has been found to be related to incident arthritis. In one 9-year study of more than 13,000 older adults throughout Europe, higher levels of well-being were associated with reduced risk of reporting a doctor diagnosis of arthritis (Okely, Cooper, & Gale, 2016). Other studies have also investigated the extent to which subjective well-being is related to functional status. In one example of this, more than 3,000 older men and women from England responded to a baseline questionnaire about how much they enjoyed life, and then were followed for 8 years (Steptoe, de Oliveira, Demakakos, & Zaninotto, 2014). Relative to those with high levels of enjoyment, those who reported low levels of enjoyment had increased odds of experiencing impaired physical functioning, as indicated by self-reported activities of daily life and objective assessment of gait speed. Findings were robust to statistical adjustment for sociodemographic characteristics, health-related factors including behaviors, and depression. To extend these results even further, another group of researchers investigated how well-being was associated with incident frailty, which tends to be preceded by impaired physical function. Using the same cohort of older English men and women, models adjusting for a variety of confounders (including depressive symptoms) indicated that those people with higher versus lower baseline levels of well-being were less likely to experience incident frailty across a 4-year follow-up period (Gale, Cooper, Deary, & Aihie Sayer, 2014). These findings have been replicated in another study of elderly caregivers (Park-Lee, Fredman, Hochberg, & Faulkner, 2009).

In People Already Diagnosed with Disease

A meta-analysis has reported that well-being is related to recovery among people who have been diagnosed with disease (Lamers, Bolier, Westerhof, Smit, & Bohlmeijer, 2012). Another meta-analysis specific to cardiovascular disease showed that well-being appears to be associated with reduced risk of hospitalization and mortality in cardiac patients (DuBois et al., 2015). For example, more than 800 patients

undergoing percutaneous coronary intervention with stent implantation had their positive affect assessed. Those with low versus high levels of positive affect were more likely to experience myocardial infarction or death 2 years later (Denollet et al., 2008). There is some conflicting evidence though. For example, in age-adjusted analyses that followed more than one thousand individuals diagnosed with coronary heart disease for 7 years, there was only a marginally significant relationship between positive affect and cardiovascular events (heart failure, myocardial infarction, stroke, or transient ischemic attack; Hoen, Denollet, de Jonge, & Whooley, 2013). Moreover, positive affect in patients who had undergone cardiac rehabilitation was not associated with hospitalizations or all-cause mortality an average of approximately 3 years later (Meyer, von Kanel, Saner, Schmid, & Stauber, 2015). However, negative affect was also included in statistical models and the two types of affect were very strongly correlated.

In cohorts of individuals with non-cardiovascular diagnoses, subjective well-being also appears to be related to healthier outcomes. Among elderly patients who experienced a hip fracture, those with high levels of positive emotion demonstrated better physical performance (i.e., walking speed and chair stands) during a 2 year follow-up period than their peers with high levels of depressive symptoms (Fredman, Hawkes, Black, Bertrand, & Magaziner, 2006). Similarly, increases in positive emotions in the 3 months following a stroke were associated with improved functional performance in the patients (Seale, Berges, Ottenbacher, & Ostir, 2010).

Mortality

In Initially Healthy People

Beyond whether happier people have lower risk for disease, reviews of prospective studies indicate that happier people tend to live longer than less happy people (Chida & Steptoe, 2008; Diener & Chan, 2011; Martin-Maria et al., 2017). For example, one meta-analysis synthesized findings through 2008 and reported that higher levels of well-being were associated with 18% reduced risk of mortality in initially healthy cohorts (Chida & Steptoe, 2008). Such findings have been replicated in more recent research as well. In one case, more than 31,000 U.S. adults ages 18 and over responded to the question: "Taken all together, how would you say things are these days – would you say that you are very happy, pretty happy, or not too happy?" (Lawrence, Rogers, & Wadsworth, 2015). Compared to those people who reported being very happy, those who reported being not happy were 14% more likely to die during as many as 30 years of follow-up. These findings accounted for sociodemographic characteristics, geographic region, and religious attendance, but not psychological distress. Similar results have been replicated in more than 9,000 men and women representative of those over 50 years old living in England (Steptoe & Wardle, 2012). Individuals who reported the highest versus lowest levels of life enjoyment had a 28% reduction in mortality risk across an average of 7 years of follow-up, accounting for sociodemographic factors, disease diagnoses, health behaviors, and depression.

In the same cohort of older English men and women, subjective well-being was assessed with ecological momentary assessment in nearly 4,000 participants (Steptoe & Wardle, 2011). This type of measurement asked participants to report on their positive feelings at four points throughout the day to capture "experienced" subjective well-being rather than the more conventional retrospective assessment. Across an average of 5 years, individuals with the highest level of positive affect had a 35% reduction in mortality risk compared to those with the lowest levels of positive affect. Notably, these analyses statistically controlled for sociodemographic factors including education and wealth, as well as negative affect, depressive symptoms, presence of disease, cigarette smoking, physical activity, and alcohol intake. Moreover, negative affect was not related to increased risk of mortality in this study, but depressive symptoms were (although positive affect's association with mortality persisted when statistically controlling for depressive symptoms).

The work reviewed thus far indicates that there is a consistent relationship between subjective well-being and longevity in Western participants, but does the relationship generalize to other groups? Work on this topic with diverse samples of participants is limited, but one notable study followed more than 5,000 older Taiwanese adults across 10 years (Collins, Glei, & Goldman, 2009). Individuals who were more satisfied at baseline had lower risk of mortality than their less satisfied peers, controlling for sociodemographic factors, indicators of health and health behaviors, and depression. This initial evidence suggests that the association between subjective well-being and longevity exists for other cultural groups as well (see also Kimm, Sull, Gombojav, Yi, & Ohrr, 2012; Yiengprugsawan, Seubsman, & Sleigh, 2014).

Other moderators of the association between subjective well-being and longevity have been increasingly explored, including the extent to which subjective well-being remains stable over time. Although subjective well-being – in particular, life satisfaction – is often thought of as being relatively consistent across time, it can change due to life circumstances such as divorce or unemployment (Lucas, Dyrenforth, & Diener, 2008). Thus, single assessments of subjective well-being at one point in time may

not capture the whole story of a person's sense of well-being. Several studies have now investigated how fluctuations in subjective well-being are related to longevity. In one study, more than 9,000 older men and women living in England reported their life enjoyment on three separate occasions across 6 years (Zaninotto, Wardle, & Steptoe, 2016). Those who reported enjoying life at all three occasions had a 24% lower risk for death up to 7 years later compared to those who reported not enjoying life at any occasion. Furthermore, there was a graded relationship such that those who reported enjoying life at only two occasions had a 17% reduced risk of death relative to those who did not enjoy life at any occasion. Findings held after controlling for demographic factors, health, and depression.

Another study of more than 4,000 Australian men and women ages 50 and over used a different approach to conceptualize maintenance of subjective well-being across time (Boehm, Winning, Segerstrom, & Kubzansky, 2015). A single item of life satisfaction was assessed annually across as many as nine years. The mean and standard deviation of each person's life satisfaction ratings were then calculated to get a sense of the stability and variability of life satisfaction across time. Consistent with past research, higher versus lower mean levels of life satisfaction were associated with reduced risk of mortality during the follow-up period. However, the variability in satisfaction that a person experienced across time modified the relationship such that the least satisfied people who also had fluctuating levels of life satisfaction had the highest risk of mortality. These results further confirm that sustaining high levels of SWB across time are important to associations with longevity, while variability may be detrimental. Moreover, these studies highlight the importance of looking at subjective well-being across time rather than as a static phenomenon, as most studies do (for another example that considers time-varying subjective well-being, see Collins et al., 2009).

Although the vast majority of studies have assessed subjective well-being via self-reported questionnaires – including single item ratings or multi-item questionnaires that have been validated such as the Satisfaction With Life Scale (Diener, Emmons, Larsen, & Griffin, 1985; Pavot & Diener, 2008) – sometimes subjective well-being is assessed via indirect methods. Such studies also point to an association between subjective well-being and longevity. For example, one group of researchers evaluated the intensity of smiles that Major League Baseball players displayed in their photographs (Abel & Kruger, 2010). Those players with Duchenne, or genuine smiles, were half as likely to die when compared to those players without a smile. Likewise, another study assessed the subjective well-being of nuns in their twenties by evaluating autobiographies the nuns had written for content related to positive emotions (Danner, Snowdon, & Friesen, 2001). There was a 2.50-fold difference in the relative risk of mortality between nuns who wrote with great positive emotion and those who wrote with little positive emotion, controlling for age and education. In short, nuns who expressed more positive emotions early in life lived longer than those who expressed fewer positive emotions. In other work, the use of activated positive emotion words (e.g., lively, vigorous) but not less activated positive emotion words (e.g., calm, peaceful) were related to longevity in famous psychologists (Pressman & Cohen, 2012).

Lest it seem that all studies have reported associations between subjective well-being and longevity, there is one notable and well-publicized study that reported conflicting evidence (Liu et al., 2016). More than 700,000 women from England and Scotland (median age of 59 years) were asked about their happiness with the single item: "How often do you feel happy?" Responses ranged from "most of the time" to "rarely/never." Mortality was assessed during a follow-up period across an average of nearly 10 years. In models adjusting for sociodemographic characteristics, body mass index, health behaviors, and religious participation, women who were unhappy had an increased risk of mortality compared with women who were happy most of the time. However, when self-rated health was also included in the analytic models, happiness was no longer associated with mortality. The authors attribute the null association to the fact that bad health can foster both less happiness and increased risk of death.

Yet other researchers have noted limitations in this study, the primary one being that the statistical analyses adjusted for too many variables (Diener, Pressman, Hunter, & Delgadillo-Chase, 2017; Kubzansky, Kim, Salinas, Huffman, & Kawachi, 2016). In particular, self-reported happiness and self-reported health are known to be robustly correlated, and judgments of one may be informed by judgments of the other (Benyamini, Idler, Leventhal, & Leventhal, 2000). To compound matters in this study, self-rated happiness and health were assessed at the same time with similar, single item self-report questions (so they not only shared common variance due to methodology, but were also less reliably measured). Thus, it is not surprising that self-reported health attenuated the association between happiness and longevity. Nonetheless, this study provides a helpful reminder for researchers to be thoughtful about which covariates are included in analyses when examining associations between subjective well-being and longevity, with a particular caution about how to interpret attenuation that could occur as a result of including highly correlated variables or potential pathway variables (Diener et al., 2017). Moreover, optimal analyses would incorporate repeated, reliable assessments of both the exposure and covariates that allow for consideration

of mechanistic relationships more explicitly (Stringer & Veldkamp, 2016). Such causal modeling has not yet been done in this area of research but is greatly needed (Diener et al., 2017).

In People Already Diagnosed with Disease

Consistent with findings in initially healthy populations, happy people who have been diagnosed with a disease seem to have a reduced risk of mortality compared with unhappy people diagnosed with a disease. Notably, however, the effect seems to be smaller. One meta-analysis estimated that on average, there was a 2% reduced risk of mortality for happy versus unhappy patients (compare that with the 18% reduced risk for initially healthy people; Chida & Steptoe, 2008). A second, more recent meta-analysis came to a similar conclusion that a small but meaningful relationship existed between well-being and survival in people with existing disease (Lamers et al., 2012). However, both meta-analyses note the heterogeneity in the studies with patient cohorts – for example, different patient populations with varying types and severity of disease, follow-up periods, and quality – all of which could contribute to smaller effects.

As an example, one year-long study found an association between a single item about enjoying life and reduced risk of all-cause mortality (Scherer & Herrmann-Lingen, 2009). Participants were medical inpatients, and statistical models controlled for physicians' estimate of the patients' prognosis, primary diagnosis, and comorbidity. In another study of more than 400 men who were HIV positive, those with higher baseline levels of positive affect – as assessed by the CESD – had a reduced risk of mortality compared to those with lower levels of positive affect (Moskowitz, 2003). Results were robust to statistical adjustment for indicators of illness progression, as well as negative affect. The same researcher has reported similar findings for people diagnosed with diabetes. That is, in more than 700 individuals who reported having a physician-diagnosis of diabetes, those with higher levels of positive affect had a reduced risk of mortality across 10 years (Moskowitz, Epel, & Acree, 2008). However, the association was attenuated when negative affect was simultaneously included in the models.

Among individuals with stable coronary heart disease, positive affect was associated with a 13% reduced risk of death across an average of 7 years (Hoen et al., 2013). These findings held when adjusting for baseline disease severity, as well as depression. However, when health behaviors – particularly physical activity – were added to the models, the association was attenuated to non-significance. Similar findings were evident in a study of six hundred Danish individuals with ischemic heart disease. People with higher versus lower levels of positive emotions had a lower risk of all-cause mortality across as many as five years, however, that relationship was mediated by physical activity (Hoogwegt et al., 2013). In contrast, baseline positive affect was not related to mortality within 3 years in nearly six hundred Dutch patients with implantable cardioverter defibrillators (van den Broek et al., 2013).

Pathways Linking Subjective Well-Being With Morbidity and Mortality

Given subjective well-being's apparent associations with health and longevity, it is worth considering the mechanisms by which it may operate to influence morbidity and mortality. Past work has identified three primary pathways: 1) buffering against the harmful effects of stress on physiological processes, 2) directly affecting physiological processes, and 3) impacting behavioral processes (Boehm & Kubzansky, 2012; Ong, 2010; Pressman & Cohen, 2005). With regards to stress buffering, evidence suggests that subjective well-being can help ameliorate the physiological effects of stress (Fredrickson & Levenson, 1998; Papousek et al., 2010; Tugade & Fredrickson, 2004). For example, during acute stressor tasks in the laboratory, higher levels of positive emotions hasten blood pressure recovery and attenuate cortisol responses (Bostock, Hamer, Wawrzyniak, Mitchell, & Steptoe, 2011). This buffering effect may occur outside of the laboratory as well. In one study, cardiac patients with high levels of negative emotions and high levels of positive emotions did not have the same increase in mortality risk as those with high levels of negative emotions and low levels of positive emotions, which suggests that positive emotions may buffer against the detrimental effects of negative emotions (Meyer et al., 2015).

Numerous studies have also established that subjective well-being has links to underlying physiological processes that have implications for disease (Ryff et al., 2006; Steptoe, Demakakos, de Oliveira, & Wardle, 2012; Steptoe, Wardle, & Marmot, 2005). For example, in the cardiovascular domain, life satisfaction has shown protective associations with cardiometabolic markers of risk including blood pressure, lipids, glycosylated hemoglobin, waist circumference, and C-reactive protein (which is an indicator of inflammation; Boehm, Chen, Williams, Ryff, & Kubzansky, 2016). Other work has also reported that subjective well-being is associated with lower levels of inflammation (Prather, Marsland, Muldoon, & Manuck, 2007; Stellar et al., 2015; Steptoe, O'Donnell, Badrick, Kumari, & Marmot, 2008), as well as healthier heart rate variability, which indexes sympathetic and parasympathetic activation (Bhattacharyya, Whitehead, Rakhit, & Steptoe, 2008; Oveis et al., 2009; Shiota, Neufeld, Yeung, Moser, &

Perea, 2011; Wang, Lü, & Qin, 2013). Notably, most of this work has examined linear relationships between subjective well-being and biomarkers, although limited work suggests that not all relationships between subjective well-being and physiological processes may be linear in nature (Kogan, Gruber, Shallcross, Ford, & Mauss, 2013).

In the behavioral domain, accumulating evidence has also shown that subjective well-being is linked with preventive behaviors that protect against disease (Grant, Wardle, & Steptoe, 2009; Sin, Moskowitz, & Whooley, 2015; Strine, Chapman, Balluz, Moriarty, & Mokdad, 2008). Moreover, often subjective well-being precedes the healthy behavior (although healthy behavior sometimes precedes subjective well-being too, e.g., Mujcic & Oswald, 2016). For example, greater levels of subjective well-being are tied with more frequent exercise (Baruth et al., 2011; Kim, Kubzansky, Soo, & Boehm, 2017; Lathia, Sandstrom, Mascolo, & Rentfrow, 2017; Melin, Fugl-Meyer, & Fugl-Meyer, 2003; Rangul et al., 2011; Schnohr, Kristensen, Prescott, & Scharling, 2005; Schwerdtfeger, Eberhardt, Chmitorz, & Schaller, 2010), healthier diets comprised of fruits, vegetables, and whole grains (Lengyel, Tate, & Obirek Blatz, 2009; van Loon, Tijhuis, Surtees, & Ormel, 2001; Yamasaki, Nagai, & Uchida, 2007), reduced likelihood of cigarette smoking (Kaprio & Koskenvuo, 1988; Leventhal, Ramsey, Brown, LaChance, & Kahler, 2008), higher quality sleep (Lacruz et al., 2016; Ong et al., 2013; Steptoe, O'Donnell, Marmot, & Wardle, 2008), and more preventive health care visits (Kim, Kubzansky, & Smith, 2015; Kim, Park, Sun, Smith, & Peterson, 2014).

Conclusions and Future Directions

The reviewed evidence suggests that there is a consistent association between subjective well-being and both incident disease and longevity such that people with greater life satisfaction and positive emotions have healthier outcomes in adulthood. Protective effects for subjective well-being often remain when psychological distress is taken account, which indicates that subjective well-being has independent associations above and beyond those already known for distress. Furthermore, associations in initially healthy people often persist when taking into account confounders like socioeconomic status. The associations between subjective well-being and disease progression and survival in people with existing disease are not quite as consistent or strong. This group of studies tended to be more diverse with numerous different types of diseases and studies taking place at different points in the disease process. Disease severity, in particular, may be an important moderating factor because as severity increases, more powerful effects are needed to overcome entrenched disease processes and other factors such as treatment become relevant (Tay, Tan, Diener, & Gonzalez, 2013). Nonetheless, overall findings seem to indicate modest relationships between subjective well-being and disease prognosis, but these are often attenuated when statistical analyses are adjusted for covariates such as psychological distress or health behaviors. Until more empirical evidence is available with similar patient types, firm conclusions about links with subjective well-being in patient populations may not be warranted.

Relatedly, it is also important to consider the extent to which findings from both the healthy and patient populations generalize to more diverse groups of people (Diener et al., 2017). For the most part, the available evidence to date has focused predominantly on white, older adults from Westernized countries (cf. Collins et al., 2009). Although some evidence suggests that positive emotions may be important to health for people from a wide variety of countries (Pressman, Gallagher, & Lopez, 2013), future research is needed to consider the extent to which the associations described here generalize to individuals from other countries, cultural groups, ages, and generations.

In addition to considerations regarding *who* associations between subjective well-being and health may be relevant for, it is critical to consider *how* subjective well-being is measured. Because much of the work to date has relied on epidemiological cohorts in which participant burden is a concern, indicators of subjective well-being have often been single items or derived from existing depression inventories (Boehm & Kubzansky, 2012). Although such measures may be better than nothing, the time has come to move away from less reliable single items or conceptually unclear scales that were originally designed with another purpose. More purposeful selection of which subjective well-being measure to include in cohort studies will shed light on conceptual issues as well. For example, does experienced subjective well-being, as assessed via ecological momentary assessment, show stronger associations with health outcomes compared with trait assessments of subjective well-being? Does the cognitively oriented facet of life satisfaction matter more for health than the affectively oriented facet of positive emotions? Are there specific positive emotions – whether high arousal ones like excitement or low arousal ones like calm – that are especially relevant for health? To date, such comparisons have rarely been made because well-being indicators have typically been selected based on convenience. Future research is ripe for such considerations though. Moreover, moving beyond assessment of subjective well-being at a single point in time to consider changes in well-being over time may provide further insight into health processes. As noted earlier, the stability in subjective well-being across substantial periods of time may itself be an

important predictor of both physical and mental health (Boehm, Winning, et al., 2015; Gruber, Kogan, Quoidbach, & Mauss, 2013; Zaninotto et al., 2016). Another outstanding issue is under what circumstances too much subjective well-being could be bad for health. High levels of positive emotions are not adaptive in every circumstance (Gruber, 2011; Gruber, Mauss, & Tamir, 2011), so a more precise look at the exact levels that are beneficial may be warranted.

Another consideration in the association between subjective well-being and health is the size of the relationship that is reported. Although effect sizes are typically in the small to moderate range, these effects are comparable with other well-established risk factors for disease. Moreover, the determinants of coronary heart disease, diabetes, cancer, and other diseases are numerous, so any one factor (whether subjective well-being, cigarette smoking, or family history) is likely to contribute rather modestly. However, at the population level, such associations can have a measurable impact, especially if effects of subjective well-being compound over time to further strengthen effects (Abelson, 1985; Friedman & Booth-Kewley, 1987).

Although the evidence reviewed in this chapter primarily assumed that subjective well-being precedes and leads to healthier outcomes, it is also possible that poor health negatively impacts subjective well-being (Diener et al., 2017). For example, one study of older adults followed across 8 years found that self-reported health predicted life satisfaction, but that life satisfaction did not predict health (Gana et al., 2013). Although this study was limited by a subjective assessment of health, it is likely that the relationship could go in either direction or is bi-directional. Nevertheless, the prospective longitudinal studies described in this chapter provide some of the strongest possible evidence available to support the idea that subjective well-being comes before and brings about healthier outcomes. The only other stronger evidence available would be a randomized experiment; however, such designs come with their own drawbacks (Diener et al., 2017). Although perhaps not feasible over the years or decades that are usually seen in prospective designs, accumulating evidence suggests that interventions designed to improve subjective well-being are effective, at least in the short-term (Bolier et al., 2013; Weiss, Westerhof, & Bohlmeijer, 2016). Moreover, well-being interventions are being developed to impact downstream health-related outcomes for healthy individuals (Jackowska, Brown, Ronaldson, & Steptoe, 2016) and individuals diagnosed with chronic conditions (Huffman et al., 2015; Moskowitz et al., 2017; Moskowitz et al., 2012; Nikrahan, Laferton, et al., 2016; Nikrahan, Suarez, et al., 2016; Ogedegbe et al., 2012; Peterson et al., 2012; Sanjuán et al., 2016). Although future research is necessary to determine whether or not well-being interventions can translate into improved health outcomes over the long-term, a large body of evidence reviewed here indicates that among initially healthy people – and to a lesser extent in people who have already been diagnosed with a disease – robust associations exist between higher levels of subjective well-being and healthier and longer lives. As the empirical evidence continues to grow, the boundary conditions and mechanistic pathways by which such associations occur will also come into clearer focus.

Abstract

We review research indicating that higher levels of positive affect help produce better social relationships for that person and those around him or her. By better relationships we mean those that are experienced as more pleasant and less aversive, are closer and more supportive, and are long-lasting. We review longitudinal, experimental, experience-sampling, cross-cultural, and other types of evidence that suggest that not only do good relationships produce positive affect, but that positive affect can lead to them as well. We also focus on the mediators that create the association going from positive affect to sociability and high-quality relationships. Finally, we review the unknowns in this area and the types of future research still needed.

Keywords: Positive affect, subjective well-being, relationships, relationship quality

Is it self-evident that those with the most positive affect would be more socially successful? We think not. For one thing, many consider happiness to be a hedonistic endeavor, which focuses the person on pleasures, often selfish ones. In popular writing, authors such as Ehrenreich (2009) have argued that happiness can lead to problems rather than to success. Thus, we find it implausible that the causal connection we review in this paper is common knowledge, making it even more important to ensure there is a wide range of literature that supports the conclusion that successful social relationships follow from positive affect.

In the following article, we review evidence that indicates that positive feelings do not simply follow from quality social relationships, but in turn increase their likelihood. Most importantly, we point out the holes still remaining in this research area since the earlier review by Lyubomirsky, King, and Diener (2005). Positive affect includes the moods and emotions that people experience as desirable and pleasant. While people who experience more frequent positive feelings tend to have stronger and more supportive social relationships, certain types of studies are still needed to further understand when and why positive affect is beneficial to social relationships. We review the correlational, longitudinal, and experimental evidence that suggests a causal arrow moving from positive affect to quality social relationships (as first proposed by Lyubomirsky et al., 2005). We will also review the mediating mechanisms that help explain the causal connections, as well as the moderators that influence the strength of the connections. Our review focuses on positive feelings as a variable that is separable from low negative affect, and which has a causal influence that goes beyond predictions from negative feelings.

Defining Quality Social Relationships

Before we define what we mean by quality social relationships, we would like to start by introducing several theories of emotion that might predict why positive feelings may benefit social relationships. First, functional approaches to emotion hypothesize that a major function of emotion is to guide behavior, as well as reinforce behaviors through feelings of reward or punishment (Keltner & Haidt, 1999; Keltner & Kring, 1998). Positive emotions have informational value, telling the individual that the activity is worth repeating, and the pleasant feelings of the positive emotions reinforce the behaviors leading to them. Thus, positive emotions can reinforce social activities such as games and conversation, which are often rewarding, leading people to seek out these activities in the future.

A related conceptual explanation of the connection between positive affect and sociability is in terms of the approach versus avoidance motivational systems (Gable, 2006). Human beings have a fundamental need to belong, and possess a powerful motivation to form and maintain strong and stable interpersonal relationships (see Baumeister & Leary, 1995; Reis, Collins, & Berscheid, 2000 for reviews). Social relationships have the propensity to provide rewards that fulfill interpersonal needs, but also threaten punishments that leave us feeling vulnerable and hurt. As such, individuals are motivated to both approach

rewards and avoid the punishments inherently found in social relationships. Positive affect may trigger the approach system, which Gable finds is related to greater relationship satisfaction and less loneliness. The idea is that the behavioral activation system, which underlies positive feelings, should trigger approach tendencies toward others. This is supported by work by Girme, Overall, Simpson, and Fletcher (2015); they studied a New Zealand sample and found that people reported greater life satisfaction when they reported higher approach goals (r = .28 & .3), and this association was stronger for people in romantic relationships.

A third theoretical explanation for the link between positive feelings and better relationship quality is Fredrickson's broaden-and-build model (1998, 2001; Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008). Fredrickson suggests that the reason we experience positive emotions is to broaden and build our resources for the future, and one key type of resource is social support. We experience positive emotions when we have been successful and there are no imminent threats. It is in these situations that people have more freedom to build resources and skills for the future. Therefore, positive feelings allow us to form tighter bonds with others by doing rewarding activities with them, and by helping others in a way that they are likely to reciprocate in the future.

What are high-quality social relationships?

1. The relationships are pleasant and rewarding. People enjoy the relationships and do not experience chronic negative thoughts and feelings in them.
2. The relationships are close and supportive. People can rely on the other person for emotional support, physical support, and understanding. Here, we will also rely on prosocial behavior as outcomes suggesting more supportive relationships. In that prosocial behavior (e.g., donations, aid) are signs of support, we feel that these findings can stand in as proxies of interpersonal support as such tendencies would likely extend to closer relationships as well.
3. The relationships tend to be long-lasting. Relationships that last longer help build predictability and security into people's lives. Although, short-term relationships can be rewarding, they usually do not provide an ongoing basis for achieving goals and providing support and security.

Thus, these are the three characteristics of high-quality social relationships that we concentrate on in this review, and we examine how positive affect increases each of them.

Causal Analysis

Beyond simply reviewing evidence that makes it plausible that there is a causal arrow pointing from positive affect to better social relationships, we plan to also describe research still needed to establish this association. Thus, to understand how positive affect improves social relationships in the natural world, we review various methods, each providing distinct information about the causal system that could provide insight as to whether positive affect causally influences subsequent improvements in social relationships.

We examine simple correlational evidence because it can quickly reveal where associations exist and do not exist. The correlational studies reveal that there is a connection between the two variables in many different groups, including in the many nations that have been studied so far. These data indicate the ubiquity of the association between the two variables. However, it is important to note that correlational research does not on its own indicate causation.

We also describe longitudinal research where we can examine whether a possible cause precedes a hypothesized outcome and whether a change in a causal variable over time precedes a change in the outcome. Although longitudinal studies do not have the same internal validity as formal experiments in terms of inferring causality, more external validity is usually present because longitudinal methods help establish not just that X can cause Y, but that it actually seems to do so in everyday settings where there are a host of interacting forces. Short-term longitudinal studies such as those using the experience-sampling method help to establish whether two variables move up and down together in short time periods. Long-term longitudinal research reveals the development of the connection over time—its dynamic unfolding.

Formal experiments can manipulate both short-term positive moods and enhance long-term positive affect and examine the short and long-term effects, respectively, on improvements in social relationships. Experiments are thus seen as the strongest evidence of causality due to high internal validity. Experimentation has limitations, despite its internal validity, that the other methodologies can complement with their strengths. For example, experiments usually are relatively low on external validity, and are focused on relatively small samples of participants. Furthermore, experimental manipulations are often not "clean," in the sense that factors are often manipulated beside the concept intended. For example, mood manipulations frequently include social content in the induction. Thus, the researcher cannot be certain that the outcomes are due to the positive affect aspect of the manipulation *per se* or to the priming of social cognitions. In addition, laboratory experiments are subject to biases such as demand characteristics.

Finally, experiments must be so carefully focused on controlling the context of the situation that we often gain little insight into the conditions that must be in place for the causal connection to occur. Fortunately, the other methods, although possessing less internal validity, tend to not have the same limitations, and thus are likely to expand understanding beyond that provided from experimentation. Taken together, these methodologies can indicate causal direction and help us understand how the dynamic system functions. Thus, when considering the link between positive affect (PA) and positive social outcomes, it is important to determine the types of studies that are lacking, as the conclusion that positive affect leads to better relationships requires comprehensive evidence.

Beyond these methodologies, scientific understanding of causality also requires understanding of mediators and moderators. The mediators explain the processes that link X to Y, and the moderators place boundaries on the causal sequence. Establishing the moderators allows us to know when the causal sequence will be stronger and weaker, and when it does not occur at all. In sum, several approaches are needed in understanding causal influences in the dynamic networks that psychologists study, such as positive mood causing sociability and social success.

Positive Affect is Linked to Positive and Rewarding Relationships

We first look at research showing how positive affect is linked to what we offered as our first definition of quality relationships, that they be positive and rewarding.

Correlational research. Based on environmental and genetic influences, sociability has been found to correlate with positive emotionality (Eid, Riemann, Angeitner, & Borkenau, 2003; *r's* = .27 to .57). In one study, participants filled out daily reports for six weeks, which were then averaged across days. While extraversion and positive affect were found to be separable, they were highly related (r = .380). These results cannot be attributed to self-report biases, as observer reports were also used to assess the variables (*r's* = .293 to .577) (Fujita, 1991).

Correlational research also supports that positive affect is linked to more rewarding relationships. One study found that extraversion (which is highly related to PA; Fujita, 1991) was associated with making more friends (Feiler & Kleinbaum, 2015; r = .34). However, no correlational research appears to directly link positive affect and the propensity to make friends. Moreover, it has been found that those with high PA are liked more by others. This may be due to the fact that they are judged as more rewarding to spend time with (Harker & Keltner, 2001; r = .70). Diener and Seligman (2002) studied the happiest 10% of students and found that they experienced better romantic relationships (η^2 = .24 to .44). In this study, happiness was determined by examining satisfaction with life, global self-reported affect, informant affect balance, and daily affect balance over 51 days. Affect balance refers to the prevalence of positive affect over negative affect and is used to define "happiness" (Diener, 1984). Thus, because of the important role PA plays in affect balance, here and at other times, we refer to results addressing affect balance because they are important leads and point to a need for additional research, especially when affect balance is the only measure currently available (i.e., little or no evidence in terms specifically of positive affect). Those who experience greater positive feelings also exchange more often during negotiations (Lawler, Thye, & Yoon, 2000; β = .58), suggesting that when people interact with those who have higher levels of positive affect, they can expect more favorable outcomes. Individuals higher in PA can be expected to have more friends, to be rated more positively by others, and to report more positive interactions.

Another correlational finding that can be explored in terms of PA is its relation to sex. While measures of subjective well-being are strongly correlated with frequency of sexual activity (Blanchflower & Oswald, 2004, p. 402; "a large effect"), to the best of our knowledge, this has not been explored a great deal in terms of its relationship to positive affect. For example, Muise, Schimmack, and Impett (2015) did find that there were curvilinear associations of sexual frequency with PA; specifically, having sex once a week was associated with greater happiness, especially for those currently in romantic/married relationships. However, no additional effect was found for people having sex more than once a week (β = .09 & .35). Thus, while there is minimal research on the association, work suggests PA is positively related to sexual activity.

The specific social skills and traits exhibited by those with high or low PA also needs to be studied in further detail. Depression is highly relevant in this regard, where a key feature of depression is low positive affect (Watson, Clark, & Carey, 1988; *r's* = -.41 to -.37), not simply high negative affect. For example, in a review, depression was associated with a variety of poor social skills (Segrin, 2000) in areas such as paralinguistic behaviors, speech content, posture and gestures, etc. Specifically, the review indicated that the depressed are more verbally aggressive and discuss more negative verbal content. Moreover, low positive affect is accompanied with feeling unsociable, being bored, as well as lacking in energy (Diener, Kanazawa, Suh, & Oishi, 2015), which might detract from maintaining good relationships and engaging in social interactions. Interestingly, anhedonia (i.e., diminished interest/pleasure in response

to previously rewarding stimuli) is a symptom of depression (Feighner et al., 1972). Anhedonia has itself been linked to social impairment, and the association between anhedonia and social impairment was partially mediated by poorer attentional control, such that deficits in the ability to engage in self-regulation negatively impacted social functioning and social relationships (Tully, Lincoln, & Hooker, 2014; r = .66). Thus, it is possible that less happy people are generally less skilled at maintaining social relationships. Anhedonia has also shown to be associated with lower than normal positivity offset (i.e., mild positive moods when no strong emotional events occur; Strauss, Visser, Lee & Gold, 2017). This might be particularly relevant because prior research has suggested that the positivity offset is beneficial for social relationships (Diener et al., 2015). However, the research on why low positive affect *specifically* is associated with poor social outcomes is still in the preliminary stages, and these effects need to be specified in future research.

Long-term longitudinal data. Studies show that over time, those with higher levels of positive affect have relationships that are more rewarding. One study suggests that positive affect may be able to compensate for low social skills in marriages. For those with low social skills and low PA, the decline in satisfaction is approximately 20+ points over 4 years, but with high PA, this decline is reduced to approximately 10+ points over 4 years (Johnson et al., 2005, p. 23). While the influence of marriage on PA has not been studied, this has been examined for life satisfaction, which we will use here as a proxy as they are closely related (e.g., Lucas, Diener, & Suh, 1996; *r's* = .28 to .52). A meta-analysis indicated that getting married is initially positive for life satisfaction (b_0 = .26), though on average it tends to return toward baseline levels over time (Luhmann, Hoffman, Eid, & Lucas, 2012). While one might expect PA to show a similar course, it would be prudent to study this directly and see how positive affect specifically rises or falls after marriage.

Experience sampling longitudinal data. Experience sampling indicates that positive moods are related to more interactions with others and feeling more sociable. PA/extraversion is related to the frequency (β = .34 & .23) and pleasantness of interactions (β = .32), even after controlling for the related variables of negative affect-neuroticism, openness to experience, conscientiousness, and agreeableness (Berry & Hansen, 1996). As mentioned earlier, correlational research shows that when people are in a naturally occurring positive mood, they also feel more sociable and this result is replicated in longitudinal experience sampling data as well (Diener et al., 2015). Feeling sociable is associated with positive affect over time within individuals. The authors signaled 42 respondents at random moments twice a day for 42 days. In a reanalysis of these data, they found the mean within-persons correlation was r = .48 between positive affect and feeling sociable. Importantly, this correlation was significant and positive for 41 of the 42 respondents (see Diener & Larsen, 1984, for a description of this data set). A similar relationship was found between-subjects (r = .39).

What the experience sampling studies indicate is that not only do trait levels of positive affect lead to sociability, momentary state levels of positive affect are also associated with feeling sociable. They also reveal that this association is found within most individuals. The within-subject data are important in revealing the effects of momentary mood, but are also pivotal in terms of indicating that the findings in this field are not just due to between-persons response styles.

Experimental—short-term moods. Experimental studies indicate that inducing positive moods in the laboratory can also lead to greater sociability and better social skills. A positive mood induction led people to feel more social (η_p^2 = .07 & .10) and prefer social situations (η_p^2 = .04 & .06) (Whelan & Zelenski, 2012). Those put in a positive mood also showed greater interest in social activities compared to those in a neutral mood (Cunningham, 1988a) as well as those in a depressed mood (Cunningham, Shaffer, Barbee, Wolff, & Kelley, 1990; r = .23). Interactions also appear to proceed more favorably when one is in a positive mood. Inducing positive moods in child psychiatric patients led them to show better social skills compared to those in the neutral condition (Kazdin, Esveldt-Dawson, & Matson, 1982). Another relevant finding is that the implementation of a positive musical mood induction led to both objectively and subjectively greater sexual responses compared to baseline and negative mood inductions (Mitchell, DiBartolo, Brown, & Barlow, 1998). Studies focused on positive mood inductions indicate that positive moods lead individuals to feel more social, exhibit better social skills, and experience greater sexual arousal.

Experimental—inductions that alter long-term PA. Experimental research has also found that manipulating a change in long-term positive affect can lead to lasting interpersonal changes, contributing to more pleasant and rewarding relationships. Loving-kindness meditation is intended to improve relations with others and increase warmth and caring for the self. In one study, those assigned to the loving-kindness meditation condition became more positive (i.e., calm, happy, loving; η_p^2 = .12) and less negative (i.e.,

angry, anxious, unhappy; η_p^2 = .04). Those in the loving-kindness meditation condition also experienced increased positivity toward others (η_p^2 = .03) (Hutcherson, Seppala, & Gross, 2008). Other studies, such as Fredrickson, Cohn, Coffey, Pek, and Finkel (2008), indicate that we can expect these effects to last at least up to nine weeks. In Fredrickson et al. (2008), loving-kindness meditation increased daily positive emotions. These positive emotions were in turn linked to increases in personal resources, such as positive relations with others. Overall, it was concluded that the increase in personal resources led people to become more satisfied with their lives.

A study by Kemeny et al. (2012) also found long-term social benefits as the result of a meditation intervention. The researchers used a meditation and emotion regulation training intervention to determine how it influenced participants emotionally and socially. The intervention incorporated concentration practices, mindfulness practices, and attempted to promote empathy and compassion and the understanding of the features of emotions and their consequences in one's self and others. Female schoolteachers were randomly assigned to a training group or a control group. Those who received training reported feeling less negative emotion (r = -.51), less depression (d = .81), and increases in positive affect and mindfulness (r = .37) compared to the control group. This was still true five months after the training (e.g., depression: d = .90). Those who received training showed greater feelings of compassion, better recognition of others' emotions, and when asked to discuss an upsetting issue with their significant other, they were less hostile during that interaction. This indicates that the intervention helped create closer and more supportive relationships.

One issue with mindfulness interventions is that social feelings tend to be included in the treatment. Thus, it is difficult to determine from these studies alone whether positive feelings alone will lead to improvement in relationships. However, the studies reviewed above have seen encouraging and lasting results. Though additional work is needed, the existing studies suggest that long-term changes in SWB also lead to better relationships and that those benefits persist over time.

Positive Affect is Linked to Closer, Supportive Relationships

We next look at research showing how positive affect is linked to what we offered as our second definition of quality relationships, that they would show evidence of being closer as well as being more supportive.

Correlational research. Relationships with those who have higher positive affect appear to be closer, characterized by holding relational values, experiencing greater liking, and having more meaningful conversations. Positive affect is correlated with having social values, such as placing importance on intimacy and social approval (Kunzmann, Stange, & Jordan, 2005; r = .27). Positive affect is also positively associated with friendship, assessed by measuring "liking" for a close friend (Cheng & Furnham, 2002; r = .31). Happiness, assessed with an affect balance score, is negatively related to discrepancies between ideal and actual best friendships (Demir & Orthel, 2011; r = -.21), indicating that happier individuals are more likely to experience the quality of friendships that they desire. In a study of call center employees, greater verbal fluency during calls (i.e., minimal pausing, fumbling, or use of fillers) was positively associated with their own positive affect after the call (Rothbard & Wilk, 2011), suggesting that higher positive affect is associated with better conversations. Gable, Reis, Impett, and Asher (2004) found that when people shared their positive events with each other, they experienced higher positive affect. Another study by Gable, Gonzaga, and Strachman (2006) established that in discussing positive events together, a phenomenon called "capitalization", couples rated their partners as more responsive when they also perceived that their partner was more excited by the event that they were discussing (r = .41 & .31). Thus, the display of positive emotions during conversation may make one appear more responsive.

Additional correlational evidence indicates that those with higher PA also experience more supportive relationships. George (1991) found in the workplace that positive mood was linked to helpful behavior, both for actions included (i.e., customer service; r = .26) and not included (i.e., altruism; r = .24) in one's job. However, the study did find that trait positive affect was not correlated with those behaviors. One possible reason for this finding may be evident in a study by Organ and Ryan (1995). They found that, in a review of 55 studies, self-ratings (vs. ratings by others) are associated with higher correlations within the organizational citizenship behavior literature (r = .14). This could be relevant as George (1991) used supervisor ratings of tendency toward behaviors. Additionally, Siedlecki, Salthouse, Oishi, and Jeswani (2013) found that provided support predicts positive affect (β = .13). Though PA was not linked to other types of social support in this study (i.e., enacted or perceived), other aspects of subjective well-being such as life satisfaction were (β = .13 & .18). In this study, enacted support constituted emotional, tangible, and informational support received from others, yet these individual types of support could also be examined separately for their relations to positive affect. This appears to be a fairly unexplored area, and much

research could still be conducted on how positive affect is correlated with specific types of support.

Long-term longitudinal research. Another sign of closeness in relationships is the experience of certain important life events, such as having children, getting separated, or getting divorced. While this has not been studied specifically in regard to PA, those with higher life satisfaction also have a greater likelihood of having children (OR: 1.05 - 1.37 to 1) and a lower likelihood of becoming separated (OR: .58 - .85 to 1), controlling for socioeconomic status (SES) and personality (Luhmann, Lucas, Eid, & Diener, 2013). Positive affect still needs to be studied long term in order to determine how it relates to the major events experienced in close relationships.

Other longitudinal work found PA was linked to less loneliness, stronger friendships, and a decreased likelihood to interact with deviant peers, all factors suggesting the presence of greater available support. Kansky, Allen, and Diener (2016) conducted a longitudinal study of individuals from early adolescence (age 14) to young adulthood (age 25), using a measure of positive affect at Time 1 to predict social outcomes at Time 2. Early positive affect predicted mean levels of later loneliness (r = -.29) and sociability (r = .30), as well as desirable changes in these over time. Data gathered from friends, a parent, and the romantic partner supported these predictions. Friend reports of attachment (r = .17), as well as improvements in this over time, were predicted by positive affect at Time 1. The father's reports of low association with deviant peers (r = -.38), as well as decreases in this across time, were predicted by levels of positive affect at age 14. Kansky et al. (2016) controlled a major potential third-variable explanation of the findings, family income, in all their analyses. Thus, this study provides evidence that the effects of positive affect on later quality social relationships emerges early in life, is confirmed by data beyond self-report, and is not due to family resources such as income that might influence both affect and relationships.

Longitudinal research also supports the association between PA and prosocial behavior. Positive affect in Korean teens predicted greater prosocial attitudes and behavior months later, even after controlling for baseline prosociality (Shin, Choi, Suh, & Koo, 2013). Thoits and Hewitt (2001) found that those more satisfied with their lives reported spending more hours volunteering when interviewed three years later. However, to the best of our knowledge, the examination of PA long-term and its relation to prosocial behavior is very rare. This appears to be an area left largely unexplored. This tendency toward helpful behavior in general should have positive effects on one's relationships with others as it indicates an overall greater willingness to provide support. Research suggests that PA should continue to be associated with prosocial actions over longer periods of time.

Experience sampling longitudinal data. Positive moods are also associated with spending more time with others. Specifically, positive moods over time are strongly correlated with time spent in fun/active (i.e., joking with friends; r = .23) and necessary/informational types of social interactions (i.e., meeting the job supervisor; r = .13), controlling for the dependency in measurement over time (Vittengl & Holt, 1998).

Other work finds a link between happiness and greater empathy toward others. An interesting study by Strayer (1980) consisted of preschool children being observed for eight weeks. Children showing happy displays (versus sad, angry or hurt) were more likely to give empathic responses to others (r = .59). This is something that should also be examined for positive mood more specifically. Such research could examine whether this is an association that exists even at a young age. It could be that experiencing positive moods more frequently as children helps establish one's first friendships, and this could lead to more experience or greater ease at socializing when one is older. This potentially greater ability to experience empathy may also help people better support others.

Experimental—short-term moods. Positive mood inductions also lead people in the laboratory to act closer, engaging in more self-disclosure, and more supportively, such as feeling more interested in prosocial activities and being more cooperative. In regards to discourse, males in a positive mood communicate and self-disclose more to females than those in a negative mood (Cunningham, 1988b; *r's* = .27 to .37). Individuals show greater interest in prosocial activities compared to those in a neutral mood (Cunningham, 1988a). Inducing positive moods in the laboratory has been linked to more helpful behavior (Aknin, Dunn, & Norton, 2012). Those in an elation condition versus a depression condition are more likely to volunteer for a future unpleasant task (Aderman, 1972). Children induced to feel a positive mood, by thinking of happy experiences, donate more money to other children than those in the control or sad conditions (Rosenhan, Underwood, & Moore, 1974). Once again, prosocial behavior as a way of providing support and help to others can be a method of fostering social bonds and increasing closeness in relationships. Thus, we use prosocial outcomes here as a proxy for support in relationships. Another finding is that participants induced with positive moods are more cooperative, using less contentious bargaining strategies (e.g., Carnevale & Isen, 1986). Thus, we see that manipulating positive mood in the lab has been found to cause greater self-disclosure, as well as more prosocial behavior and cooperation.

Experimental—inductions that alter long-term PA. Most of the long-term experimental emotion interventions focus on alleviating depression rather than directly on raising PA in normal populations. Research suggests these interventions can make relationships closer and more supportive. Treatment for depression has been associated with significant increases in one's perceived social support (η^2= .27), utilized social support (η^2= .27), and satisfaction with support (η^2= .09) (Mohr, Classen, & Barrera, 2004), where changes in social support were fully explained by changes in depression. Those in complete remission for depression show less social functioning impairment compared to those in partial remission (Romera et al., 2010). Additionally, Whisman (2001) found improvements in marital adjustment after individuals were treated for depression (η^2= .55), and this change was mediated by changes in depression. Prior research has established that positive affect rises when patients are treated for depression, but only when those patients show a significant decline in depression over time (Kring, Persons, & Thomas, 2007). Overall, research shows that the treatment of depression is linked to better social outcomes over time.

Positive Affect is Linked to Long-Lasting Relationships

Finally, we look at research showing how positive affect is linked to what we offered as our final definition of quality relationships in terms of relationship stability. That our review showed that there was a lack of correlational or experimental evidence should not be surprising, as longitudinal data would be the gold standard in examining the link between positive affect and relationship stability.

Long-term longitudinal research. From the perspective of longitudinal research, those with higher positive affect appear to be in longer lasting relationships. For example, positive expressions in photos predicted future favorable marital outcomes (Hertenstein, Hansel, Butts, & Hile, 2009: *r's* = -.10 to -.28; Seder & Oishi, 2012: *r's* = .25 to .44; see Freese, Meland, & Irwin, 2007 for a non-replication). Similarly, Harker and Keltner (2001) found evidence that more positive facial expressions in photographs predicted better marital outcomes up to 30 years later (r = .20), which was little changed when controlling for physical attractiveness (r = .16) or social desirability (r = .18). While research on subjective well-being has linked it to a greater likelihood of getting married (Marks & Fleming, 1999; OR: 1.5 to 1), this has not yet been studied for the specific construct of positive affect. Thus, while we cannot yet say this conclusively, it is likely married people have higher PA because these individuals are also more likely to get married.

Mediators Established

How do those with greater positive affect experience better relationships? Understanding the mediators of an association between two variables is essential to scientific understanding—what are the processes connecting the cause to the effect? For example, if those with higher PA have better marriages, why is this so? Do they tend to overlook the faults of their partner, do they have more fun with their partner, or do they spend more time with their partner? In order to fully understand causal connections, we need to establish the processes that mediate this connection. For the effects of positive affect on the quality of social relationships, researchers have uncovered a number of mediators.

Sociability

Several studies point to the fact that positive affect is tied to both feeling more motivated to socialize and to actually engaging in more social behavior. It may be this propensity toward sociability which helps drive positive interpersonal outcomes. In a study examining reports of affect balance, those with higher levels of subjective well-being were more social (Diener & Seligman, 2002; η^2'*s* = .24 to .44). Positive affect is linked to more time engaging in social activities (r = .19) and with friends (r = .18) (Lucas, Le, & Dyrenforth, 2008). A lack of positive affect is associated with feeling unsociable (Watson et al., 1995; r = .19). As indicated before, extraversion is correlated with PA (Fujita, 1991). Thus, it makes sense that research indicates that introversion is correlated with feeling less positive affect (partial η^2 = .05) *and* holding less positive attitudes (partial η^2= .04) about an imagined group discussion (Besner, 2009). Positive affect appears to be linked to feeling more sociable, as well acting on those feelings by actually being more social. As a result of these interactions going well, people may come to expect good outcomes in future interactions. This is supported by a study on customer service. This study found that in salespeople, extraversion (r = .194) and conscientiousness (r = .111) predicted better sales performance, which appeared to be because those individuals also had higher self-efficacy. This then made them more motivated to interact with customers and to have favorable interactions (Yang, Kim, & McFarland, 2011). This area of research could be strengthened by relying less on a related measure (i.e., extraversion) and focusing on positive affect and its direct links to feeling or acting sociable.

It is More Rewarding to Interact with High Positive Affect Individuals

Not only are those with higher PA more sociable, but a number of studies also suggest that their

social interactions are actually more rewarding for them and their partners, which may be another factor causing better relationship quality. Others are more satisfied when interacting with those with higher PA, which may be because they too end up experiencing more positive emotions as a result of those interactions. Individuals who exhibit more positive emotions are viewed as more attractive social partners (as opposed to emotional downers). They are more popular and well liked (see review by Diener & Tay, 2012). The strength of employees' smiles has been found to be positively associated with customers' satisfaction with their interactions (Barger & Grandey, 2006; $r = .20$). Chi, Chung, and Tsai (2011) found that leaders' positive moods were related to better team performance ($r's = .31$ to .38), and emotional contagion was one of the factors mediating this relationship. Thus, spending time with more positive individuals is likely to make a person more positive too. In a longitudinal study, Fowler and Christakis (2008) found that individuals with higher levels of subjective well-being in a social network were arranged in clusters, and this appeared to be due to SWB spreading throughout the network. For example, "a person was 15.3% more likely to be happy if a directly connected alter was happy" (p. 5). For both a short-term positive mood and more long-term positive affect, PA appears to be contagious. Others will find it rewarding to be around those with high PA because they will also end up experiencing more positive affect.

Cooperation and Prosociality

It may also be that those with higher PA are more cooperative and engage in more prosocial behavior and that it is this greater generosity and helpfulness that leads to their interpersonal success. In a longitudinal study from age 14 to age 25, Kansky, Allen, and Diener (2016) found that positive affect in early adolescence predicted lower levels of conflict in relationships in young adulthood ($r = -.27$), as well as a greater decrease in conflict over the intervening years. These trends were supported both by self-report measures and by partner-report assessment ($r = -.25$). Several studies indicate that positive affect reduces the tendency to use contentious strategies when bargaining (Barsade, 2002: $r's = -.11$ to .39; Baron, Rea, & Daniels, 1992; Baron, 1990: $\omega^2 = .02$; Carnevale & Isen, 1986). Specifically, those in a positive mood condition made more concessions in negotiations (e.g., Carnevale, 2007). Even at a young age PA appears to be linked to more cooperative behavior that persists over time, and extensive negotiations research supports this finding. There are many articles indicating PA is linked to more cooperation in negotiations, but future researchers should move beyond this area and explore links to cooperative behavior in other types of social situations.

In general, these individuals also tend to feel more prosocial (Carlson, Charlin, & Miller, 1988: Mean effect size = .54; George, 1991: $r = .24$; Priller & Schupp, 2011: 1-2% more frequent donations). In an experimental study, those placed in an elated mood were more likely than those in a neutral mood to help with both high-interest and low-interest tasks. This was true when they simply offered to help someone else who was volunteering on his or her own and when that person encouraged participants to assist (Cunningham, Shaffer, Barbee, Wolff, & Kelley, 1990). In the workplace, George (1991) found that positive mood was positively associated with helpful behavior, both for behaviors related ($r = .26$) and not related to one's job ($r = .24$). Thus, the finding that PA is linked to prosocial behaviors is not only true in the laboratory, but also in a work setting. This tendency to provide help and support is not limited to only fun or interesting tasks, nor does it appear to only be the result of outside pressure.

Empathy, Compassion, and Perspective Taking

Positive affect is related to feeling interested, caring, and in harmony with others (Diener et al., 2015). Yet another possibility is that the ability of PA to enhance a person's compassion for others may be a factor that benefits them in their relationships. An experimental study found that being in a positive mood helps people show greater compassion, perspective taking, and sympathy for someone in distress (Nelson, 2009). Induced positive affect increases the likelihood that one will mirror the actions of another person (Kuhbandner, Pekrun, & Maier, 2010; $d = .64$). Positive affect then not only makes us feel more interested and invested in others, it also helps us take on their perspective, feeling greater sympathy for them and unconsciously mimicking them in a potential effort to facilitate this desire. However, research is still needed in this area. Other than self-reporting that they feel more compassionate (e.g., Nelson, 2009), it also needs to be determined whether people actually act in a more compassionate manner. In addition to mimicking others (e.g., Kuhbandner et al., 2010), taking a more situational perspective (versus dispositional) when viewing another's behavior, or assessing if another's emotional reaction was appropriate (e.g., Nelson, 2009), we need to investigate in what other ways people with higher levels of positive affect attempt to take on others' perspectives. Some research has found that individuals with compassionate goals want to be more supportive ($r's = .23$ to .56) as they have goals to contribute to others' well-being (Crocker & Canevello, 2008). Perhaps future researchers could explore this avenue: do those with higher levels of positive affect show evidence of wanting to contribute to others' well-being? For

example, do they report this as a goal or work toward this goal? This could be another way to assess compassion.

Trust and Respect

Other work suggests that PA is tied to the values of trust and respect. Perhaps a focus on these key qualities helps relationships thrive. In the Gallup World Poll we found a positive association between positive affect and both trusting others (r = .06) and feeling respected (r = .36), both at the individual and national levels. Across cultural regions positive emotions are associated with social and respect needs (Tay & Diener, 2011). PA is linked to being more trustful and feeling and desiring respect. There may be something about these qualities that leads to better interactions. Perhaps the need for respect or feeling respected is also linked to showing others more respect. In that case, it would be clear as to why PA is linked to better relationships: because those with higher levels of positive affect treat people with more respect and are more trusting. However, a direct link between PA and treating others with more respect will need to be established. PA also appears to be linked to giving one's trust wisely. Researchers have found that being in a positive mood helps us adjust our level of trust in another person in response to corresponding cues (Lount, 2010; d = 1.21). Thus, this does not appear to be a tendency toward reckless trust. Replications should be conducted to further establish trust as a mediator though.

More Substantive Interactions

Higher PA is also associated with a higher quality of interactions when meeting others. Those with higher trait positive affect experience better interaction quality during first meetings (Berry & Hansen, 1996: *r's* = .27 to .38). More specifically, over time positive emotionality has been found to broaden our feelings of self-other overlap within new relationships (Waugh & Fredrickson, 2006; r = .21 & .27). These studies suggest PA is associated with a higher quality of interactions in new relationships. More work should be conducted on this topic, but it is possible that PA provides a boost when forming relationships that could have long-term positive consequences.

Beyond initial first encounters, other research points to a promising area to further explore: PA and substantive interactions. Research links PA to deeper conversations and positive relationship goals. A study examining satisfaction with life found that those more satisfied spend less time alone (r = -.36), talk to others more (r = .31), and have more meaningful conversations (r = .26) (Mehl, Vazire, Holleran, & Clark, 2010). Determining that this is also true for positive affect would lead to stronger evidence that PA leads to better relationships due to its influence on more meaningful interactions. Another way to assess deeper interactions may be to examine one's relationship goals. Referring back to Crocker and Canevello (2008), they found that those with compassionate goals wanted to be more supportive of others. Perhaps by measuring the goals those with PA have for their relationships (or that their friends/partners have for them), we could examine another way in which those with high positive affect may be experiencing more meaningful relationships and interactions. For example, if those with higher levels of positive affect are more likely to have compassionate goals for their relationships than those with lower positive affect, this would be additional evidence of their more substantive interactions.

Accurate Self and Person Perception

Those with greater levels of positive affect may also be better understood by others, which likely enhances their social interactions. Research by Human and Biesanz examined the "well-adjusted" who are identified using measures of self-esteem, satisfaction with life, positive relations with others, depression, etc. The well-adjusted are more "judgeable" by others (Human & Biesanz, 2011a: *r's* = .09 to .77), probably because they act more genuinely (Human, Biesanz, Finseth, Pierce, & Le, 2014: d = .59). The well-adjusted also accurately understand what other people are typically like (Human & Biesanz, 2011b: *d's* = -.72 to .58). While not directly focused on measures of positive affect, this does point to one possibility as to how those with higher levels of PA experience better social relationships—by being more readable and by more easily reading others. Initial research supports this, where a sad mood induction caused participants to exhibit significantly lower accuracy in social judgments compared to those in the happy or control group (Ambady & Gray, 2002; r = -.42). Future studies should be conducted to further confirm that positive affect makes one a more accurate judge and to explore whether PA makes one more judgeable.

Coping: A Buffer Against Stress

Positive affect may help people create a reserve of rewarding times or experiences with others, which they can draw upon to serve as a buffer during negative times, protecting their relationships from the negative consequences of stress. For example, Gottman (1994) found that in stable marriages, couples have more positive interactions when trying to resolve conflicts. Their ratio of positive to negative interactions was 5 to 1, in comparison to a ratio of .8 to 1 in unstable marriages. The ability to create more positive

moments, even during a conflict, could be one of the ways that positive affect helps people buffer their relationships from the ill effects of stress, but this has not yet been thoroughly tested. This is a particularly interesting area for future research though as we also know that visible emotional support can be helpful for individuals who are highly distressed, but costly for nondistressed recipients (Girme, Overall, & Simpson, 2013). Thus, the creation of these positive moments to help create a buffer against future stress will likely have limitations or may need to be initiated in certain ways so as not to be detrimental to the relationship instead. Another promising line or research regarding this has focused on shared leisure time. Couples were interviewed prior to becoming parents and then were followed up with afterwards. It was found that when wives and husbands reported more shared leisure time prenatally, they experienced more love one year later (Claxton & Perry-Jenkins, 2008). It may be that shared leisure time is one way in which couples build positive moments.

The broaden-and-build theory created by Fredrickson (1998) proposes that positive emotions, such as interest, contentment, and joy, help broaden our thoughts and behavior. Specifically, in a social context, we exchange social smiles, engage in social play, and are more likely to help others. In this way positive emotions help us accumulate lasting social resources. Other research links better social support to more effective coping as well. For example, when people feel they do not have others with whom to share their thoughts and feelings, it can lead to distress, such as rumination and intrusive thoughts (Lepore, 2001). At times, people may also feel that there are *limits* to what they can share about their stress with others. These feelings are also associated with greater distress and poorer adjustment (e.g., Lepore & Helgeson, 1998; β = -.14 & -.18). Furthermore, poor coping is linked to social interactions that are briefer, including the tendency of others to distance themselves from the person in need (Silver, Wortman, & Crofton, 1990). Thus, while this should be more directly examined, it appears that positive affect is likely associated with a greater reservoir of social resources; these resources may help buffer them from the negative effects of stress, allowing their relationships to remain stable.

Mediator Conclusions

Not all of the above mediators contribute to all three of the qualities of a good relationship that were listed previously: pleasant and rewarding, closer and more supportive, and long-lasting. Studies should be conducted that directly test the proposed mediators and to which of the three outcomes they contribute. On the one hand, if a person with high PA is also more sociable, does that sociability lead to a more rewarding relationship? On the other hand, being more sociable may be less likely to contribute to a long-lasting relationship. All of these avenues should be directly explored in future research.

The Need for Moderators Research

Moderators tell us when a causal sequence does and does not occur. Moderators also describe when the relation is stronger or weaker. Understanding the moderators of causal connections is essential to scientific understanding, as these boundaries are needed for complete understanding. Not only do we want to know, as laboratory experimentation can show, that a causal connection can occur, but whether it actually does so in everyday life, and under what conditions. To draw an analogy from medicine, it is not enough to know that a bacterium can make people sick, but that it does so in everyday life, and under what conditions. For example, the bacterium Clostridium difficile can lead to severe gastrointestinal symptoms and even death, but tends to do so primarily when a person's natural gastrointestinal bacteria have been depleted by antibiotics. To understand and control this infection, one must understand the conditions in which the disease-causing bacteria can thrive. Fecal transplants that reintroduces healthy bacteria have thus been much more effective in curing c. difficile than antibiotic treatments. It is not enough to simply know that one factor can cause another; it is also essential to know when and why it does so in the natural world.

While there is evidence that some of the links exist across an array of cultures, a few studies point to possible limitations to the relationship between subjective well-being and social outcomes. Forgas (2007) found that those in a negative mood actually created better, more effective persuasive interpersonal messages (β*'s* = .288 to .401). Tan and Forgas (2010) also established that positive moods led to more selfish distribution of resources in a game, which may be due to a possible increase in internal focus. Casciaro, Carley, and Krackhardt (1999) found that while positive affect improved accuracy when assessing one's friendship network structure (r = .21), it hindered accuracy in terms of perceiving one's local ties (r = .02), in that they had more unrealistic assessments of those ties. These studies suggest that positive moods may not always lead to more cooperation and prosocial behavior, though the specific reasons for these findings are not yet clear. It also indicates that the benefits of a positive mood may not extend to persuasive communication and that trait positive affect may lead to unrealistic assessments of one's personal ties. Thus, it is clear that negative emotions can help relationships in some cases and positive moods are not invariably beneficial. Thus, we need more systematic research on the circumstances and activities where positive versus negative moods will be most beneficial.

Lucas, Diener, Grob, Suh, and Shao (2000) found that although extraversion and positive affect were related across cultures of the world, this association was stronger in some cultures. Specifically, the correlation between extraversion and positive affect was weaker in collectivist nations (r = .59 vs. .77). Related to this, Fulmer et al. (2010) found that extraverts reported higher life satisfaction if living in an extraverted versus introverted culture (R^2 = 3.30%).

Another interesting moderator may involve the manner in which one seeks subjective well-being. Materialism, or the pursuit of happiness/success based on acquisition of social status and goods, is linked to a decreased desire for interpersonal relationships, including negative attitudes toward marriage and children (Li, Lim, Tsai, & O, 2015: β *'s* = -.26 to -.27). Thus, it may be that when one's positive affect is tied to certain sources, the link between positive affect and good interpersonal outcomes will not occur.

It is also possible that the link between positive affect and good relationship outcomes could be more complicated depending on the attachment style of the person with whom you are interacting. For example, avoidantly attached individuals exhibit negative responses to low or moderate levels of practical support, but they exhibit positive responses to high levels of practical support, showing a curvilinear effect (Girme et al., 2015: r = -.12).

Finally, partner aggression may play a part as well. Arriaga, Capezza, Goodfriend, Rayl and Sands (2013) found that individuals see themselves as being less happy if they were to leave their aggressive relationship. However, they are actually happier compared to their forecast when they finally do exit the aggressive relationship. It could be the case that if positive affect keeps individuals in aggressive relationships, then partner aggression may also eliminate the association we have typically observed between positive affect and relationships.

However, much more research needs to be conducted to clarify the above findings so that we understand when positive affect does not enhance relationships.

Causal Conclusions

An earlier review on subjective well-being and success by Lyubomirsky, King, and Diener (2005) focused on the link between SWB and relational success. This review provided initial evidence (cross-sectional, longitudinal, experimental, etc.) that the causal arrow appeared to go both ways. After examining a greater body of research, the current review focused on positive affect supports their initial conclusion.

So far, the literature indicates that positive affect does not just result from good relationships but can also cause them. The most powerful evidence comes from experimental and longitudinal research, which shows that manipulating subjective well-being in the lab can influence social outcomes and that the naturally occurring association is evident over time, with positive feelings at Time 1 predicting better relationships at Time 2, often controlling for Time 1 relationships (e.g., Kansky et al., 2016). Not only do positive emotions predict better quality social relationships, but they can, at least in some cases, predict relationships that improve over time. Long-term research indicates that often both state and trait positive affect are linked to better relationship outcomes over time. For example, positive moods from moment to moment are linked to more pleasant interactions, and trait PA is also linked to better marital outcomes. The experimental literature also makes a strong case for a link between positive affect and better social relationships. It has been found that inducing a positive mood in the laboratory can positively affect one's interest in social and prosocial activities. We hope that this article can serve as a model for reviewing what evidence exists in a field and what additional evidence is needed.

Conclusions

We have presented compelling evidence that positive affect is likely to be a benefit to high quality social relationships. Several complementary methodologies all point to this conclusion. Although each method has limitations, they tend to converge in their conclusions and not suffer from identical limitations. Another fact that adds to our confidence that positive affect can enhance relationships is that the findings are based on a variety of mood manipulations in the experimental studies and on a variety of types of measures of both positive moods and relationships. Thus, our conclusion is not based solely on correlations found in global self-report measures.

Psychologists have long maintained that supportive social relationships are one key to psychological health and well-being (e.g., Frisch, 2005; 2014; Seligman, 2011). Thus, the fact that positive affect leads to higher quality social relationships has a number of applied implications. First, raising PA and lowering feelings of ill-being has the potential to substantially improve people's social relationships, and such interventions might be useful in both clinical and organizational settings. Alleviating depression and other negative states is likely to lead to both increases in positive affect and to improvements in social relationships. Similarly, raising the positive affect of workers has the potential of improving relationships within the organization, with coworkers, customers, and supervisors.

An important implication of our review is that researchers must be cautious in interpreting correlations that show a relationship between PA and social outcomes. Often it is assumed that the social outcomes have caused higher levels of PA, but our review suggests that PA could be the cause of better relationships.

Despite the extensive research in this field, there is still a need for more studies in many areas, for example experimental treatments to raise long-term levels of positive affect. There is also a need for much more research to determine the moderators, the bordering conditions, in which positive affect enhance relationships. Very little is currently known. Thus, although a connection going from affect to social relationship quality now seems likely, there is much we do not yet understand, and this area continues to be a very promising area of research.

Wellbeing and Work Performance

Abstract

This chapter reviews research into the happy worker-productive worker thesis, which suggests that individuals and groups with raised wellbeing perform better in their jobs than do those with lower wellbeing. We examine different types of context-free and job-related wellbeing, and explore work performance in terms of in-role and extra-role behaviors and through specific activities such as being creative or proactive. In studies of individual workers, small-to-moderate cross-sectional and longitudinal associations with performance are demonstrated, for example when focusing on wellbeing in the form of job satisfaction or certain types of affect. We also review research into potential moderators of these associations, finding that the magnitude of correlation depends, for example, on the opportunity for personal discretion, occupational grade, and expected benefits from good performance. However, in the absence of adequately controlled experiments in working organizations it is impossible to determine causal direction. Turning to group-level wellbeing, we find that group affective tone is also moderately related to performance. Some group characteristics, such as the number of members, have been suggested as important moderators, but group-level research into possible moderators has been extremely rare. We finish the chapter by suggesting some desirable developments in research, and offering an overall speculation about causal influences in this area.

Keywords: Performance, Wellbeing, Jobs, Affect, Satisfaction, Engagement, Groups

Performance in paid work has for many years been studied as an important form of individual and group behavior, with researchers and practitioners often aiming for its enhancement through job design, staff selection and development, or shaping managerial style and organizational culture. In parallel with this interest in performance, psychologists in employment settings have also worked to understand the sources and consequences of wellbeing, and the two variables will be examined together in this chapter.

A substantial association between wellbeing and job performance is widely envisaged. For example, as many as 92% of Australasian employees in Fisher's (2003) study believed that 'a happy worker is likely to be a productive worker'. Although academic researchers are cautious about the direction of causation, many lay-people emphasize the impact of wellbeing on performance. Ledford (1999) notes that this belief in the productive power of happiness fits comfortably with the hopes of all parties involved – employers, employees and academic researchers. Employers can value worker wellbeing as a possible source of good performance; employees recognize wellbeing as desirable in itself; and for researchers the prospect of jointly optimizing both variables can support claims that neither management nor labor is being favored by their research. As Ledford (1999, p. 27) points out: 'If interventions based on our theories lead to outcomes that are good both for organizations and individuals, who can complain?'.

Types of Wellbeing

In thinking about and measuring wellbeing, it is important to differentiate between its various forms. In respect of scope, the broadest wellbeing is 'context-free' – in terms of life in general rather than concerned with a particular setting. Wellbeing of that broadest scope has been measured through satisfaction with life, global happiness, and similar constructs. Next, medium-scope wellbeing is that which is experienced within one segment of a life-space, focused on one's family, health, leisure, or other domains. In the present chapter, domain-specific wellbeing concerns a person's job, being referred to as 'job-related' wellbeing and measured through job satisfaction, job strain and similar variables. Most narrowly, we might examine wellbeing experienced in respect of one particular element. This can be termed 'feature-specific' wellbeing, in terms of positive or negative feelings about a particular thing, person, group, episode, or idea. Much studied in job settings is 'facet-specific' job satisfaction – with one's pay, supervisor or other elements.

Studies have varied in the wellbeing scope under investigation, and have also differed in their emphasis on longer-term versus shorter-term experiences. Longer-term wellbeing, that which extends across time, has sometimes been viewed as a trait or disposition, and must be distinguished from wellbeing within a short period – 'state' or 'situational' wellbeing. Dispositional forms may be viewed as aspects of

personality; they are sometimes referred to as 'affectivity' in contrast to shorter-term 'affect'.

It is also important to examine separately two types of wellbeing indicator, either in terms of a compound of thoughts and feelings or directly through particular feelings. Cognitive-affective compounds of wellbeing have been investigated through multi-item questionnaires about satisfaction, engagement, strain, burnout, depression and the like, bringing together thoughts, recollections, expectations, and mental networks. As illustrated in this chapter, workers' wellbeing has been measured through compounds indexing job satisfaction, or work[1] engagement as well as life satisfaction. Self-assessments of wellbeing in these compound terms call for more reflection and mental processing than do assessments through specific feelings – attending to and remembering particular elements and episodes, interpreting, evaluating and integrating what is recalled, and perhaps making comparisons with other people or other settings (e.g., Staw & Cohen-Charash, 2005; Warr, 2013).

Wellbeing measures of the second kind, in terms of feelings, often ask about core affect – pleasant or unpleasant experiences that are 'primitive, universal, and simple, irreducible on the mental plane' (Russell, 2003, p. 148). Illustrated by 'happy', 'relaxed', 'anxious' and 'sad', feelings range along a positive-negative continuum and also occur within emotions, moods, values, attitudes, orientations, and ideologies.

However, as well as in positive or negative direction, affects and cognitive-affective compounds also differ in other respects, one of which is particularly important here. In addition to their direction, the circumplex model introduced by Russell (1980) characterizes feelings through the degree to which they are physiologically and/or psychologically activated, being in an elevated 'state of readiness for action or energy expenditure' (Russell, 2003, p. 156). Positive feelings of high versus low activation have been studied in terms of, for instance, enthusiasm and elation (high activation) versus calmness and relaxation (low activation) (e.g., Warr, Bindl, Parker, & Inceoglu, 2014), and a lower level of activation is tapped in many compound scales of life or job satisfaction; 'satis' derives from the Latin word meaning 'enough'. On the other hand, raised activation in job tasks is central to compounds of job engagement (e.g., Bakker, Albrecht, & Leiter, 2011). That is a combination of positive orientation and raised motivation, so 'is fundamentally a motivational construct that represents an active allocation of personal resources towards the task' (Christian, Garcia, & Slaughter, 2011, p.91), whereas the notion of satisfaction implies merely acceptance of a situation.[2]

Types of Work Performance

Wellbeing thus takes several forms which need to be distinguished in reviewing associations with other variables. It is also essential to differentiate between kinds of performance[3], and researchers in job settings have concentrated on the five types outlined below (e.g., Borman & Motowidlo, 1993; Griffin, Neal, & Parker, 2007; Koopmans et al., 2011; Viswesvaran & Ones, 2000). Objective indicators of individual workers' performance (their output, sales, etc.) are rarely available, for example because output is recorded for groups rather than individuals or because job activities are not readily quantifiable. Many researchers have therefore investigated subjective assessments of performance – either ratings by supervisors, colleagues or customers, or self-descriptions by research participants themselves. Performance ratings by other people can be problematic, because observers may lack adequate knowledge or because target behaviors depend on mental processes which are unobservable; furthermore, self-descriptions might err towards positive assessment. In this and other fields, published results can powerfully depend on researchers' operationalization of variables so that reported findings from different studies are not necessarily comparable with each other.

Of the principal aspects of performance, *task performance*, sometimes referred to as 'in-role performance' or 'proficiency', has been of primary interest. Focusing on behaviors which are formally required to meet organizational goals, research has investigated either overall indicators of a person's effectiveness in a job or the summation of separate behavioral assessments.

Second, *specific job behaviors* have been examined without setting those in the overall-performance category above. Examples have included work quality, adaptability, innovativeness, proactivity, participation in learning, and technical competence.

Organizational citizenship behavior (OCB), also referred to as 'extra-role'. 'contextual', or 'pro-social' activity, is that which goes beyond formally prescribed job goals ('task performance' above), for example through helping colleagues, guiding new workers, or choosing to take on additional tasks.

Counterproductive work behavior has negative value to an organization, violating accepted conventions, for example through damaging equipment, stealing property, bullying subordinates or other people, avoiding effort, and abusing drugs.

Workers' *absenteeism*, another key negative variable in this area, can create difficulties for team colleagues and for wider organizational success, especially when a person's non-attendance is unexpected or long-lasting. Research problems can arise in separating medically-prescribed periods of ('involuntary') absence from those which might result more from a worker's personal choice (e.g., Johns, 1997; Johns & Miraglia, 2015).

Research into these five types of work performance has mainly focused on individual workers, and the chapter will first review research of that single-person kind. However, many job activities involve collaboration within a group, and we will also examine the smaller number of studies on group-level performance and wellbeing.

Individual-level Research

Considerable non-occupational research has identified positive relationships between individual wellbeing and success in diverse areas of life. Cross-sectional, longitudinal and experimental studies have pointed to possible benefits of wellbeing for health, longevity, family and social relationships, social relationships, cooperativeness, creativity, self-evaluation, and self-regulation (De Neve, Diener, Tay, & Xuereb, 2013; Diener et al., 2017; Lyubomirsky, King, & Diener, 2005; Tenney, Poole, & Diener, 2016). In job settings, research has explored associations of performance with different aspects of wellbeing as follows.

Wellbeing Measured as Job Satisfaction

Partly-overlapping meta-analyses by Petty, McGee, and Cavender (1984), Iaffaldano and Muchinsky (1985), Judge, Thoresen, Bono, and Patton (2001), and Harrison, Newman, and Roth (2006) have yielded average uncorrected correlations between overall job satisfaction and *task performance* of .23, .25, .18 and .18 respectively. A subsequent study by Halbesleben and Wheeler (2008) found a correlation with supervisor-rated performance of .22, Edwards, Bell, Arthur, and Decuir (2008) reported a correlation of .15, and Schleicher, Watt, and Greguras (2004) found correlations of .15 and (averaged from two satisfaction scales in two samples) .28.

Researchers into job satisfaction have often examined task performance as rated by supervisors or (less often) by colleagues, but a small number have obtained self-ratings by workers themselves. Only rarely have satisfaction-performance associations been directly compared between self-ratings of performance and parallel ratings by other people, with apparently similar findings (Iaffaldano & Muchinsky, 1985).[4]

Moving on to the second type of performance introduced above, *specific job behaviors,* personal innovation in a job was investigated by Ayala, Peiró Silla, Tordera, Lorente, and Yeves (2016). They found that young workers' job satisfaction was correlated .41 with their self-reports of innovation at work.

Significant associations have also been found between job satisfaction and *organizational citizenship behavior* (OCB). A meta-analysis by Organ and Ryan (1995) identified uncorrected average cross-sectional correlations of .23, .20, and .38 with altruism, generalized contribution and overall citizenship, and the review by Harrison et al. (2006) recorded average correlations of .26 (concurrent analyses) and .22 (predictive, with satisfaction measured before OCB). Later cross-sectional research by Edwards et al. (2008) found a correlation of .15 with supervisor-rated citizenship. A two-week diary study by Fisher (2002) revealed workers' average job satisfaction to be correlated .23 with self-reported citizenship behavior, and for average satisfaction across three weeks that correlation was .52 in the study by Ilies, Scott, and Judge (2006).

Job satisfaction has been found to be negatively correlated with *counterproductive work behavior*, for example -.33 and -.25 with self-reports and peer-reports in the study by Penney and Spector (2005). For employee *absenteeism*, negative correlations have also been found, for example -.20 and -.25 in research by Johns (1997) and -.14 in the meta-analysis by Harrison et al. (2006). Almost all studies in this field have recorded absence from work at a time before wellbeing is measured, but Hardy, Woods, and Wall (2000) studied job satisfaction in advance of information about absence frequency; the correlation was found to be -.23. Focusing only on intrinsic aspects of job satisfaction (for instance, with opportunity to learn new skills) and subsequent short-term absence, Mirvis and Lawler (1977) recorded a correlation of -.81.

Task performance as a function of different facets of job satisfaction has less often been studied. However, it appears that satisfaction with the work itself and with one's supervisor are significantly associated (around .20) with task performance (Edwards et al., 2008; Petty et al., 1984), but smaller correlations are found with other facet satisfactions – concerning pay, promotion, co-workers and so on. Slocum (1971) reported that managers' task performance was more strongly correlated with the satisfaction of self-actualization needs than, for instance, with security needs.

Wellbeing Measured through Other Cognitive-Affective Compounds

In addition to examining associations with job satisfaction, research into work performance has also explored links with other forms of wellbeing. This section will review compound cognitive-affective indicators beyond job satisfaction, before associations with wellbeing in terms of a worker's affect are considered in the next section.

In recent years, increasing attention has been devoted to the construct of job engagement, a motivated state of positive wellbeing characterized by vigor, dedication, and absorption in one's work (e.g., Bakker et al., 2011; Schaufeli, Salanova, González-Roma, & Bakker, 2002; Warr & Inceoglu, 2014). Meta-analyses of findings by Rich, Lepine, and Crawford (2010) and Christian et al. (2011) drew on then-available (fewer than ten) studies to report mean correlations of job engagement with task performance of .35 and .36 respectively[5], and mean correlations with organizational citizenship behavior of .35 and .26. In addition, Christian et al. (2011) showed through incremental analyses for both kinds of behavior that job engagement accounted for significant additional variance over and above job satisfaction.

Studying a wide range of jobs, Halbesleben and Wheeler (2008) found a correlation of .32 between job engagement and supervisor-rated task performance. Among employees in a fast-food company, Xanthopoulou, Bakker, Demerouti, and Schaufeli (2009) reported a correlation of .34 between day-level job engagement and that day's branch income. A significant association with engagement was also found in a broader sample of workers by Demerouti, Bakker, and Halbesleben (2015) for self-reports of day-level task performance and (negatively and less strongly) for self-reported counterproductive work behavior. Bakker and Bal (2010) similarly observed in a weekly diary study that teachers' self-rated performance co-varied with their level of job engagement. Among self-employed entrepreneurs (individuals who founded or owned a private company), Gorgievski, Moriano, and Bakker (2014) observed a correlation of .56 with self-described innovative behavior. In another sample of entrepreneurs, job engagement was found by Djkhuizen, Gorgievski, van Veldhoven, and Schalk (2016) to be significantly associated with subjective personal, but not financial, success. Overall, it appears that job engagement is more strongly associated with task performance than is job satisfaction, but a meta-analysis of comparative levels in the same sample is still required.

Negative forms of wellbeing have been investigated through reports of job-related emotional exhaustion[6], sometimes treated as a component of job burnout. For example, Taris (2006) brought together the few studies of emotional exhaustion available at the time of writing (16 of them, with different measures and samples), and reported mean correlations with task performance and citizenship behavior of -.19 and -.17. Subsequent findings about emotional exhaustion and task performance include a nonsignificant association in the study by Demerouti et al. (2015) and significant correlations of -.13 (Janssen, Lam, & Huang, 2010), -.27 (Demerouti, Bakker, & Leiter, 2014), -.19 and -.18 with self- and other ratings (Mastenbroek et al., 2014), and (across time) -.28 (Petrou, Demerouti, & Schaufeli, 2015). In respect of organizational citizenship, Janssen et al. (2010) obtained *r*'s of -.19 and -.23 with two measures, but that association was insignificant in the study by Mastenbroek et al. (2014).

Finally in this section on compound measures of wellbeing, we turn to context-free indicators. Examining senior managers' life satisfaction in relation to their self-rated job performance, Zelenski, Murphy, and Jenkins (2008) found an intercorrelation of .25, very similar to their finding for job-related satisfaction (.22). Bringing together an unspecified number of publications, Erdogan, Bauer, Truxillo, and Mansfield (2012) reported an average correlation between life satisfaction and task performance of .14, and in a parallel analysis by Ford, Cerasoli, Higgins, and Decesare (2011) the average *r* was .16 from six studies. Other context-free research has focused on negative forms of wellbeing. For example, in the meta-analysis by Ford et al. (2011, above) generalized anxiety and depression were on average correlated -.15 and -.14 (uncorrected) with measures of job performance. Hardy et al. (2000) studied context-free psychological distress in relation to subsequent lost-time absence, finding a correlation of .25.

A wellbeing indicator combining job-specific and context-free measures (job satisfaction, job engagement, and life satisfaction) was studied by Djkhuizen, Gorgievski, van Veldhoven, and Schalk (2017). They described how the wellbeing of entrepreneurs predicted reports of subjective personal and financial success after an interval of two years; however, the lagged association with business performance (annual profit, financial turnover and number of employees) was non-significant.

Wellbeing Measured as Job-related Affect

Given that all compounds of wellbeing contain some positive or negative feelings, the patterns illustrated above are expected in general to be paralleled by findings about affect. Affect research outside employment settings has been summarized by, for instance, Isen and Baron (1991) and Barsade and

Gibson (2007), and also within organizations by Forgas and George (2001). This section will instead examine research into workers and their job-related feelings.

Applying the Multiple Affect Adjective Checklist (MAACL) to feelings at work, Motowidlo, Packard, and Manning (1986) obtained nurses' reports of job-related negative and positive affect. They recorded depression through self-descriptions of feeling miserable, sad, enthusiastic, inspired, etc., and assessed anxiety in terms of feeling tense, worrying, cheerful, happy, and so on. Feelings which can be viewed along an axis from job-related depression to enthusiasm were significantly correlated (-.31 and -.21) with supervisors' ratings of interpersonal and cognitive/motivational effectiveness, but feelings of anxiety were unrelated to performance in those terms. Staw, Sutton, and Pelled (1994) also investigated supervisor ratings of task performance in relation to job-related feelings along the depression-enthusiasm axis (which they referred to as 'positive emotion'), finding an overall concurrent correlation of .30 and a predictive *r* of .16 over 18 months. Activated positive affect was found by Eisenberger, Armeli, Rexwinkel, Lynch, and Rhoades (2001) to be correlated .16 with supervisor-rated task performance. For citizenship behavior (here, supervisor-rated altruism), George (1991) recorded a correlation of .24 with activated positive affect, although the correlation with subsequent sales was only .10. In the diary study by Zelenski et al. (2008), positive affect was concurrently associated .36 with self-rated productivity, but correlations with negative affect were around zero.

For self-reported citizenship behavior, a stronger association with positive than with negative affect was also found by Fisher (2002) in analyses of average job feelings across two weeks (*r*'s = .48 and -.01 respectively). Average diary levels of activated positive affect across three weeks were found by Ilies et al. (2006) to be correlated .61 with self-reported organizational citizenship behavior. Examining momentary feelings, self-reported allocation of job effort was found by Foo, Uy, and Baron (2009) to be correlated on average .20 with positive affect but only .06 with negative affect. Two diary studies by Dalal, Lam, Weiss, Welch, and Hulin (2009) yielded significant concurrent associations between job-related affect and self-reported citizenship and counterproductive behavior, such that positive affect was typically related to citizenship but not to counterproductive behavior, and negative affect was more often related to counterproductive activity than to citizenship[7].

Some research has directly compared activated versus non-activated positive affect. Studying a range of self-reported task and citizenship behaviors in six different samples, Warr, Bindl, Parker, and Inceoglu (2014) showed that work performance is principally associated with positive job feelings that are activated, as did Madrid, Patterson, Birdi, Leiva, and Kausel (2014) in a single-sample diary study of self-reported work innovation.

Positive mood at work was found by George (1989) to be correlated -.28 with subsequent absenteeism, but negative mood was unrelated (-.03). In research by Hardy et al. (2000), feelings of job-related anxiety and depression were correlated .30 and .25 with subsequent absenteeism.

Wellbeing Measured as Context-free Affect

Work behaviors are also moderately associated with wider-ranging feelings, those which are context-free. For example, Tsai, Chen, & Liu (2007) found that the context-free[8] activated positive moods of insurance sales agents were correlated .46 with their supervisors' ratings of task performance and .36 with their self-assessments. Reviewing organizational citizenship behaviors across 23 previous investigations, Dalal (2005) found average correlations of .28 and -.08 with varied measures of positive affect and negative affect. For counterproductive work behavior, those average values were -.28 and .34.

A few investigations of context-free affect have focused on specific aspects of work performance. For instance, Fritz and Sonnentag (2009) asked about proactive work behavior as a function of context-free activated positive and negative affect, finding average correlations of .36 and .13 respectively. Other studies obtaining significant correlations between proactivity and positive affect (but mixed results for negative affect) have been reviewed by Cangiano, Bindl, and Parker (2017).

Links with creativity at work have been investigated longitudinally by Amabile, Barsade, Mueller, and Staw (2005) and considered non-empirically by James, Broderson, and Eisenberg (2004). Amabile and colleagues studied 222 members of innovation-tasked teams at the end of a day for the duration of each individual's personal project extending up to 38 weeks. A person's creative contribution was assessed through researchers' coding of that individual's daily accounts of experiences and through monthly ratings by colleagues. Both performance indicators were modestly but statistically-significantly associated with a day's positive feelings.

What Do the Correlations Mean?

This summary of empirical research has revealed a consistently positive but small association

between individual workers' wellbeing and performance. Many studies have additionally controlled for potentially-distorting demographic and other variables, and a modest cross-sectional association seems to be well established across many work behaviors. How might it be explained?

Perhaps greater wellbeing causes better performance. For that causal pattern to be inferred from empirical findings, a minimum requirement is for wellbeing to be measured before performance. The field has been dominated by single-occasion research[9], but a few publications have considered longitudinal associations across time, finding that lagged patterns are similar to, but can be reduced from, those cross-sectional associations (e.g., Riketta, 2008).[10] It is certainly desirable to investigate patterns in which wellbeing is measured in advance of performance. However, even when greater job satisfaction, for instance, has been shown to precede better performance, causal impact from satisfaction cannot be inferred.

For example, influence might instead flow in the reverse direction, from good performance to, say, job satisfaction (e.g., Lawler & Porter, 1967). Successful task performance could lead to intrinsic rewards (for instance positive feelings linked to self-esteem) and/or extrinsic rewards such as promotion or an increase in pay. The two sequential directions between wellbeing and performance have been compared by Harrison et al. (2006) and Riketta (2008), in both cases showing that average longitudinal correlations are almost identical irrespective of direction. In the meta-analysis of across-time studies by Harrison and colleagues, longitudinal correlations between job satisfaction and task performance averaged .17 when job satisfaction was measured before task performance and .19 when performance preceded satisfaction. Riketta analyzed a smaller number of panel studies, and reported average correlations of .11 between job satisfaction and subsequent task performance and .10 when performance was measured before satisfaction. For organizational citizenship behavior, Riketta found that the two average correlations with job satisfaction were .23 and .22 respectively.

A third possible causal interpretation combines the previous two. Influence might be reciprocal, flowing in both directions, so that wellbeing causes good performance and good performance causes wellbeing. Personal experiences lead many people to suspect that this is often the case, even though processes within a single individual cannot be generalized to the between-person analyses which make up the bulk of the empirical literature. However, assuming that some causal influence is reciprocal in that way, we might also expect that the relative weight of each varies between situations and the operation of other variables and processes.

However, an additional causal possibility has special merit. In some cases, both wellbeing and performance may be influenced by omitted, unmeasured features, sometimes labeled as a study's 'third variables'.[11] Such potentially causative variables may operate either as short-term 'occasion factors' or as longer-term, continuing influences (e.g., Zapf, Dormann, & Frese, 1996). Thus, concurrent short-term impacts on both wellbeing and behavior might derive from characteristics of a setting occupied only briefly or from immediately preceding events; and more extended influences can include continuing supervisor behavior, support from colleagues, equipment limitations, particular stressors, etc. or from dispositional worker characteristics such as ability, gender, personality, value preferences, and so on. Although researchers have sometimes statistically controlled a number of these possible 'third' variables, other potential influences of this kind can be envisaged in all published investigations.

It is logically impossible to be certain that no other features or groups of features also require consideration as potentially important omitted variables.[12] More generally, it is widely recognized that learning about causality requires some form of experimental manipulation. Within a working organization, tightly controlled experiments are almost always unacceptable to managers, non-managers or both, and any organizational experiments which may be undertaken in this area are likely to be fatally flawed.

Researchers into wellbeing and behavior have therefore turned to laboratory experiments to examine the impact of induced positive or negative feelings. Affect-induction procedures in this research have included watching a film clip, receiving an unexpected small gift, reading about positive occurrences, or being exposed to an attractive scent, and research participants have almost always been university students. Laboratory experiments which induce affect have revealed several consequential changes in cognition and behavior (e.g., Baas, De Dreu, & Nijstad, 2008; Baron, 1990; Barsade & Gibson, 2007; Erez & Isen, 2002; Fredrickson & Branigan, 2005). For instance, increases in positive affect have been shown to give rise to significantly more speedy and more comprehensive mental processing, more positive judgments about neutral material, greater persistence, and more positive expectancy motivation, enhanced optimism, increased creativity and self-esteem, and more cooperation with other people.[13] Oswald, Proto, and Sgroi (2015) described three laboratory comparisons of arithmetic task productivity, finding that the output of participants with induced positive-mood exceeded control groups by an average of 12%.

Experiments of this kind have yielded consistent findings in comparisons between positive and

neutral affect[14] (induced positive affect yields positive behaviors), but it is of course uncertain how readily those findings can be generalized to organizational settings. Laboratory effects are unlikely to endure beyond about 20 minutes, and a range of additional variables and social processes also operate in organizations. Furthermore, activities in a job and elsewhere often bring together behaviors of several different kinds and embody sequences of experiences that shift between evaluatively negative and positive and perhaps back again. Nevertheless, although laboratory-derived patterns cannot be directly applied to a workplace, published causal evidence from experimental research together with personal experiences in everyday life suggest to many people that wellbeing has some influence on performance. Furthermore, measured compounds of wellbeing such as job satisfaction or life satisfaction derive from the accumulation of feelings throughout life, many of which are themselves only brief; short-term affects are cumulatively important in the long term when combined with other short-term affects (e.g., Diener, 1984; Diener, Suh, Lucas, & Smith, 1999; Fisher, 2000; Kim-Prieto, Diener, Tamir, Scollon, & Diener, 2005). However, other causal influences on performance are also probable, outlined above, and multiple causal routes should often be envisaged. In general, patterns of influence are likely to vary between different feelings, events and situations.

Varied Associations between Wellbeing and Performance: Possible Moderators

Given that observed correlations between wellbeing and job performance can differ between studies, it is important to examine possible moderator variables. Furthermore, by learning about the conditions under which an association between wellbeing and performance is either larger or smaller, we can form hunches about the causes of that association. There is a sense in which moderator analyses, contrasting high and low levels of a possibly moderating variable, can be viewed as notionally manipulating that variable – a form of 'thought experiment'.

Early research into moderators in this area focused on the level of constraints on personal decision-making and action. In some jobs, a person is free to decide how work is done, but in other cases external constraints, such as instructions from a supervisor, strong social norms, or control of behavior by machine, reduce personal autonomy so that associations between individual characteristics and behavior are then likely to be reduced. Herman (1973) studied attitude-behavior links in the absence of situational pressures – when voting for or against trade union representation in one's company. In that low-constraint setting, voting in favor of union representation was strongly negatively correlated (-.57) with satisfaction with the company. Across a range of constraint levels, Bhagat (1982) examined external restrictions on department-store managers in terms of perceived organizational pressure for high performance; correlations between job satisfaction and supervisor-rated task performance averaged .56 among managers reporting low organizational pressure, but were only .01 among high-pressure employees. For reported time pressure, the low- and high-constraint sub-group correlations were .49 and.06 respectively.

The continuum between external and internal influences on behavior was viewed by Mischel (e.g., 1977) in terms of 'situational strength', a major component of which is the degree to which an environment acts to constrain self-initiated behavior (e.g., Bowling, Khazon, Meyer, & Burrus, 2015; Meyer, Dalal, & Hermida, 2010). The opportunity to use personal discretion is limited in situations of high constraint – 'strong' situations in terms of Mischel's model, A meta-analysis by Bowling et al. (2015) revealed a correlation of -.34 between the magnitude of constraints in a job and the association between job satisfaction and task performance; that is, stronger associations between wellbeing and performance were found when jobs impose fewer constraints. From structural equation analyses of six sets of data, Warr et al. (2014) observed substantial associations more widely among discretionary (i.e., low-constraint) forms of job behavior. This theme was central to George and Brief's (1992) model of positive mood at work, which was viewed as having 'the most effect on behaviors that are performed of one's own free will' (p. 324).

Some researchers have examined a second possible moderator – the degree to which good performance yields personal benefits for an individual. In those terms, associations between wellbeing and performance are predicted to be stronger when good performance brings the potential for some personal reward. That was seen to be the case in a laboratory experiment by Cherrington, Reitz, and Scott (1971), comparing the presence versus absence of performance-based payment, and among salespeople and managers by Jacobs and Solomon (1977), who found that associations between job satisfaction and supervisor-rated task performance were moderated by the perceived presence or absence of organizational performance-reward contingencies.

In the same vein, Schwab and Cummings (1970) emphasized the assessed instrumentality of good performance – the degree to which it provides a path to personally-important goal achievement. Intrinsic rewards, rather than those which are extrinsic such as pay or better work conditions, were central to the models of Lawler and Porter (1967) and Slocum (1971) and to the perspective of Hochwarter, Perrewé,

Ferris, & Brymer (1999) on workers' attainment of outcomes which are consistent with their personal values. Perceived distributive justice (an acceptable balance between personal effort and reward) has been shown by Janssen et al. (2010) to significantly affect the association of emotional exhaustion with supervisory ratings of both task performance and organizational citizenship: Emotional exhaustion was negatively associated with performance when justice was perceived to be high, but unrelated for workers experiencing low justice.

Some moderators of these kinds are reflected in differences between organizational grades. Managers and professional staff have more freedom than others to determine their own activities and wellbeing. It might therefore be expected that correlations between wellbeing and work performance will be greater among managers and professional staff than among lower-grade workers. In Sheridan and Slocum's (1975) study in a steel company, wellbeing-performance correlations were found to average .23 and .10 for managers and machine operators respectively.[15] Doll and Gunderson (1969) contrasted scientists against enlisted naval personnel on Antarctic assignments, finding correlations between job satisfaction and supervisor-rated performance of .34 and .05 respectively. The review of overall job satisfaction in relation to task performance by Petty et al. (1984) found average correlations of .31 and .15 for professional/managerial versus other workers, and the meta-analysis by Judge et al. (2001) identified average correlations of .26 for jobs rated as highly complex and .18 for low-complexity work.

Social pressures provide another potential constraint on discretionary behavior, for example through the operation of work-group norms about acceptable performance. In cases where a work group has established a normatively prescribed level of acceptable performance, it may be that a person's own feelings and values will less determine behavior than in the absence of a strong norm. Early research in this area emphasized that work-group cohesiveness is likely to promote norms of either low or high productivity (e.g., Seashore, 1954), and parallel themes have been developed in terms of social identity theory by van Knippenberg (e.g., 2000) and Tanghe, Wisse, and van der Flier (2010); individuals who more strongly identify with a group are thought more likely to accept the group's norms so that their behavior is more likely to be shaped by them.

That between-person variation might also be construed in terms of an individualist versus collectivist orientation, some aspects of which have been examined through peoples' tendency to experience guilt when deviating from the expectations of others. Guilt-prone workers are likely to be particularly troubled if they break the norms of a reference group, and those who are more driven by individualist rather than collectivist motives might be expected to experience less guilt when deviating from socially-prescribed norms. That difference was observed in two studies of absenteeism from work by Schaumberg and Flynn (2017). They predicted from the positive value placed by colleagues and superiors on attendance in a work-role that job satisfaction would be more strongly associated with low absenteeism among workers who were less prone to guilt than among those who were more guilt-prone. Full-sample correlations in the two studies between job satisfaction and subsequent absenteeism were found to be around zero, but in both cases the predicted interaction was statistically significant. At lower levels of guilt-proneness, personal feelings were more associated with attendance behavior than among guilt-prone individuals.

Bowling (2007) emphasized the role of personality characteristics, drawing on earlier meta-analyses to show that associations between job satisfaction and task performance are reduced after the introduction of Big Five traits such as conscientiousness, extraversion, and neuroticism, and after separate inclusion of core self-evaluations and organization-based self-esteem. However, as he pointed out, the satisfaction-performance correlation 'remained statistically significant after employee personality was controlled' (p. 177).

Other personal attributes might also contribute to this pattern. For instance, impaired health reduces the number and kind of options that are available to a person, and individual differences in skill level can overwhelm any possible importance of variation in wellbeing. Similarly, certain personal value and motivational systems are likely to have a wide-ranging impact on links between wellbeing and performance. For example, workers who wish to avoid excessively stressful inputs from their job, perhaps more valuing their activities outside paid work, can intentionally limit their work output ('taking it easy'), so that for them high wellbeing can be associated with moderate or even low task performance.

Reviews by Lyubomirsky et al. (2005) and others have stressed the role of social behavior and interpersonal relationships. High-wellbeing individuals tend to be more socially involved than others, and links between raised wellbeing and organizational citizenship behavior are widely found (above). Given the operation of norms of reciprocity, such that help given to others is accompanied by help in return (e.g., Bowling, Beehr, Johnson, Semmer, Hendricks, & Webster, 2004), it is possible that correlations between wellbeing and performance are in some cases partly attributable to task assistance from colleagues (e.g.,

Tsai et al., 2007). Such interpersonal assistance varies between settings and is of course only possible in jobs which permit interaction and collaboration with others.

Steers (1975) drew attention to the possibility that workers with higher need for achievement are likely to more strongly value the successful attainment of job objectives, so that for them high task performance would be especially strongly linked with job satisfaction. In a study of office staff, he found that supervisor-rated performance was correlated .32 with job satisfaction in the sub-set of high-need workers but only .10 among low scorers.

In overview, a small number of studies have pointed to environmental and personal variables which might influence the strength of an association between worker wellbeing and performance. Also important is the aspect of wellbeing under consideration. For example, Lawler and Porter (1967) and Slocum (1971) showed that associations with supervisor-rated task performance varied between different needs, with self-actualization satisfaction being most strongly related to performance.

Some characteristics of wellbeing also influence the magnitude of association with performance. For instance, in the few studies which examined both positive and negative indicators of affect, positive feelings have consistently been found to be more important than negative feelings, at least in respect of positive performance. In addition, the activation level of wellbeing has a particular impact on observed correlations. Only a few investigations have measured affects of both low and high activation, instead recording feelings which are all activated[16], so that much of the research literature reports significant associations between wellbeing and performance which are in fact restricted to activated forms of wellbeing. However, Warr et al. (2014) found in structural equation analyses of findings about a variety of job behaviors across six investigations that activated job feelings were substantially more strongly associated with self-reported behavior than were low-activation feelings – average path coefficients of .48 and -.17. In respect of creativity, the meta-analysis by Baas et al. (2008) contrasted more versus less activated affect, finding average correlations of .17 and .01 respectively.

Associations between wellbeing and job performance are also likely to be influenced by aspects of research design. For example, the size of observed correlations depends in part on the range of values examined. Many projects in work settings have used five-point response scales when obtaining performance ratings; that small range of scores is further truncated by the fact that few retained employees are rated as low performers. And longitudinal studies have differed in their interval between measuring wellbeing and performance, so that results from longitudinal research can vary between studies using different intervals.

In addition, evidence from earlier research does not always meet today's more rigorous methodological requirements. For example, reported comparisons between wellbeing-performance correlations among high- and low-scorers on a possible moderating variable often lack supporting tests of statistical interaction or incorporate controls for demographic and other features. It is important now to apply current criteria to new studies in the areas outlined here.

Group-level Research

Although organizations depend heavily on the performance of individual people, recent years have seen increased attention to the operation and effectiveness of teams. This section will examine research into wellbeing and performance at the level of groups. Group wellbeing has typically been computed by aggregating individual scores, but a few studies have instead used items asking about the team as a whole (e.g., Mäkikangas, Aunola, Seppälä, & Hakanen, 2016). Occasionally, collective wellbeing has been viewed as group 'morale' – positive feelings linked to a desire to contribute to effective performance (e. g., Bowles & Cooper, 2009; Peterson, Park, & Sweeney, 2008).

Social contagion theory (Hatfield, Cacioppo, & Rapson, 1994) builds on the fact that emotions arise not only internally but also from social interaction with others; we share emotions with other people, and our own emotions are influenced by their emotions. Group-level wellbeing is thus partly the result of social exchanges as we share our work experiences with other people and are affected by the experiences of others (e.g., Barsade, 2002). In addition, individuals in a group can be exposed to common external conditions which can provoke similar affective reactions.

Convergence in groups has been shown to be affected by several moderating influences. For example, studies have pointed to the importance of stable membership and interdependence between individuals (Bartel & Saavedra, 2000), and differences between people are influenced by a person's individualism or collectivism – the preference for individual versus communal activity; collectivistic group members have been found to be more susceptible to affective influences than are individualistic members (Ilies, Wagner, & Morgeson, 2007). Drawing on social identity theory, Tanghe et al. (2010) showed across 71 teams that members' stronger identification with their group was associated with more homogeneous

levels of group affect, and that members' identification with the group was correlated .33 with self-perceived task performance.

Despite a growing research interest in social dynamics, there have been relatively few investigations into links between group-level wellbeing and work performance (Barsade & Knight, 2015). In this section, we give an overview of the literature in this area, looking first at compound indicators of wellbeing and then at group affective tone.

Group-level Job Satisfaction, Job Engagement, and Other Wellbeing Compounds

In a meta-analysis of previous research into job satisfaction, Whitman, van Rooy, and Viswesvaran (2010) reported average sample-size-weighted correlations of group-level satisfaction with task performance and citizenship behavior of .29 and 34 respectively. They also recorded an average correlation between group-level job satisfaction and absenteeism of -.37, and an average of .25 with customer satisfaction. In addition, Whitman et al. (2010) found that the relationship was stronger for specific work groups than at the branch level and also in work groups with fewer than ten members. They observed that group-level associations with job satisfaction were stronger when scores within a collective were more similar to each other, emphasizing the importance for links with performance of shared rather than fragmented wellbeing. In general, more interdependent activities and experiences within a group are likely to give rise to more similar experiences.

In a sample of retail stores, Brown and Lam (2008) found a corrected mean correlation between group-level job satisfaction and customer satisfaction of .29. Furthermore, the relationship between store satisfaction and customer satisfaction was stronger at the group level than at the individual level – as confirmed in the wider examination by Whitman et al. (2010).[17] Across 328 stores, Grandey, Goldberg, and Pugh (2011) observed a significant association (r = .28) between store-level job satisfaction and customer satisfaction, and found that store busyness (the number of sales transacted) significantly reduced that association, suggesting that in busier stores employees had less time to identity and respond to customers' need for help.

Work engagement has traditionally been measured as an individual-level construct, but has also received some attention at group level (Schaufeli & Salanova, 2011). Group-level work engagement has been positively associated with supervisors' ratings of groups' task performance among office and similar workers (McClelland, Leach, Clegg, & McGowan, 2014; Torrente, Salanova, Llorens, & Schaufeli, 2012). Similarly, among hotel and restaurant staff Salanova, Agut, and Peiró (2005) found that group-level work engagement predicted a positive service climate which in turn predicted group performance measured as service provided to customers. Gracia, Salanova, Grau, and Cifre (2013) observed that group work engagement was related to good service through staffs' greater empathy and extra assistance to customers. Extending that theme, García-Buades, Martínez-Tur, Ortiz-Bonnín, and Peiró (2016) found that group-level work engagement in hotels was positively related to service performance, measured through customer's positive reports of experience and intentions to return. The association between work engagement and service climate was reinforced by groups' high climate for innovation.

Studying 102 work-groups, Mäkikangas et al. (2016) recorded a correlation of .86 between members' perception of group-level job engagement and their perceptions of group performance. Examining possible moderation by personal job crafting (informal shaping of one's job to better meet individual needs) (e.g., Tims & Bakker, 2010), they found that crafting to increase self-development and support from others strengthened the relationship between group-level work engagement and performance.

In a study of joviality (viewed as the extent to which individuals are enthusiastic, excited, and enjoy what they do), O'Neill and Rothbard (2017) found that firefighters who worked in groups high on joviality spent less time coordinating their response to calls, so could be seen as more effective, but when outcomes were measured two months later they also had more vehicle accidents and property loss, probably because they took more risks. For low wellbeing measured as group-level emotional exhaustion, Leiter, Harvie, and Frizell (1998) found a strong negative correlation (-.73) across 16 medical units between emotional exhaustion and patient satisfaction with their care.

Group Affective Tone

This section moves on from cognitive-affective compounds to examine group wellbeing in terms of positive or negative feelings. Work-group affective tone is usually assessed through the average of members' feelings that are 'consistent or homogeneous' (George, 1995, p. 108; George & King, 2007, p. 98). Research has pointed to moderate associations between group affect and aspects of performance. For example, the positivity of group affective tone has been shown to be significantly associated with self-perceived group performance (Tanghe et al., 2010) and with specific behaviors such as group coordination

(Sy, Côté, & Saavedra, 2005) and cooperation (Barsade, 2002). Totterdell (2000) described how collective mood in cricket teams was related to individual players' match performance, and Hmieleski, Cole, and Baron (2012) reported that the performance of new venture companies is better when group affective tone is more positive. Across 26 work-groups George (1995) found that negative aspects of group affective tone were associated with poorer self-rated customer service 'in your work group', but correlations with positive affective tone were not significant.

Negative group tone has been linked to lower levels of citizenship and customer service behavior by George (1990); and Cole, Walter, and Bruch (2008) found that more negative group moods in manufacturing work groups were related to poorer performance as rated by supervisors. Examining possible moderators of this relationship, Cole and colleagues (2008) found that the inverse relationship between group-level negative tone and performance was weaker when group members' nonverbal behavior was openly negative towards each other.

The meta-analysis by Knight and Eisenkraft (2015) suggested that when negative group affect stemmed from a source outside the group, groups with more negative affect were better performers, possibly because external threats make group members coordinate their actions and direct attention towards tackling that threat. On the other hand, when the source of a negative group tone was internal to the group (such as unpleasant interpersonal behavior), more negative affect was related to poorer group performance, possibly because negative feelings in that case are associated with members viewing the group in a negative light or because the source of the negativity has not been modified (Knight & Eisenkraft, 2015).

Knight (2015) explored the importance of group affective tone during different phases of a project in military teams on training exercises, and found that a shared positive mood at the middle of the project, but not at other stages, was related to better group performance, as group members were more focused on their collective task. On the other hand, a shared negative mood hindered team performance, as members continued to explore alternative ideas even as the deadline for the project drew nearer. Stephens and Carmeli (2016) found that groups in which members felt able to express negative emotions reported better group performance, that was associated with greater adherence to project budgets and increased knowledge-sharing.

Group affective tone has also been considered in relation to creativity. Barsade and Knight (2015) drew attention to the possibility that positive group affect can enhance creativity because group members who share positive feelings and associated ideas may collectively become better at innovation and problem solution. However, Tsai, Chi, Grandey, and Fung (2012) failed to find that relationship with group creativity. They observed that in groups where interpersonal trust was high a positive group affective tone was related to *lower* creativity, and suggested that this atypical finding could be explained in terms of group-centrism (George & King, 2007): If group members trust each other, they are more likely to gravitate towards to the center of expressed opinions and to reject novel ideas and suggestions, thus reducing the group's creativity.

In addition to average wellbeing, the diversity in affect between members is important. For example, Barsade, Ward, Turner, and Sonnenfeld (2000) found that, where members' affect in senior management groups was more varied, the groups performed less well, perhaps because of more internal conflict and reduced cooperation. George and King (2007) argued that homogeneity in group members' affect is likely to be most beneficial when tasks are routine and when homogeneity encourages a single appropriate shared reality. On the other hand, some between-person heterogeneity in feelings can be particularly desirable in complex or novel tasks to promote multiple perspectives and associated suggestions for action.

Some Desirable Research Developments

The two-variable possibility that happy workers are more productive than others has long attracted researchers and the general public, and no doubt will continue to do. However, it is important also to look beyond those two variables on their own. Most behaviors have multiple causes, and a person's wellbeing is usually only one of many possible influences. Models and empirical studies of wellbeing and performance should therefore also include other continuing or transient conditions, in the environment and/or within the person. Inputs from a job situation (task demands, supervisor behavior, the availability of feedback, relations with colleagues, etc.) and from within-person variables, such as values, traits, health, and task-relevant ability, may contribute to observed patterns as 'third' variables which are often unmeasured in studies of wellbeing and performance. A primary research need in this area is thus for the conduct of multiple-variable investigations to broaden the focus beyond wellbeing and performance alone. For example, does measured wellbeing account for additional variance in task performance over and above specified job conditions?[18]

Another pressing need is for increased attention to possible moderator variables. In what circumstances is the association of behavior with an investigated form of wellbeing likely to be higher or lower? As summarized above, a small number of studies have examined this question, but research in earlier decades can sometimes be questioned on methodological or conceptual grounds. Furthermore, published moderator studies tend to be disconnected from each other, lack replication, and be conducted in the absence of overarching theories. It is essential to place new moderator research in a conceptual framework which includes other variables which can influence the strength of an association.

Some studies should focus on sets of individual workers. The happy-productive worker hypothesis expects people on average to be either happy and productive or unhappy and unproductive, but the fact that observed positive correlations are only moderate indicates that many workers do not fit that pattern. We need to learn more about individuals who are outside the hypothesized pattern. Recognizing that, Ayala et al. (2016) used data from a study of young employees to place workers in one of four categories: happy and productive, unhappy and unproductive, happy and unproductive, and unhappy and productive. Indicators of the two variables were job satisfaction and self-reported job innovation, and almost 15% of the sample fell outside the two groups expected by the hypothesis; around 9% were classified as unhappy and productive, and about 5% were defined as happy and unproductive. Average levels of educational qualification, proactivity and job self-efficacy were found to differ between sets of workers. Further research along these lines is now desirable, investigating additional measures of wellbeing and performance and identifying situational and personal features associated with membership of each cluster.

Moderators require particular attention at the work-group level. Research questions and methods have differed considerably between studies of group wellbeing and performance, and we need to learn whether principal differences have affected findings. For instance, what is the impact of group size on associations between wellbeing and performance? Tanghe et al. (2010) studied work-groups containing two to four workers, but those examined by Mäkikangas et al. (2016) had four or more members; George (1990) investigated as groups people who worked for the same departmental manager. We do not know whether size differences of that kind are influential. Also potentially important are dimensions of task complexity and uncertainty. Perhaps in routine work effectiveness is more linked to homogeneous positive affect, whereas more complex and uncertain tasks are better performed by groups with more diverse wellbeing. 'Group-think' is likely to be especially dangerous in uncertain and unpredictable conditions (e.g., George & King, 2007).

Behavior of all kinds is sometimes brought about by external pressures which generate unhappiness as well as action. When provoked into action by physical, economic, or social threats, people can experience low wellbeing but generate behavior which is effective; 'necessity is the mother of invention'. Occupational research needs to identify situations of this kind and trace extra- and intra-person developments across time. Zhou and George (2001) focused on job creativity, and showed that job dissatisfaction was associated with greater creativity when continuance commitment (a perceived need to remain in post) was accompanied by support for creativity from a worker's colleagues and organization. These and associated ideas about the occurrence of zero or negative correlations between wellbeing and performance now deserve further investigation.

A general requirement is for additional qualitative research in this field, through interviews, observation, group discussion, video-recording, analysis of company records, and similar procedures. In many cases, particular behavior sequences can embody both negative and positive experiences, as a problem first generates strain when solutions are sought and applied and then yields satisfaction or pleasure after progress has been made. Many personal projects, in a job and elsewhere, are of that threat-then-resolution kind, and these are poorly served by current research approaches.

Two research designs are conventional to investigate sequential possibilities. Diary studies obtain research material on several occasions across one or a few days[19], and more extended longitudinal research gathers information on discrete occasions often separated by a period of months. Time intervals have varied between different longitudinal studies, and study-specific periods of lag have rarely been justified explicitly in relation to a project's hypotheses.

It is particularly desirable to develop qualitative research across time [20] in addition to studies of those kinds. For example, partially structured interviews can be conducted on repeated occasions to learn more about perceptions of and reactions to evolving situations, possibly seeking the occurrence of self-sustaining spirals and evidence relevant to Fredrickson's 'broaden and build' developmental model (e.g., Fredrickson, 2001; Fredrickson & Branigan, 2005). That model envisages positive emotions broadening the scope of attention, cognition and action, with benefits accumulating across time. In studying possible changes of those kinds, it is desirable to explore mental processes and actions in depth through a series of detailed discussions. Similarly, qualitative investigations into processes of job crafting, as workers shape

their job activities to enhance wellbeing, can benefit from personalized, continuing information-gathering.

Social contagion theories are based on individuals interpreting verbal and non-verbal cues in face-to-face interaction, but work environments increasingly involve virtual team and remote working, where direct interaction is replaced by text-based services, email, messaging, and several types of social media. In those cases, emotions and affect are communicated less directly, and it is important to incorporate that change in our research methods (Barsade & Gibson, 2007). Does the development of group affective tone differ between face-to-face and virtual groups?

Research in this field has usually measured group affective tone as the average of individual scores, and the conceptual and methodological bases and implications of this procedure also need examination (van Mierlo, Vermunt, & Rutte, 2009). It is important to examine the degree of heterogeneity between different group members (e.g., Barsade et al., 2000; Bliese, 2000; Cole, Bedeian, Hirschfeld, & Vogel, 2011; George & King, 2007), perhaps in terms of measured variance in individual scores, the number of extreme-scoring members, or average deviation from the overall mean (Burke & Dunlap, 2002)[21]. For example, it is likely that a small number of individual group members who are in a particularly negative mood have an overall disruptive impact on processes within the group (Felps, Mitchell, & Buyington, 2006). Other methodological studies should compare the factor structure of compound indicators between individual and group levels (van Mierlo et al., 2009).

It is also important to expand thinking about the concept of wellbeing. Traditionally, research has examined hedonic forms of the kind illustrated in this chapter, but it is possible also to envisage additional aspects which are loosely based on Aristotle's (384-322 BC) ideas of 'eudaimonia' – a good, virtuous or fulfilled life. This notion has been developed by some psychologists into wellbeing as personal 'flourishing', variously considered by different scholars to embrace an active engagement in the world, experienced meaning or purpose in life, autonomous self-regulation, perceived competence in personally important activities, having vitality, and relating positively to others (e.g., Baumeister, Vohs, Aaker, & Garbinsky, 2013; Huta & Waterman, 2014; McGregor & Little, 1998; Ryff, 1989; Seligman, 2011; Waterman, 2008). As an aspect of wellbeing beyond traditional hedonic indicators, flourishing deserves more attention in the area of this chapter. For instance, for workers who flourish in terms of a high sense of personal accomplishment in their work, a strong association appears likely between job performance and that aspect of wellbeing. Previously applied hedonic measures of worker wellbeing do not cover all of that construct, and flourishing should be included in future studies.

Another desirable research development is an increased concern for non-linear relationships between wellbeing and performance (e.g., Tenney et al., 2016). For example, a curvilinear pattern might reflect the fact that above a moderately high level of wellbeing the two variables are negatively rather than positively associated with each other, parallel with Warr's (2007, 2017) Vitamin Model. Or perhaps job performance is not associated with wellbeing across higher levels of wellbeing, but the two are positively intercorrelated at low to moderate levels.

Academic research into possible influences on wellbeing and performance has failed to investigate practical processes of their joint optimization. Concern has often been directed at enhancing either wellbeing or performance, but rarely at improving the two together. There is now a great need for research into the processes and outcomes of interventions in work settings which are aimed to enhance both of them, rather than merely one alone. For example, interventions in terms of self-management training can build mental effectiveness in goal-setting, self-assessment and self-evaluation (Frayne & Geringer, 2000) in addition to improving task performance. These changes can yield personal rewards and positive experiences, linked to reduction in anxiety, improvement in mental health, and perhaps to improved job wellbeing (Richardson & Rothstein, 2008).

At the group level, social support and collective job crafting have been found to be associated with wellbeing and performance (Nielsen et al., 2017), and interventions to increase mutual support or collective job crafting may yield increases in both wellbeing and performance. Such interventions aim to increase resources widely within a group through knowledge-sharing, helping behaviors, and working towards overall group benefits, rather than merely gains for an individual. Whereas one individual worker's job crafting may have consequences which are negative, for instance from avoiding disliked tasks or competing with colleagues for activities which are most interesting, explicitly collective job crafting can be of wider benefit to the work-group as a whole, in terms perhaps of both wellbeing and performance.

Speculation about Cause and Effect

The chapter opened by noting that a positive association between worker wellbeing and job performance is widely expected. Subsequent sections have shown that across principal forms of wellbeing and performance the association is indeed positive, although it is small and depends on the operation of

moderating factors.

We have stressed that it is not appropriate to draw conclusions about causal processes from the evidence presented here. Firmly controlled experiments are required, but those have proved impossible within organizations, which must maintain their financial viability throughout the months or years of an experimental period. In any case, the limited experimental control which might be achieved is insufficient to rule out the impact of potential 'third variables', which can be responsible for observed associations between wellbeing and performance even despite statistical control of a limited number of variables. Although cross-sectional and longitudinal research are both important to map out a current or extended situation, they cannot provide the basis for causal interpretation.

Nevertheless, positive findings from laboratory experiments indicate clearly that changed wellbeing can modify behavior in the short term. Short-term experiences and activities are essential building-blocks of longer-term wellbeing, as multiple short-term feelings become aggregated across time, repeatedly recalled, and perhaps elaborated (e.g., Diener et al., 1999; Fisher, 2000; Kim-Prieto et al., 2005): life satisfaction is based on thousands of earlier short-term experiences stretching across years. Furthermore, positive wellbeing tends to be associated with traits of optimism, confidence, sociability and other dispositions which encourage goal-orientation and active involvement in situations which can themselves generate wellbeing. In subjective terms, personal experiences suggest to many people that wellbeing can sometimes make a difference to their job performance, as they observe how their positive or negative moods appear to be shaping their behavior. Both conceptual argument and personal introspection thus argue for some causal impact from wellbeing.

Many perspectives and decisions in daily life are based on imperfect evidence, and in those terms it is our belief that wellbeing does often influence performance. However, this influence can be relatively small, other variables are also causally important, and causality may run in other or multiple directions.

Footnotes

[1]Although the term 'work' often refers to a job, it is widely used in other settings – in respect of housework, social work, voluntary work, and so on. Researchers differ in their use of either 'work engagement' or 'job engagement'.

[2]In practice, that conceptual distinction is not always maintained in scales used to measure satisfaction, which can include items reflecting activated positive reactions rather than mere acceptance.

[3]The label 'performance' is usually applied to behaviors of a particular kind – those which are considered important and desirable within the investigated setting, in this case behaviors which are desirable in a job.

[4]Correlations with job satisfaction and job engagement were very similar between supervisor-, colleague- and self-ratings of task performance in research by Halbesleben and Wheeler (2008). For job engagement, Christian et al. (2011) reviewed the few available associations with task performance and organizational citizenship. Mean correlations across the two types of performance together were .31 for self-reports and .29 for other-reports. For emotional exhaustion, Mastenbroek, Jaarsma, Scherpbier, van Beukelen, and Demerouti (2014) found correlations with task performance of -.19 and -.18 respectively.

[5]Their two data-sets were very similar.

[6]Measured for example by 'I feel emotionally drained by my work'.

[7]However, longitudinal affect-behavior associations were generally non-significant in these studies.

[8]We are grateful to Wei-Chi Tsai for the unpublished information that mood ratings were context-free since participating sales agents can work at any time of day.

[9]A high proportion of publications fail to provide precise details of when information was collected. It appears that in most cases (apart from in longitudinal studies) behavior has been investigated through information about a period (often of unspecified duration) in the past. Analyses of cross-sectional findings therefore often concern current wellbeing in relation to behavior at an earlier time.

[10]In part, the smaller size of longitudinal associations might be attributed to the duration of interval between measurement of the two variables, since correlation sizes are found to be smaller as time lag increases (e.g., Riketta, 2008).

[11]'Third' variables in the sense that they are additional to the two in a bivariate study. Taking a now-unfashionable behaviorist view, Skinner (e.g., 1969) argued that feelings are mere accompaniments of behavior, and that both are the products of common environmental variables.

[12]However, knowledge often expands through the accumulation of slightly different sets of findings, each of which lacks some important controls but which as a whole widen the possible confounds that have been held constant.

[13]Although these processes are desirable in many job situations, that is not always the case. For instance, more rapid mental activities often rely on the use of simple heuristics which can be inappropriate in many detailed tasks.

[14]On the other hand, negative manipulations have resulted in more variable outcomes (e.g., Davis, 2009).

[15]This comparison may be confounded by the use of different indicators of performance – supervisor-ratings for managers and actual output for non-managers.

[16]The chapter's account of affect studies has sometimes described a measure as 'activated', although activation level was not explicitly discussed in the published report. In those cases, the 'activated' label has been applied after studying the items presented in the source publication.

[17]One possibility is that measurement reliability is increased by aggregating individual scores.

[18]Several variables treated in one publication as correlates of performance in addition to wellbeing might for different purposes also be viewed as mediators (e.g., Tenney et al., 2016).

[19]However, diary studies have rarely focused explicitly on within-person changes during their period of study.

[20]Qualitative approaches can also be justified on wider grounds as well as in this particular respect (e.g., Pratt & Bonaccio, 2016).

[21]Researchers into organizational culture have emphasized the notion of culture 'strength' – the level of agreement between members of an organization (e.g., Schneider, Ehrhart, & Macey, 2013).

Optimal Levels of Happiness

By Robert Biswas-Diener, Portland State University and Noba, & Christopher W. Wiese, Purdue University

Abstract

In the post-material era, people are increasingly focusing on the pursuit of happiness. This popular interest has been met by a growing number of authors and interventionists who promise routes to happiness. In large part, these avenues to the good life are anchored in the results of scientific studies. Here, we offer the caution that there may be an optimal level of happiness. While it is true that happiness is widely beneficial, there is also a growing body of research suggesting that it is not always beneficial for all people. In this chapter, we define happiness and review the literature suggesting that more nuance discussion is needed. We focus on three ways that happiness might be sub-optimal, including mood dysregulation (being happy regardless of circumstance), complacency (curtailing effort), and affect imbalance. We conclude by discussing three contexts that interventionists and policy makers ought to consider when promoting happiness. These include attention to happiness in specific life domains, distinguishing between short and long-term happiness, and a deeper appreciation of how cultural factors affect the pursuit and experience of happiness.

Keywords: Optimal levels; happiness; well-being; interventions

Everyone makes attributions. We believe our neighbor is a jerk, our spouse is generous, and that our pet dogs are loyal. Nowhere are these attributions more prevalent, perhaps, than in the context of happiness. Someone on holiday in Jamaica? Happy. Someone recently divorced? Unhappy. Someone whose team just won the championship? Happy. Someone who was in a minor collision on the way home from work? Unhappy. Interestingly, there is an unspoken assumption that happiness is the preferred emotional mode. Most of us would prefer to see more Jamaican vacations and sports wins and fewer divorces and fender benders. Simply put, we all want to be happy (Lomas, 2016). In fact, people—especially those living in Western or industrialized cultures-- treat happiness largely as they treat money: with an appetitive attitude. Indeed, Hobbes described happiness as the fulfillment of our human appetites (Kitanov, 2011). Just as people tend to desire more money, so too do they tend to desire more happiness. But, should they?

The money metaphor is instructive. Results of research on economic conditions suggest that national wealth is associated with better environmental policy, infrastructure, education, and social justice (Biswas-Diener, Diener, & Lyubchik, 2015). Similarly, very wealthy individuals appear to experience a high quality of life (Diener, Horwitz, & Emmons, 1985). Despite the appeal of money, it should be noted that it is not the wealth itself that confers benefits but the possibilities it represents. Money can, for example, be used to purchase rewarding experiences (Van Boven & Gilovich, 2003) or can be used altruistically (Aknin et al., 2013). On the other hand, materialism—placing too heavy an emphasis on the importance of money—appears to be toxic to happiness. We can see, therefore, that it is not that having (or not having) of money, itself, that is good, but—rather—the potential psychological benefits are to be found in our perceptions of money and in how we use it (Diener & Biswas-Diener, 2008). It may be that happiness represents a similar case. It may be that happiness is generally, but not perfectly, beneficial. Hence, it makes sense to wonder if a person can have "too much happiness."

The question of optimal levels of happiness is important in the modern context. We live in a post-materialist era in which large numbers of people are able to focus on happiness as important areas for personal development. This trend can be seen in the rise in popularity of the positive psychology movement (Seligman & Csikszentmihalyi, 2000) both among researchers and consumers. The sales of happiness related self-help books are further evidence that many people view happiness as highly desirable (Bergsma, 2008). This behavioral trend is echoed in survey results showing that people from widely differing cultures all believe that happiness is an important life outcome (Diener & Oishi, 2000). Further, there is increasing evidence that happiness is directly malleable – either through designed interventions (Tay & Kuykendall, 2013) or through deep brain stimulation (Synofzik, Schlaepfer, & Fins, 2012). We are entering an age where happiness is both highly valued and can be easy induced. Therefore, it is important to take a step back and question: Is there a downside to happiness?

In this chapter, we begin by stepping back – Defining first what is meant by happiness. There are a

variety of definitions of happiness and it is important that we define the boundary conditions of our discussion. Next, we elaborate upon what is meant by 'optimal levels.' Specifically, optimal levels of happiness may or may not result in detrimental outcomes and we discuss the forms in which these relationships can take. We build upon this foundation by examining what is currently know about optimal levels of happiness and present considerations for those looking to take the next steps in this endeavor. It is our hope that this chapter may be informative to those looking to understand the potential downsides of happiness and provide important considerations to those looking to extend the existing literature.

What is Happiness?

The question of whether there can be "too much happiness" hinges, in large part, on definitions of this elusive concept. There are a variety of research traditions that address happiness. Perhaps the most widely known is that of subjective well-being (SWB; Diener, 1984). SWB is comprised of three separate but related elements. These are positive affect, negative affect, and life satisfaction. At the heart of SWB is the notion that happiness is a subjectively experienced phenomenon, and that it includes both affective and cognitive appraisals of life. A happy person, according to the SWB framework, would be someone who feels generally satisfied with her life, experiences a preponderance of positive emotion and only occasional and appropriate negative emotion.

By contrast, there are a number of lines of research that focus more broadly on well-being, and which include what are, arguably, more objective phenomena. Perhaps the best-known example is psychological well-being (PWB; Ryff & Singer, 1998). Psychological well-being includes mastery, autonomy, relatedness, growth, self-acceptance, and meaning. A happy person, according to this framework, would be someone who has a sense of competency, balances autonomy with high quality relationships, experiences opportunities for personal growth, accepts herself, and enjoys a sense of being engaged in meaningful goals.

Recently, it has become *en vogue* in the field to classify these two types of approaches to studying happiness as if they represent 2 distinct happiness concepts. These include "hedonic" happiness, which emphasizes the affective dimension, and "eudaimonic" happiness, which emphasizes the objective functioning of the individual (Ryan & Deci, 2001). For an in-depth discussion of this topic see Keyes and colleagues (2002) and Kashdan and colleagues (2008). For our purposes in this chapter, we will largely confine our discussion of optimal levels of happiness to the subjective, emotional aspects of the topic. In part, we do this because a comprehensive coverage of every model of well-being is beyond the scope of any single work. That said, we will give brief coverage to both, including attention to life satisfaction (a cognitive dimension of happiness).

Regardless of the specific definition, it is important to note that research from all traditions support the idea that happiness does not just feel good; it is good. That is, happiness confers tangible benefits in a wide range of domains. Reviews examining the hedonic tradition show that, across different study types (cross-sectional, experimental, longitudinal) and across different domains (health, work, and relationships), those experiencing more positive emotions tend to live longer and healthier lives (De Neve, Diener, Tay, & Xuereb, 2013; Lyubomirsky, King, & Diener, 2005; Pressman & Cohen, 2005). Similarly, Ryan and Deci (2001) argue that eudaimonic experiences of happiness are, by definition, beneficial. When people experience growth, self-acceptance, or connectedness with others, for example, they are experiencing high functioning. As evidence, Ryan and Deci (2001) review research linking physical health to eudaimonic states. In both eudaimonic and hedonic frameworks these benefits appear to be consequences of happiness as well as causes. Thus, happiness can be seen as a means as well as an end.

What is Optimal?

The aforementioned literature on the benefits of happiness are from studies that assume the relationship between happiness and other outcomes are exclusively linear. It is only recently that researchers have explored the potential downsides of happiness and employ the analytic techniques that could detect such a relationship. Non-linear relationships can take on many forms; however, we are concerned with only two in our discussion of optimal levels of happiness. First is what is commonly referred to as the inverted-U shaped curve. This curve (Figure 1) represents the 'too much of a good thing' hypothesis, where happiness is beneficial for an outcome only until a certain point, after which happiness actually becomes detrimental. Figure 1 also shows a less severe version of the curve in which there are diminishing returns. With the diminishing returns curve, happiness reaches an optimal level, but higher level of happiness do not necessarily detract significantly from the outcome of interest. Both theoretical curves indicate optimal levels of happiness, however, they differ in terms of what happens after happiness reaches an optimal level.

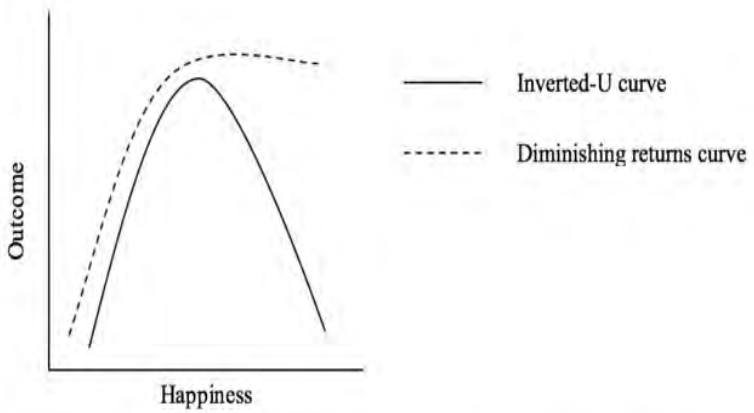

Figure 1. *Illustration of the different types of curvilinear relationships between happiness and other outcomes*

How Can Happiness Be Bad?

For as popular a topic as happiness is, there appears to be a conspicuous absence of cautionary restraint regarding the topic (Kashdan & Biswas-Diener, 2015). Although happiness feels good, and is associated with a variety of benefits, we know little about how much happiness is optimal, and for whom, and when. As noted earlier, the research evidence seems to indicate that happiness is always beneficial, and this is also true of popular press books. An example of this can be seen in Achor (2010), "We can all reap the benefits of the happiness advantage if we work hard enough at it. Remember, happiness is not just a mood—it's a work ethic" (p. 50). This view of happiness leads one to question: How can happiness be bad? To answer that, we discuss three different possibilities that bring the unilateral goodness of happiness into question.

Affect-as-Information Theory. Among the most highly cited theories in emotion research is "mood as information" (Carver, 2003; Schwarz & Clore, 1983). This theory emphasizes the idea that mood states offer useful information to those experiencing them on how to respond to their environment. Anger, for example, is a signal that an individual's person, group, property, ideals, or love ones are under immediate threat (Kashdan & Biswas-Diener, 2015). Similarly, happiness can be a signal that no such threats are present and that it is safe for a person to be more sociable, exploratory, or relaxed (Ito & Cacioppo, 1999; Fredrickson, 2001). When modern self-help gurus advocate more happiness, they often miss the informational value of emotion. They operate from the premise that negative moods feel bad, should be avoided, and can be side-stepped through mental and behavioral intervention. By the same token, positive moods can be amplified and extended through similar intervention. In both cases—positive and negative moods—the idea of artificially promoting one state, regardless of context, may be encouraging a process that divorces people from an important channel of information about the world. Hence, individuals who are 'too happy' may be overlooking important information, dampening their ability to function personally and socially.

Valuing Happiness. Another way happiness can be bad is if individuals place too much value on it. Mauss and colleagues (2012) present the case that individuals who value happiness too much may set unrealistic happiness goals. Ultimately, when they fail to achieve these unreachable goals, they experience feelings of disappointment and sadness. In a series of two studies, Mauss and colleagues (2011) found evidence for this effect such that those who valued happiness actually experienced less positive emotions and more negative emotions. Valuing happiness too much may also come at a price to one's social relationships. Mauss and colleagues (2012) demonstrated that when individual value happiness (defined as personal gains) too much, they a bound to destroy social connections leading to feelings of loneliness. They found evidence of this through both self-report and salivary measures. Taken together, these studies offer potential nuance to the "happiness is beneficial" narrative.

Affective Forecasting. The last way through which happiness could have adverse consequences is through errors in affective forecasting. When projecting future emotional states, individuals tend to underweight the potential impacts of negative events, believing instead that tomorrow will hold a bright

future (Schacter & Addis, 2007; Sharot, 2012). This optimism is, in part, functional – as it helps individuals persevere through difficult times in hopes for a better tomorrow. However, much like valuing happiness too much, these expectations could act as a double-edged sword (O'Brien, 2013). Individuals tend to hold onto an optimistic attitude even when there are several signs to the contrary. Hence, when that better future does not come, they are often left discouraged and frustrated.

Evidence of Optimal Happiness

With these three possibilities in mind, we now move to reviewing the existing evidence for optimal levels of happiness. Although research on this topic is relatively new, we believe that there are three clear trends attempting to tackle this issue: Mood dysregulation, nonlinear happiness, and balanced happiness.

Mood Dysregulation. There is a substantive rationale for inquiring about a potential optimal level of happiness. The most obvious point of reflection on this topic is to be found in instances of mood dysregulation. People suffering from bi-polar disorders, for instance, often experience intense positive affect in a disruptive way (Gruber, Mauss & Tamir, 2011). People experiencing mania may be likely to take risks or act in inappropriate ways that are damaging to themselves or those they care about. In a review of clinical research literature Gruber and colleagues (2011) conclude, "I argue that troubled emotional functioning in bipolar disorder might be explained by an unrelenting experience of heightened positive emotions regardless of the external context…. In fact, feeling 'too good' may actually be detrimental" (p. 362). However, evidence of mood dysregulation is not limited to those with clinically diagnosed psychological disorders.

Another line of research on affect regulation comes from Diener and colleagues (1991). They examined the effects of various cognitive strategies on affect regulation across five studies. They discovered that the mental strategies people use to amplify happiness might have a psychological price. For example, cognitively amplifying positive affect can also have a spillover effect such that it amplifies negative affect as well. This dovetails with research showing that people with clinical depression who attempted to dampen negative emotions also showed diminished capacity to react expressively to amusement (Chentsova-Dutton, Chu, Tsai, Rottenberg, Gross & Gotlin, 2007; Chentsova-Dutton, Tsai & Gotlib, 2010). Although the research on this topic is relatively small, it appears that effortful regulation strategies such as dampening and amplification are "blunt instruments" in that people may not be able to regulate either positive or negative affect without also regulating the other.

Unbridled Happiness. Researchers have also begun to investigate the potential nonlinear relationship between happiness and several interesting outcomes. To the best of our knowledge, Oishi and colleagues (2007) were the first to directly raise the issue of linear versus non-linear benefits of happiness. They provide analyses of social survey and quasi-experimental data on the association of happiness with a variety of outcomes. The lion's share of their scholarly attention is found in two areas: income and academic performance.

With regards to the former, they reviewed a wide range of evidence showing that moderate, but not consummate, happiness is associated with higher income. For example, using data from a long-term longitudinal study of Australians they found that people who were a 4 out of 5 on a measure of life satisfaction enjoyed higher outcomes than did those who were a 5 out of 5. This same finding was replicated in a longitudinal study of students attending the University of Illinois. In this case, students who were a 4 out of 5 on cheerfulness made more money two decades later than did their happier counterparts. This trend—that happy people make more money than do very happy people—emerged again and again in nationally representative samples in Germany and in the United Kingdom.

In addition to income, amount of positive affect also appears to be associated with academic performance. Specifically, Oishi and colleagues (2007) evaluated a variety of academic, social and psychological variables among University of Illinois students. To do this, they computed an affect balance score by dividing positive emotional experiences such as joy, affection, and contentment by negative emotional experiences such as anger, sadness and guilt. They found that those who were in the top quintile for affect balance ("very happy") reported the highest levels of gregariousness, close friendships, self-confidence, energy, and spent the most time on romantic dates. By contrast, those who were in the 4th quintile ("happy") had the highest grade point averages, the best class attendance, had the best balance of positive to negative life events, and were the most conscientious.

Although Oishi et al (2007) represents a large-scale attempt to demonstrating the nonlinear relationship of happiness, several smaller scale studies have also attempt to answer this question. Recently, there has been increased interest on this topic in the organizational sciences. Baron, Tang, & Hmieleski (2011) showed that entrepreneur's positive emotions could eventually lead to a downturn in firm performance. Interestingly, the severity of the downturn was more significant for smaller firms than larger

firms. Relatedly, Lam Spreitzer, and Fritz (2014) found an inverted-U shape curve between positive emotions and prosocial behaviors at work. These researchers subscribe to the idea that too much happiness leads to complacency. If the perception is that things are going well, there is no need to be more financially successful or engage in prosocial behaviors. Hence, some have argued that the key to avoiding this downturn is a balance of the positive and the negative.

Affective Balance. Could the key to optimal levels of happiness be a mix between positive and negative feelings? Many researchers have tangentially touched on this issue by examining the effects of ratios of positive to negative experience (e.g., Meeks, Van Haitsma, Kostiwa, & Murrell, 2012; Fredrickson & Losada, 2005; Gottman & Levenson, 1992). Rather than charting boundary conditions, however, these researchers were primarily interested in the finding that ratios need to favor positivity in order for people to function well. However, there have been some notable exceptions. A study conducted by Friedman and her colleagues (2002) assessed outcomes, such as self-deception, aggressiveness, and hypomanic symptoms, of 72 people who had above average emotional balance ratios and determined there was little support for "too much happiness." Even so, this is only a single study, and not without its limitations. It could be that the average affect balance score was not sufficiently high to reach a threshold for "too happy." Alternatively, it might be that the outcome variables of interest were not those most likely to capture the "too much happiness effect." Specifically, the researchers were looking for instances in which happiness is actually negative for the person experiencing it. It may be that high levels of happiness remain beneficial, but less beneficial than are moderate levels of happiness.

Hence, it is not too surprising to find other studies using affective balance have found significant effects. Specifically, Regu, Sousa, Marques, and Pina e Cunha (2012) were concerned with testing whether a balanced positivity ratio is necessary for creativity such that if one is too positive, they may not be creative. Indeed, they did find that this was the case – those with an excessively positive ratio were less creative than those with more balanced ratios. Although Barker, Howard, Galabos, and Wrosch (2016) did not use a positivity ratio, they found the happiest students who experienced some negative emotions had the highest GPAs. In fact, during semesters when negative emotions were below average, the happiest students had lower GPAs than those with lower positive emotions.

Considerations

Thus far, we have laid down the conceptual underpinning of why happiness could be a detrimental and reviewed the existing evidence on the topic. In this next section, we take a look to the future and provide several considerations for those interesting in optimal levels of happiness. Specifically, we discuss how optimal levels may depend on life domain, short- vs. long-term happiness, intensity vs. frequency, and culture.

Life Domain. Oishi and colleagues (2007) conducted many analyses whose results suggest that there may be an optimal level to happiness. Interestingly, the majority of their results point to achievement oriented domains as being likely contexts in which the advantages of additional happiness are non-linear. In their examination of university students, for example, the happiest students seem to have the highest scores for social relationships, confidence and energy, while the next happiest group showed superior academic achievement. This is in line with prior research suggesting that the variable that best distinguishes the happiest and least happy people is the presence of high quality social relationships (Diener & Seligman, 2002).

In fact, Oishi and colleagues (2007) analyzed data from the World Values Survey and found an optimal happiness effect (non-linear) for achievement domains but not for social domains. A variation of their findings is presented in Table 1. As can be seen, happiness appears to be generally beneficial but the very happiest people do not perform quite as highly as do happy people. This effect holds for both men and women.

Table 1. ***Outcomes by Level of Satisfaction***

	Highest Income	Highest Education	Most Political Action	Most Volunteerism	Highest Relationship Satisfaction
Life Satisfaction (1-10)	9	8	8	10	10

These points raise the issue of one possible way that too much happiness might interfere with functioning in achievement oriented domains. Namely, through cognition. Researchers have noted stark

differences in the thinking styles of happy and unhappy people (Lyubomirsky & Ross, 1997). Baumeister and colleagues (2007) noted that emotions can deleteriously influence behavior by interfering with optimal cognitive processing. For example, researchers have found that happy people are more likely to perceive less risk (Haase & Silbereisen, 2011) and more likely to be susceptible to false memories (Storbeck & Clore, 2005). Further, research reveals that people in a good mood perform worse than others on tests of moral reasoning (Zarinpoush, Cooper & Moylam, 2000) and make worse estimates of correlation (Sinclair & Marks, 1995).

It is possible that the potentially negative impacts of positive affect on cognition are less relevant to the social arena. Indeed, Oishi and colleagues (2007) did not report an optimal level of happiness for social domains. Although the strong link between high quality relationships and happiness is often reported in research, little is known about how the quantity of relationships relates to happiness. It may be that very high levels of happiness have a direct and causal influence on relationship maintenance. Happy people appear to be more sociable and connected with others (Lyubomirsky, King, & Diener, 2005). This does not mean, however, that more time socializing is associated with greater happiness dividends in a linear fashion. In fact, Diener and colleagues (2008) found evidence for diminishing marginal utility of time spent socializing.

Short- vs. long-term happiness. Another consideration in the context of optimal levels of happiness is the trade-offs between short-term and long-term happiness. The recent focus on hedonic (emotional) and eudaimonic (non-emotional) aspects of well-being may have distracted from attention to timeframe. Historically, researchers have examined momentary happiness (Scollon, Diener, Oishi, & Biswas-Diener, 2004), frequency of happiness (Schimmack & Diener, 1997), and a continuum of happiness that includes the past, present and future (Pavot, Diener, & Suh, 1998). For instance, Wirtz and colleagues (2003) examined anticipated, experienced, and recalled happiness among college students during and around the period of their spring break.

It may be that the answer to the question of whether there can be too much happiness depends upon whether one is referring to short term or long term happiness, or to the trade-offs inherent between them. For instance, a person experiencing high satisfaction with her grades may choose to study less than someone with only moderately high satisfaction. In essence, she would be counterbalancing short term happiness (current level of satisfaction) with estimated future levels of happiness. The way that people allocate resources and make decisions in the short and long term is likely of crucial importance to the idea of optimal happiness in achievement oriented domains. Initial research is suggestive that people differentially preference pleasure in the short term, and meaning in the long term (Kim, Kang & Choi, 2014).

Intensity vs. Frequency. One important consideration in the question of optimal happiness is related to the question of "what is happiness?". Indeed, if happiness is defined as meaning in life then the idea of too much meaning may be less sensible than if happiness is defined as emotion. As happiness research was becoming established in the 1980s and 1990s researchers were interested in which aspects of emotionality appeared to capture this elusive concept best. Research revealed, for instance, that people who experience intense negative emotions are also more likely to experience intense positive ones (Diener et al., 1985; Larsen, Diener & Emmons, 1986). However, positive and negative affect does not often co-occur at high rates of intensity (Diener & Iran-Nejad, 1986). Diener and colleagues (1991) concluded that frequency (but not intensity) of positive affect is both necessary and sufficient to produce high scores on a wide range of happiness measures. Pressman and Cohen (2005) suggested those experiencing high arousal positive affect might experience decrements in their physical health. This leaves open the question of whether—when considering optimal levels of happiness—it might be possible that happiness is "too intense" and/or that happiness might be "too frequent." Both considerations need further investigation.

Culture. Another consideration involves the question of who, specifically, is experiencing the happiness. Cultural factors may moderate the relationship between happiness and its benefits. Psychologists often research culture as divided into two broad categories: individualist and collectivist cultures (Triandis, 1998) and these roughly map onto so-called Eastern and Western societies. There is also a robust research literature on the ways that culture affects the experience of emotion (see, for example, Tsai, 2007; Suh, 2000). Researchers gave especially identified the ways that cultural leanings in cognition can affect emotional processes. For example, Lam and colleagues (2005) examined differences between individualists and collectivists with regards to affective forecasting (predicting future emotional states. They found that people from Eastern cultures (collectivists) were less likely to cognitively focus and were, therefore, less likely to experience the types of affective forecasting biases common in individualists. Other studies have shown striking cultural differences in the experience of emotion itself. For instance, Chentsova-Dutton and her colleagues (2010) investigated the emotional reactivity of Eastern and Western people diagnosed with clinical depression. They found that Westerners with depression showed dampened

responses to amusing films whereas their depressed Eastern counterparts did not. This suggests that Westerners have a different predisposition to distress tolerance and attempt to suppress their negative emotions. In doing so, they also suppress positive emotions. A similar pattern was not seen among the participants from Eastern cultures. Relatedly, the consequence of expression emotions may depend on the culture. Kitayama et al. (2015) found that expression of anger led to higher health risk in American samples, but lower health risk in Japanese samples.

Given these stark cultural differences in emotion, it makes sense to wonder whether a possible optimal level of happiness would be similar across cultural groups. In a related study, Ford and colleagues (2015) investigated whether motivation to pursue happiness produced different results for people from various cultures. They found that for people from the United States, high motivated to pursue happiness experience lower well-being but this was not the case with people from East Asia. The authors posit that the *how* of happiness pursuit may be implicated. Specifically, East Asian may be more likely to pursue happiness through social connectivity. This is important in the context of social relationships discussed above. It may be that Americans rely more heavily on cognitive strategies (those most likely to be affected by high levels of positive emotion) and that they are more likely to treat happiness as an achievement (a stance with, possibly, a greater link to optimal levels of happiness). Although there is no definitive study or line of research linking cultural factors to optimal happiness it is a worthwhile area of focus for future study.

Conclusion

In the end, charting the boundary conditions at which happiness is beneficial is an important undertaking. A small but growing body of research suggests that there may, indeed, be an optimal level of happiness. Our preliminary understanding of this threshold suggests that this might especially be true for achievement oriented life domains but not necessarily for social ones. In addition, it may be that the answer to the question of optimal happiness depends, in part, on type of happiness as well as on cultural factors. Differences in cultural background may be not be the only between-group factor influencing what is considered optimal. For example, Diener, Nickerson, Lucas, and Sandvik (2002) show that cheerfulness predicts job outcomes differently depending on financial background. Further, these differences were found with regards to a discrete emotion (cheerfulness) as opposed to evaluating general happiness, which is the focus of most of the existing research. Additional research is needed to sufficiently explore these areas and graduate students, especially, are encouraged to look to this as a largely unexplored area for investigation.

Regardless of specific thresholds, domains, or intrapersonal factors involved, it should be noted here that we are not suggesting overtly deleterious consequences of happiness. Indeed, a robust literature points to the conclusion that happiness is widely beneficial. We are merely arguing that there may not be a linear relationship between happiness and its many dividends. Rather, in some cases the very happiest people may fare slightly less well than do their moderately happy counterparts.

This area of happiness research is especially important in an era of increasing attention to happiness intervention and policy. As clinicians, coaches, and policymakers offer training programs and allocate resources to enhance well-being the cautionary note of optimal levels is worth consideration. This is especially true in the context of mood as information. Lay people ought to be encouraged to promote happiness when it is contextually appropriate. Too strong an emphasis on the pursuit of happiness or the experience of happiness when other emotions are more appropriate may, in fact, be deleterious. Further research on the question of optimal happiness will ultimately lead to more sophisticated, more individualized, and more effective interventions and policies.

Abstract

This chapter provides a guide to help people understand the complex effects that affect, a component of subjective well-being, might exert on various cognitive processes, including the use of abstract information, heuristics, stereotypes, and the effect of affect on persuasion and creativity. It reviews a number of different theories about how affect alters processing and suggests recommendations for future work to address current knowledge gaps. The key argument within this chapter is that affective states provide people with information. This information, when relevant, shapes how people think. Much of the research on this topic has focused on how happy or sad moods might shape processing by providing affective information. Specifically, happy moods indicate that one should feel safe, which results in people using more top-down, abstract information processing strategies. Sad moods indicate that one should be wary, which results in people using more bottom-up, detail-focused strategies. This view is helpful; however, it is an over-simplification. In particular, affective states are like basic ingredients. Just as the taste of an ingredient can change from one recipe to another, affective states can provide a range of different types of information depending on the context. This versatility is highly adaptive, but results in a greater need for specificity when it comes to understanding how affect alters thought.

Keywords: Affect, Mood, Persuasion, Creativity, Abstraction, Heuristics, Stereotypes

"To have a basic ingredient that can be prepared a million different ways is a beautiful thing."

~ Chef Alice Waters (as quoted in Baker, 2013)

When it comes to understanding how affect influences thought, people often ponder questions such as — Are people who feel happy easier to persuade? Does sadness foster creativity? Will anger result in people relying on derogatory stereotypes? Typically, people desire "yes" or "no" answers, but the truth is often not that simple. This chapter discusses how everyday affective experiences alter some common information processing tasks, including persuasion, creativity, and reliance on abstract concepts, heuristics, and stereotypes. The chapter reviews basic findings, different theoretical explanations for them, and the debates within the literature. It also provides recommendations for future research, in order to address some of the knowledge gaps. Throughout this process, we argue that many of the contrasting ideas within the literature can be resolved by viewing affective states as akin to basic ingredients in a recipe. Follow one recipe and affect will produce one outcome; but change the recipe, and it might produce another. As Alice Waters notes in the quote above, this is a beautiful thing – for such ingredients are highly versatile and functional.

Before discussing how affect influences thought, we want to first discuss what affect is. Affect is a key component of subjective well-being, in that subjective well-being includes "…specific feelings that reflect how people are reacting to the events and circumstances in their lives" (Diener et al., 2017, p. 87). This affective component is comprised of both positive and negative affect (Diener, Lucas, & Oishi, 2002). Two kinds of affective states are moods and emotions. Moods are diffuse, long-term affective states that generally have no salient cause; whereas emotions are more specific, short-term affective reactions that have a specific source (see Beedie, Terry, & Lane, 2005). Two core dimensions of affect are: valence (positive or negative), which signals whether something is good or bad; and arousal (activated or deactivated), which signals urgency (Russell, 2003; Storbeck & Clore, 2008). Much of the work on how affect alters processing centers on how commonly experienced, mild positive/happy and negative/sad moods alter thought. Given this focus, we will concentrate on this work, occasionally mentioning research on more specific emotional states when they are relevant.[1]

Background

Researchers have proposed a range of theories to explain why and how affect alters thought. If affect is akin to an ingredient, then these different theoretical approaches are akin to different styles of cooking (e.g., Italian, Mexican, Ethiopian). These theories have different flavors, but often share some core assumptions about how affect might operate as an ingredient. First, many theories assume that affect alters

information processing because it provides people with information that is experienced as being relevant to the task at hand (Schwarz, 2012; Schwarz & Clore, 1983, 2003). Second, if affect is experienced as irrelevant to the task, then affect exerts no influence. Thus, feelings are not constantly shaping thought. Third, variations in context can shape the meaning of this affective information (Martin, Ward, Achee, & Wyer, 1993). In sum, affect is not in every recipe, but when it is relevant to the recipe, the flavor that it adds will depend on what else is in the mix.

Theories about affect and information processing generally fall into one of three categories. These categories are theories that focus on affect as (1) interfering with people's mental capacity, which alters people's ability to think about the task, (2) providing a hedonic cue, which alters the extent to which people feel that they can cope with the affective consequences of the task, and (3) informing the task, which alters how people think about the task.

Affect: Interfering with Mental Capacity

In the 1980s and 1990s, researchers often argued that affect altered thought because it occupied working memory, thereby reducing people's cognitive capacity or mental resources (Ellis & Ashbrook, 1988; Mackie & Worth, 1989; Oaksford, Morris, Grainger, & Williams, 1996). Since then, research has cast substantial doubt on this idea (Bless, Clore, et al., 1996; Isen, 2001). For instance, positive affect, which was often thought to reduce capacity (Mackie & Worth, 1989), might not reduce it and could even enhance it (Gasper & Hackenbracht, 2015; Van Dillen & Koole, 2007; Yang, Yang, & Isen, 2013). Moreover, as this review will reveal, the effect of affect on thought often is context-dependent, with both positive and negative affects potentially inhibiting and promoting thought – something that would not happen if these effects solely were due to capacity deficits. Thus, capacity arguments are akin to a style of cooking that has gone out of favor.

Affect: Providing a Hedonic Cue

Some theories focus on the idea that affect shapes processing because it signals whether or not one can handle the affective consequences associated with performing the task. These theories, such as the *hedonic contingency hypothesis* (Wegener, Petty, & Smith, 1995) and the *mood-as-resource model* (Raghunathan & Trope, 2002) assume that when people perform a task, they might be concerned with how that task will make them feel. Affective states shape whether people are willing to endure the affective costs associated with performing the task (e.g., people in happy states might be less likely than those in sad states to perform a task that could dampen their good mood). The hedonic consequences of doing the task thus are the chief determinant of how affect will influence performance. Therefore, in this style of cooking, the concern is whether the outcome will result in too much or too little of a particular type of affective flavor.

Affect: Informing the Task

According to the *affect-as-information approach*, affective states provide people with information about their environments (Schwarz, 2012; Schwarz & Clore, 1983, 2003; see also *mood-as-input,* Martin et al., 1993). Happiness and some positive states indicate that the situation is safe and all is well; thus, people are free to explore and have fun (see Ashby, Isen, & Turken, 1999; Fredrickson, 1998). Sadness and some negative states indicate that the situation is problematic; thus people should be wary and diligent. Building on this idea, the *mood-as-general-knowledge approach* (Bless & Burger, 2017; Bless, Clore, et al., 1996; Bless, Schwarz, & Kemmelmeier, 1996), the *dual force model,* (Fiedler, Nickel, Asbeck, & Pagel, 2003; Fiedler, Renn, & Kareev, 2010) and the *cognitive-tuning account* (Schwarz, 2012) generally propose that because happy states signal safety, people in them feel that they can trust generalized knowledge structures (e.g., schemas, scripts, categorical information, procedural knowledge) as a means to organize and think about information. Happy states therefore encourage people to assimilate new information into their prior, generalized knowledge. Conversely, because sad states signal something is problematic, people in them feel that they should be wary of what they already know and focus on the current situation's details and data as a means to solve the problem. Sad states therefore encourage people to accommodate/update what they already know to adapt to the new information (see: Schwarz & Clore, 2007). This logic often underlies researchers' arguments that happy and sad mood states, respectively, promote the following processing strategies: top-down vs. bottom-up (Bless & Burger, 2017), loose vs. tight (Fiedler, 1988), assimilative vs. accommodative (Fiedler et al., 2010), global vs. local (Gasper & Clore, 2002), heuristic vs. systematic, abstract vs. concrete/detailed (Schwarz & Clore, 2007), satisficing vs. optimizing (Kaufmann & Vosburg, 2002), and knowledge driven vs. stimulus driven (Fiedler, et al., 2003). This view differs from the hedonic view in that affect informs how information is processed rather than shapes the degree to which people think that they can cope with the affective consequences associated with doing the task.

The hypothesis that happiness promotes reliance on general strategies and sadness promotes reliance on detailed strategies is akin to a chef's go-to style of cooking – it is a theoretical view that is

commonly employed and seems to work well for most occasions. But like all good styles of cooking, other versions of it have developed, including the *motivational dimensional model*, the *mood-congruent expectancies approach*, and the *affect-as-cognitive feedback* account. Each of these approaches has a different take on what type of information affect provides. We will discuss these views, as well as the hedonic views, in more depth below. In the process, we will review how affect influences various cognitive outputs, such as the use of abstract information, heuristics, stereotypes, and its effects on persuasion and creativity.

Cognitive Outputs

Abstract Information

Consistent with the view that happy states promote reliance on abstract/global concepts, numerous studies indicate that happy moods encourage a focus on the forest (i.e., abstract/global information); whereas sad moods encourage a focus on the trees (i.e., concrete/local information; Basso, Schefft, Ris, & Dember, 1996; Curby, Johnson, & Tyson, 2012; Derryberry & Reed, 1998; Johnson, Waugh, & Fredrickson, 2010; Moriya & Nittono, 2011; Rowe, Hirsh, & Anderson, 2007). For instance, relative to sad moods, happy moods encourage people to focus on the global shape of an image more so than the local elements that comprise it (Fredrickson & Branigan, 2005; Gasper, 2004a; Gasper & Clore, 2002). Similar preferences occur in language use with people in positive moods using more abstract than concrete language (Beukeboom & Semin, 2006; Forgas, 2011a; Isbell, McCabe, Burns, & Lair, 2013), framing actions in terms of why (abstract) rather than how (concrete) they were done (Beukeboom & Semin, 2005; Labroo & Patrick, 2009; Watkins, Moberly, & Moulds, 2011), and focusing on more abstract, idealistic rather than concrete, pragmatic arguments (Burger & Bless, 2016). Furthermore, these links might be bi-directional, in that construing action at abstract levels also can lead to positive affect (Freitas, Clark, Kim, & Levy, 2009).

Valence, however, might not be the sole determinant of these mood effects. According to the *motivational dimensional model of affect*, these effects might stem from the motivational qualities of the affective states (Gable & Harmon-Jones, 2008; Gable & Harmon-Jones, 2010a; Gable & Harmon-Jones, 2010b; Harmon-Jones & Gable, 2009). Affective states vary in the degree to which they are low or high in motivational intensity. In the motivational dimensional model of affect, affective states that are low in motivational intensity (affect that does not focus people on obtaining a goal, such as amusement), regardless of whether they are positive or negative, promote global processing because these states signal that one is free to explore. In contrast, affective states that are high in motivational intensity (e.g. affect that focuses people on obtaining a goal, such as desire or fear) promote local processing because they signal that one should focus on the goal (for a review see: Gable & Harmon-Jones, 2010b). Yet, there is disagreement concerning this view, in that others argue that motivational intensity might not be key, and instead one should focus on differences in affective activation to understand how affect alters attentional scope (Friedman & Förster, 2010, 2011). Regardless of which view one endorses, the key point is that affective valence, although important, is probably insufficient to capture how affect influences these processes. This work reveals that a more nuanced approach, which considers the many ways that affect can inform thoughts, is needed.

The finding that affective states can influence people's use of abstract information provides a crucial stepping-stone, in that it helps incorporate affect into a wide number of theories that discuss the importance of abstraction for both information processing and motivation (see Burgoon, Henderson, & Markman, 2013; Förster & Dannenberg, 2010; Fujita & Carnevale, 2012). For instance, abstract information plays a large role in construal level theory, which has implications for prediction, preference, and action (Trope & Liberman, 2010; for discussion see Bless & Burger, 2017). By establishing these connections, it becomes apparent that affect could serve as a key ingredient within a wide range of psychological processes.

Heuristics

Heuristics are rules of thumb that people employ to solve problems. If happy moods promote reliance on generalized knowledge, then happy moods should increase the use of heuristic reasoning strategies. Indeed, relative to sad and neutral moods, happy moods promote the use of the following heuristics: the fundamental attribution error (Forgas, 1998; Stalder & Cook, 2014), the halo effect (Forgas, 2011b; Sinclair, 1988), the ease of retrieval heuristic (Greifeneder & Bless, 2008; Ruder & Bless, 2003), the conjunction fallacy (Gasper, 1999; but see Jundt & Hinsz, 2002), and the use of processing fluency as well as other cues as judgmental heuristics (Forgas, 2015; Koch & Forgas, 2012; Wyland & Forgas, 2010).

Happy moods also reduce the degree to which people use systematic strategies. For instance, happy moods can decrease reliance on clear, logical decision rules (de Vries, Holland, Corneille, Rondeel, & Witteman, 2012; Elsbach & Barr, 1999), lessen one's ability to accurately estimate correlation

coefficients from graphic data (Sinclair & Mark, 1995), reduce reliance on Grice's principles for conversations (Koch, Forgas, & Matovic, 2013; Matovic, Koch, & Forgas, 2014), hurt syllogistic reasoning (Gasper, 1999; Melton, 1995; for exception see Radenhausen & Anker, 1988), and lessen the extent to which people use theory of mind when making judgments about others' mental states (Converse, Lin, Keysar, & Epley, 2008).

These differences in processing strategies also shape how mood alters evaluations of fairness (Hertel, Neuhof, Theuer, & Kerr, 2000). Sinclair and Mark (1991) proposed that happy moods promote attention to equality (50/50), whereas sad moods promote attention to equity (you get out what you put in) because equity is determined by systematically attending to the details. Indeed, when people learned that they had done 60% of the work, 84% of those in happy moods and 90% of those in neutral moods paid their partner using the equality norm; whereas only 33% of those in sad moods did so because they followed an equity norm (Inness, Desmarais, & Day, 2005). This focus on fairness also is evidenced by sad moods being associated with lower acceptance of unfair offers in the ultimatum game (Chung, Lee, Jung, & Kim, 2016; Harlé, Chang, van't Wout, & Sanfey, 2012; Harlé & Sanfey, 2007; Riepl, Mussel, Osinsky, & Hewig, 2016) and with making fairer offers relative to happy moods (Forgas & Tan, 2013). It should be noted that others did not find that sadness lowered acceptance of unfair offers, but rather disgust (Moretti & di Pellegrino, 2010) and anger (Srivastava, Espinoza, & Fedorikhin, 2009) did, presumably because these emotions signaled a negative view of the unfair offer (see also Harlé & Sanfey, 2010; for a meta-analysis on affect and justice, see Barsky & Kaplan, 2007).

At first glance, these effects suggest that positive affect might not be ideal, for it encourages the use of simple, heuristic strategies. This view, however, is a mischaracterization. First, reliance on heuristics does not always lead to poor decisions. Heuristics generally serve people well and are efficient (Ambady & Gray, 2002; Baron, 1990). For instance, happy moods promote reliance on small samples, which can be beneficial because it can lead to faster and more correct decisions (Fiedler et al., 2010). Heuristics also are a type of mental habit that allows people to devote their attention to other challenges (see Lyubomirsky, King, & Diener, 2005). Second, not all heuristics are promoted by happy moods. For instance, the anchoring heuristic occurs when individuals extensively think about the possibility that the anchor is correct. Research indicates that sad moods encourage people to think about the anchor, thereby increasing the anchoring bias relative to happy moods (Bodenhausen, Gabriel, & Lineberger, 2000; Englich & Soder, 2009; Estrada, Isen, & Young, 1997; for non-replication see Jundt & Hinsz, 2002). Third, as we will discuss later, when the situation is important and demands attention, happy moods promote complex thought (Isen, 2001; Schwarz & Clore, 2007). Thus, it might be best to view this work as indicating that compared to sadness, happiness promotes greater acceptance of generalized knowledge in relatively benign situations.

Persuasion

Research on mood and persuasion also suggests that happy moods promote less systematic processing strategies than sad moods. Numerous studies indicate that respondents in happy moods are less likely to be influenced by the strength of the persuasive agreements than those in neutral (Mackie & Worth, 1989; Worth & Mackie, 1987) and negative moods (Bless, Bohner, Schwarz, & Strack, 1990; Bless, Mackie, & Schwarz, 1992; Bohner & Weinerth, 2001; Schwarz, Bless, & Bohner, 1991; Sinclair, Mark, & Clore, 1994; for meta-analysis see Hullett, 2005). Moreover, when asked to write their own arguments, respondents in happy moods even produced less persuasive arguments than those in sad moods (Forgas, 2007; Forgas, East, & Chan, 2007). Thus, these data suggest that relative to neutral and sad moods, happy moods decrease the use of systematic processing strategies.

Yet, it is important to keep in mind that valence alone is not the sole determinant of these effects. Other characteristics of the state might matter. For instance, happy moods could have these effects because they signal certainty. Tiedens and Linton (2001) found that certainty emotions (anger, contentment, and sadness with certainty) resulted in people relying less on the quality of the message than uncertainty emotions (worry, surprise, and sadness with uncertainty; see also Rydell et al., 2008). If so, affective states are flexible ingredients, providing a range of information that could alter the processing of persuasive communications.

Moreover, there are contextual factors that also shape how affective states might provide information during the persuasion process. First, the effects of affect can depend on people's motivation and ability to process the persuasive communication. Research indicates that affect may alter how people process the message when people possess *moderate* levels of motivation and ability to pay attention to the message. However, when people possess either low motivation and ability or high motivation and ability, then affect alters how much people like the message (for reviews see Petty, Fabrigar, & Wegener, 2003; Petty, Wheeler, & Tormala, 2003). That is, instead of affect altering how people think about the message,

affect alters their evaluation of the message (see Petty, Schumann, Richman, & Strathman, 1993).[2] Not all research supports this view, however (see Albarracín & Kumkale, 2003; Batra & Stayman, 1990; Smith & Shaffer, 1991), but the findings bring up a critical issue – when does affect alter how a message is processed vs. how a message is evaluated?

Second, another key element to consider concerns the hedonic implications of the message. According to the *hedonic contingency hypothesis*, people in happy moods are motivated to sustain their positive feelings, resulting in them being uninclined to process mood-threatening messages that might make them feel bad (Wegener et al., 1995). In contrast, people in sad moods already feel bad. Hence, they are less concerned about processing mood-threatening messages because these messages would have limited affective consequences. Indeed, positive affect promotes message scrutiny when messages are hedonically rewarding (e.g. positive content, likeable source), but not when they are mood-threatening (Sinclair, Moore, Mark, Soldat, & Lavis, 2010; Turner, Underhill, & Kaid, 2013; Van Kleef, van den Berg, & Heerdink, 2015; Wegener & Petty, 1994; Wegener et al., 1995; see also Handley & Lassiter, 2002, for meta-analysis see Hullett, 2005). Similar findings also arise when the message is framed using a more positive, promotion-focused frame (e.g., attaining positive outcomes) than a more negative, prevention-focused frame (e.g., avoiding negative outcomes; Baek & Reid, 2013; Van Kleef et al., 2015). Thus, happy moods can promote message scrutiny as long as doing so is hedonically rewarding and not mood threatening.

Third, people in happy moods do not always focus on sustaining their mood. According to the *mood-as-resource model* (Das & Fennis, 2008; Das, Vonkeman, & Hartmann, 2012; Raghunathan & Trope, 2002; Trope, Ferguson, & Raghunathan, 2001), positive moods can operate as a resource that allows people to better cope with negative, self-relevant information (Lazarus, 1999). Specifically, people in happy states might be better equipped to cope with negative, self-relevant messages, because they have more positive affective reserves to draw upon to feel good when receiving negative feedback than those in negative moods. Consequently, positive moods increase the processing of self-relevant, negative information (Das & Fennis, 2008; Raghunathan & Trope, 2002). This effect is thought to occur because, when a negative message is highly self-relevant, the need for accuracy and knowledge can overpower the need to feel positively about one's self, thereby encouraging people to more thoroughly process the negative information.

At first glance, the mood-as-resource model seems to contradict the hedonic contingency hypothesis. The two views, however, operate under very different contextual situations. The mood-as-resource model predicts that happy states should encourage acquiring negative information because it is needed; whereas the hedonic contingency hypothesis suggests that happy states might encourage avoiding negative information when it is not needed. Indeed, Gasper and Zawadzki (2012) found that when help was needed, positive moods increased seeking out critical information in order to improve; whereas when help was not needed, negative moods increased seeking out critical information in order to ward off potential future problems (see also Albarracin & Hart, 2011; Trope & Pomerantz, 1998). Thus, positive affect can be a highly adaptive ingredient. It focuses people on acquiring negative information when it is needed, but ignoring it when it is not needed and perhaps mood threatening.

Lastly, mood can also influence persuasion by creating expectancies. According to the *mood-congruent expectancies approac*h (Ziegler, 2010, 2013, 2014; Ziegler & Diehl, 2011; Ziegler, Schlett, & Aydinli, 2013; see also work on *affective coherence*, Huntsinger, 2013b; DeSteno, Petty, Rucker, Wegener, & Braverman, 2004), one's mood state creates an expectancy for what should happen. Happy moods encourage people to expect the world to be a good place; whereas sad moods encourage people to expect it to be a bad place. When people encounter a message that is congruent with their expectations (e.g., happy moods and a trustworthy source, sad moods and an untrustworthy source), they are less likely to scrutinize that message than when they encounter a message that is incongruent with their expectancies (e.g., happy and untrustworthy source, sad and trustworthy source; Ziegler & Diehl, 2011). Thus, mood still provides information, but this information shapes what one expects, which in turn alters processing, rather than mood directly informing how one should process the information.

Clearly, there are many ways that affect can alter persuasion. As in the previous sections, researchers need to consider carefully how affect informs these processes. They also need to understand the context. Is the context promoting a moderate desire to process the information? Creating concerns about sustaining one's feelings? Activating concerns about learning negative and self-relevant information? Or altering one's expectancies? The answers to these questions should help determine how affective ingredients will influence persuasion.

Stereotyping

When people rely on a stereotype, they are using a pre-existing knowledge structure (specifically,

information about a group or category) to judge a group member rather than relying on individuating information. Because positive affect often promotes the use of generalized knowledge structures, it should promote reliance on stereotypes. Indeed, numerous studies indicate that people in happy moods are more likely to rely on stereotypes to make judgments than those in neutral or sad moods (e.g., Bless, 2000; Bless, Clore, et al., 1996; Bless, Schwarz, & Kemmelmeier, 1996; Bless, Schwarz, & Wieland, 1996; Bodenhausen, 1993; Bodenhausen, Kramer, & Süsser, 1994; Curtis, 2013; Forgas, 2013; Huntsinger, Sinclair, Dunn, & Clore, 2010; Isbell, 2004; Park & Banaji, 2000; Stroessner & Mackie, 1992). For example, Bodenhausen, et al., (1994) had participants in positive or neutral moods read an alleged misconduct case and make judgments of guilt. Half of the participants learned that the person belonged to a stereotyped group. Participants in a happy mood judged the target as more guilty when the stereotype was activated than when it was not, but participants in a neutral mood did not differentially judge the target. Additionally, some negative moods seem to counteract processes associated with stereotyping, for they can promote concrete thought, accommodation of new information, or a focus on local, individuating, or behavioral information (e.g., Bless, Schwartz, & Wieland, 1996; Bodenhausen, Kramer, et al., 1994; Bodenhausen, Sheppard, et al., 1994; Isbell, 2004; Krauth-Gruber & Ric, 2000; Unkelbach, Forgas, & Denson, 2008).

As noted in the previous sections, affect is a versatile ingredient. These effects might not stem from the valence of the affective information, but rather from other qualities associated with the affective information. For example, Tiedens and Linton (2001) argued that people might rely on stereotypes more when they feel certain rather than uncertain. They found that disgust, a certainty-based emotion, promoted greater reliance on stereotypes than fear, an uncertainty-based emotion. Similarly, anger, another certainty-based emotion, also increased reliance on stereotypes compared to sad and neutral moods (Bodenhausen, Sheppard, et al., 1994).

In addition to considering the information the affect provides, one also needs to consider how the meaning of that information might be context dependent. For instance, Dasgupta, DeSteno, Williams, and Hunsinger (2009) found that the effects of anger and disgust on bias depended on whether the out-group's stereotype was one that typically aroused anger or disgust. They found that disgust, but not anger, elevated implicit outgroup bias when the targets were gay (an outgroup that was more associated with disgust than anger). Moreover, anger, but not disgust, elevated implicit outgroup bias when the targets were Arab (an outgroup that was more associated with anger than disgust). Thus, emotions provide information about the degree to which an outgroup is a threat, but only if the emotion is applicable to one's existing knowledge about that group. Another example comes from Unkelbach et al. (2008). They asked respondents in happy, angry, or neutral moods to play a game in which respondents decided whether to shoot an un/armed person; some targets wore an Islamic headdress. Happy participants exhibited a bias toward selectively shooting more Muslim targets, and angry participants had an increased tendency to shoot all targets. This finding suggests that happy moods might promote reliance on stereotypes; whereas anger increases the general tendency toward aggressive responses. Additionally, it is possible for affective states to shape evaluations of in/out group members via the mood-congruent expectancies model. Ziegler and Burger (2011), for example, found that people engaged in more effortful processing when the outgroup's membership was incongruent, rather than congruent, with one's mood-based expectancies. Together, this work underscores how the characteristics of the task can shape the way in which affective ingredients function.

In addition to examining whether stereotypes are applied, researchers have examined how affect alters the extent to which respondents perceive groups as being homogenous. Compared to neutral or sad moods, happy moods often increase perceptions of group homogeneity (Park & Banaji, 2000; Queller, Mackie, & Stroessner, 1996; Stroessner & Mackie, 1992; Stroessner, Mackie, & Michalsen, 2005). This finding might occur because positive moods either decrease systematic thought, thereby preventing people from noticing differences, or because happy moods promote assimilation, which encourages seeing connections within the group. Indeed, positive moods promote broader inclusion of others into one's ingroup (Dovidio, Gaertner, Isen, & Lowrance, 1995; Ensari, Stenstrom, Pedersen, & Miller, 2009; Urada & Miller, 2000). This inclusion effect is interesting for it suggests that even though happy states might increasing stereotyping, they also increase the inclusion of others into one's in-group.

In sum, happy moods generally promote stereotype use, perhaps by conveying that it is fine to rely on generalized knowledge or by signaling certainty in one's existing knowledge. Along these lines, anger, another certainty emotion, also can promote stereotype use, especially with regards to groups that often spark feelings of anger. Yet, even though happy moods increase reliance on stereotypic knowledge, they also encourage people to be more inclusive and more likely to assimilate others into one's group. Thus, an interesting avenue for future research is to explore when people will rely on stereotypes and when they will instead focus on connections and similarities between oneself and others.

Creativity

Numerous researchers have examined whether mood influences creativity (for meta-analyses see Baas, De Dreu, & Nijstad, 2008; Davis, 2009; Lyubomirsky, et al., 2005). Much of this work indicates that happy states promote creative thought. The idea being that because happy states encourage a focus on abstract information, people in them are better able to make higher-order connections and links promoting novel thought (Ashby et al., 1999; Estrada, Isen, & Young, 1994; Isen, 2001; Isen & Daubman, 1984; Isen, Niedenthal, & Cantor, 1992). This idea is supported by the *broaden and build theory* of positive emotions (Fredrickson, 1998), which argues that positive states might promote creativity because they signal safety, and hence one is free to play and explore (Friedman, Förster, & Denzler, 2007). Indeed, people in happy moods tend to perform well on tasks that are interesting and fun (Hirt, Devers, & McCrea, 2008). In support of these views, three meta-analyses revealed that, compared to neutral moods, experimentally induced positive moods increase creativity, effect sizes: d = .30 (Baas, De Dreu, & Nijstad, 2008), d = .52 (Davis, 2009), d = .32 (weighted; Lyubomirsky, et al., 2005). Moreover, the link might be bidirectional, in that creativity and inspiration also promote well-being and happiness (Thrash, Moldovan, Oleynick, & Maruskin, 2014).

The effect of negative moods on creativity is more complicated. In his meta-analysis, Davis (2009) concluded that positive moods promote more creativity than negative moods. However, Baas et al., (2008) concluded that there were no differences between positive and negative moods. Additionally, both meta-analyses found no significant difference between negative and neutral moods. These null effects could stem from the fact that research on positive mood often focuses mainly on happy/amused mood states; whereas research on negative moods often encompasses a wider range of states, such as sadness, fear, anger, and boredom. These negative states vary dramatically in terms of the types of information they provide, which could obscure an overall meta-analytic effect.

One promising approach to address the role of affect in creativity is to move beyond valence and consider other relevant affective elements, such as whether the affective states reflect an approach or avoidance orientation (Baas et al., 2008; Friedman & Förster, 2010). Approach states, such as excitement, might foster creativity because they signal that it is safe to explore; whereas avoidance states, such as fear, might dampen creativity because they signal the need for vigilance, especially when they are high in activation. Indeed, Baas et al., (2008) found a meta-analytic effect indicating that fear hampered creativity (r = -.12, 95%CI: -.22 to -.02), and later, Byron and Khazanchi (2011) found meta-analytic effects indicating that both state ($r_{corrected}$ = -.028, 95%CI[-.051, -.012]) and trait ($r_{corrected}$ = -.166, 95%CI[-.186, -.147]) anxiety hindered creativity. Part of the problem Baas et al., (2008) ran into testing the role of approach/avoidance in creativity is that they could find studies that examined high, but not low, activation states. Since then, more research has been conducted using low activation states, and it too suggests that even these states might differentially alter creativity depending on whether they activate approach or avoidance motivations (Bench & Lench, 2013; Gasper & Middlewood, 2014; Mann & Cadman, 2014; Middlewood, Gallegos, & Gasper, 2016). Furthermore, a recent meta-analysis on the association between psychopathology and creativity also supports this view (Baas, Nijstad, Boot, & De Dreu, 2016; but see also Taylor, 2017). Thus, what makes affect an influential ingredient in the creative process might be whether it signals approach/avoidance rather than its valence.

In addition to understanding which moods promote creativity, another key question concerns how they do so. One argument is that the abstract thought promoted by happy moods facilitates connections and links, encouraging the production of creative ideas (Ashby et al., 1999). Additionally, mood might alter the likelihood of accepting creative ideas. Affective states that signal caution and vigilance might indicate that creative ideas or strategies are inappropriate, undesired, or too risky to employ. For instance, individuals in sad moods are creative when it is clear that creativity is appropriate and desired (Friedman et al., 2007; Gasper, 2003; Gasper, 2004b; Yamada & Nagai, 2015). Thus, some moods could have detrimental effects not because they influence the production of creative ideas, but rather because they influence the acceptance of them (de Vries et al., 2012).

In sum, approach states might promote more creativity than avoidance states, but clearly, more research needs to be done to confirm this hypothesis. In addition, research would benefit from employing an approach that considers not only what information the state is providing, but also how that information might shape the types of processes are involved in various types of creative tasks. That is, just as it matters in cooking *when* one adds an ingredient, so too might it matter at what stage of the creative process affect is operating.

Affect-as-Cognitive Feedback: Everything is Reversible

There is one last view of how affect alters processing that we want to discuss — the *affect-as-cognitive feedback account* (also called the *cognitive malleability approach*, for reviews see Huntsinger, Isbell, & Clore, 2014; Isbell, Lair, & Rovenpor, 2013; Ray & Huntsinger, 2017). This newer theoretical

perspective argues that happy and sad moods do not directly promote the use of one processing strategy over the other. Instead, affect provides information that signals whether one should use the accessible strategy. Happy moods signal all is well and operate like a go-signal, providing information indicating that it is okay to use whatever strategy is accessible. Sad moods signal that there is a problem and operate like a stop-signal, providing information that one should be wary of and not use whatever strategy is accessible. Proponents of this view argue that happy moods have promoted the use of abstract knowledge, heuristics, and stereotypes not because they promote these strategies per se, but because these global strategies are typically the accessible, default strategy.

To test this idea, researchers primed various processing strategies (global vs. local, heuristic vs. systematic) to make one strategy more accessible than another. When global/abstract/heuristic strategies were accessible, relative to sad moods, happy moods promoted the effects that were typically found in the literature, such as increased out-group homogeneity effects (Isbell, Lair, & Rovenpor, 2016), greater attention to global features (Huntsinger et al., 2010, Huntsinger, 2013a), increased use of category information as a basis for judgment (Hunsinger, Isbell, & Clore, 2012), greater adoption of accessible goals (Huntsinger & Sinclair, 2010), engaging in more creative thought, greater use of the conjunction fallacy, but less use of the anchoring heuristic (Huntsinger & Ray, 2016). More importantly, when detailed/local/systematic process strategies were accessible, ALL of these effects reversed. That is, when detailed processing strategies were primed, people in happy moods used less global, abstract processing strategies than those in sad moods did.

This work has at least two interesting implications. First, prior work that found reversals in mood effects (e.g. happy moods promoting local strategies and sad moods promoting global strategies), which might seem to contradict current wisdom, could have found these effects because the studies activated local, rather than global, strategies as a means to complete the task. Second, this work also provides an interesting explanation for why null results might occur. Specifically, null effects might arise when no clear processing strategy is accessible, for when this happens, happy and sad moods do not differentially alter processing (Isbell et al., 2016). Thus, affect might shape the extent to which people use accessible strategies, and if no strategy is accessible, then affect might not alter information processing.

A key question is whether this view really challenges past work – is it a revolutionary way of cooking? In the affect-as-cognitive feedback experiments, researchers first prime a processing strategy (e.g. global vs. local). In doing so, they actually might be activating procedural knowledge about how to perform the task. According to Bless & Burger (2017), accessible prior knowledge can include procedural knowledge. Thus, one could argue that these studies are merely changing what type of procedural/prior knowledge (e.g., global vs. local procedural knowledge) is accessible. Happy moods therefore are still increasing reliance on prior knowledge; it is just that the priming manipulation changes what kind of prior knowledge is accessible. If so, it is unclear if affect provides a signal about relying on prior, generalized knowledge or if it provides a signal about relying on accessible knowledge (as the affect-as-cognitive feedback account proposes). Regardless of one's take on this issue, the affect-as-cognitive feedback account makes the important point that the effect of affect on processing is highly malleable. That is, affect is a wonderfully flexible ingredient that adapts to the situation, producing a range of outcomes depending on the how it informs the context.

When the Effects Disappear

Lastly, it is important to keep in mind that all of these effects depend on whether affect is experienced as providing *relevant* information. When affect is irrelevant, it should not influence processing. Greifeneder, Bless, and Pham (2011) provide an excellent review of the factors that determine when feelings are experienced as relevant to various judgments. Presumably, many of these factors would apply to understanding when feelings are experienced as relevant to processing, but a systematic review is needed to confirm this hypothesis. In terms of when affect is irrelevant, research indicates that irrelevance can be achieved by either (a) altering the perceived source or meaning of the affective cues or (b) changing the situational or task cues in such a way to override the affective information (Albarracín & Kumkale, 2003; Bless et al., 1990; Bodenhausen, Kramer, & Süsser, 1994; Faraji-Rad & Pham, 2012; Friedman et al., 2007; Gasper, 2004a; Isbell, McCabe, et al., 2013; Ruder & Bless, 2003; Sinclair et al., 1994; van Reijmersdal, Lammers, Rozendaal, & Buijzen, 2015). In addition, the intensity of the affective state might matter. If the affect manipulation is too mild, affective cues might not be noticed and not employed; if affective cues are too salient, they might be viewed as task-irrelevant and not employed (Bohner & Weinerth, 2001). Indeed, Davis's (2009) meta-analysis revealed that mood effects were stronger for moderately intense affective states compared to mild or very intense states. The mood effects also were stronger when a cover story was present rather than absent, perhaps because a cover story enhanced the degree to which affect was experienced as task-relevant. These factors are not minor considerations, for if any of them are present, they can negate whether affective ingredients play a role in shaping thought.

Recommendations for Future Research

Recommendation 1: View Each Affective Ingredient as Providing Multiple Rather than Single Sources of Information

When research on affect and information processing began, the key focus was on the state's valence, but affective states possess other key qualities that can provide information. These include such factors as the state's underlying appraisal dimensions (Arnold, 1960; Clore, Ortony, & Foss, 1987; Frijda, Kuipers, & Ter Schure, 1989; Lazarus, 1991; Moors, 2009; Roseman, Spindel, & Jose, 1990; Smith & Ellsworth, 1985; Smith, Tong, & Ellsworth, 2014), motivational orientations (e.g., approach/avoidance, motivational intensity; Fischhoff, Gonzalez, Lerner, & Small, 2012; Gable & Harmon-Jones, 2008; Gasper & Middlewood, 2014; Lerner, Li, & Weber, 2013; Tiedens & Linton, 2001) arousal/activation level (Storbeck & Clore, 2008), and intensity (Hackenbracht & Gasper, 2013; Lench & Bench, 2015). In this chapter, we only scratched the surface through our discussions of how motivational intensity, approach/avoidance, and differences in certainty might underlie these effects. There are many other ways that affective ingredients could shape thought. For instance, Griskevicius et al., (2009) used evolutionary theory to hypothesize that fear would activate self-protection, resulting in one wanting to blend in and not stand out among others in order to be safe; whereas romance would activate the desire to differentiate oneself from others, resulting in one wanting to stand out among others in order to attract a mate. Using this reasoning, they predicted and found that people in fearful moods were more persuaded by messages about being part of the group; whereas those in romantic moods were more persuaded by messages about differentiating oneself from others (see also, Griskevicius, Shiota, & Neufeld, 2010; Keltner, Haidt, & Shiota, 2006; Ng et al., 2017; Sauter, 2010). This example nicely illustrates how other affective elements, in this case the potential evolutionary functions of affect, might shape the information that affective provides.

The fact that affect can have so many influences is a beautiful thing, but this versatility also creates ambiguity concerning what cue is responsible for the effect. Fear, for instance, could signal negativity, avoidance, uncertainty, a focus on the future, urgency, and need for protection. With so many dimensions to consider, it becomes very important to delineate which of these possible signals underlies the effect. Right now, researchers often theorize that if affective state "x" signals "y", it should result in "z". They establish that "x" produces "z", but often do not adequately test or acknowledge all the possible "y"s. The field would benefit by trying to establish what piece(s) of information (the potential "y"s) underlie the effect. It is only with this information that one can know when fear will function more like sadness (a negative emotion), hope (an uncertainty emotion), or excitement (a high urgency emotion).

Recommendation 2: Consider How Affective States Might Operate in Conjunction with One Another

Researchers should consider how two or more affective states might operate together to alter information processing. Affect inductions often create more than one state, such as when sad mood manipulations elevate anxiety or disgust (Westermann, Stahl, & Hesse, 1996). Yet, researchers often assume that only one state predominates, not taking into account other potential affective influences (Gasper & Danube, 2016). Multiple affective states can interact with each other to alter thought (Middlewood et al., 2016). For instance, emotional ambivalence (e.g., experiencing happiness and sadness at the same time) has been found to benefit problem-solving. Happiness promotes the exploration needed for creative solutions; whereas sadness promotes the systematic thought needed to evaluate them (George & Zhou, 2007; Kaufmann & Vosburg, 2002; Moss & Wilson, 2014; Rees, Rothman, Lehavy, & Sanchez-Burks, 2013; Rothman, Pratt, Rees, & Vogus, 2016; van Harreveld, Nohlen, & Schneider, 2015). Even though people might simultaneously feel multiple states, research is currently lacking concerning how these complex states function together to shape thought.

Recommendation 3: Develop Models that Delineate When Affect Would Influence Processing, Judgment, or Both

Researchers often distinguish between affect altering judgment (evaluations of some object) and processing (how people think). This review focused on how affect alters processing, but a close examination of this discussion reveals that sometimes affect might alter these various cognitive outputs via judgment. For instance, affect might alter how people use a stereotype to process information about a group-member or it could just alter one's judgment of the group-member (e.g., I dislike members of group x). Affect might alter the generation of creative ideas or it might influence the evaluation of the suitability of those ideas. Affect also might alter how a persuasive message is processed or one's liking of the message. But when does affect alter processing, judgment, or both? In the persuasion domain, researchers have begun to address this issue by arguing that affect alters how people process messages when motivation and ability are moderate and how they judge the messages when motivation and ability are either both low or high (Petty, Fabrigar, & Wegner, 2003; Petty, Wheeler, & Tormala, 2003). This model,

however, has not always worked, but at least it reflects an attempt to tackle this issue. The field desperately needs more theorizing that focuses on how the role of affect might change depending on the various stages and mechanisms that are involved within each of these various domains.

Recommendation 4: Examine to What Extent These Effects Extend to Naturally Arising Affective States and Traits

Most of the studies reviewed here examined how some type of manipulated affective state altered various cognitive outcomes. A few studies have examined how naturally arising state and trait affect might influence these outcomes, especially with regards to the processing of abstract information (Basso et al., 1996; Derryberry & Reed, 1998; Gable & Harmon-Jones, 2008) and creative thought (for meta-analysis see: Byron & Khazanchi, 2011). But our literature search revealed very little work examining these affects with regards to the use of heuristics (for exceptions see; Greifeneder & Bless, 2008, Hilbig, 2008; Riepl et al., 2016; also work exists looking at justice, see Barsky & Kaplan, 2007), persuasion (for exception see: DeBono, & McDermott, 1994), and stereotyping. Examining naturally arising state and trait affect is important, for these states might differ from manipulated affects in terms of the degree to which they seem relevant and salient – two qualities that could influence whether affect will alter thought (Gasper & Danube, 2016; Greifeneder et al., 2011). In addition, trait affect might not only alter processing, but also alter the meaning and relevance of state affect (Gasper & Clore, 1998). For instance, extroverted and neurotic individuals tend to differ in how much positive and negative affect they experience, and they also differ in how they view and use the information provided by positive and negative affective states (Augustine & Larsen, 2011; Rusting, 1999).[3] Thus, there is a clear need to consider how naturally arising state and trait affective influences might operate independently and together to shape the way in which information is processed.

Recommendation 5: Move Toward Greater Scientific Rigor and Openness

In reviewing this literature, another issue that deserves attention is replicability. There are many conceptual replications (many researchers doing the same type of work), but not many "exact" replications (conducting the same study), let alone preregistered replications (registering hypotheses and methods before conducting the study). The only preregistered replication of mood and processing effects that we could find was by Domachowska et al., (2016), which replicated the work of Gable and Harmon-Jones (2008) on how positive affects high in motivational intensity narrow attentional scope. In terms of judgment, Yap et al. (2016) sought to replicate the effect of mood on judgments of life satisfaction (Schwarz & Clore, 1983). They found rather small effect sizes relative to the original work. Even though there are many reasons why a replication study might fail to find an effect, these studies provide information relevant to determining the strength and scope of these effects, which is needed to understand the practical significance of these findings.

A related issue is that there is not a lot of work that clearly delineates the overall magnitude of these effects. With the exception of research on affective influences on creativity, meta-analyses for some of these effects are scarce and many were conducted prior to the availability of newer techniques to detect bias. The affect and creativity meta-analyses revealed that the effect size for positive affect on creativity ranged from d = .30 to .52 (see creativity section). Lench, Flores, and Bench (2011) conducted a meta-analysis that estimated the effect size of affect on cognition to be Hedges g = .24. This knowledge is important, for it suggests that many of the experiments on mood and processing might be underpowered. If a medium effect size is assumed (d = .50), then for an experiment that compares happy vs. sad moods, assuming 80% power, alpha = .05, two-tailed test, one needs a sample size of 128 people. If the effect size is closer to d = .25, then the sample increases to 506 people. Many of the studies reviewed here had 20 to 50 participants per cell, resulting in studies that are either somewhat underpowered (if d = .50, then estimated power is .70 assuming 50 participants per cell) to very underpowered (if d = .25, then estimated power is only .24). If the original studies are underpowered, then they might be difficult to replicate. Of course, it is important to keep in mind that because these meta-analyses examined very heterogeneous samples, the true effect size could be higher or lower depending on the study's characteristics. Nevertheless, it would be fruitful if researchers increase their sample sizes, preregister their hypotheses, and share their data, materials, scripts and laboratory practices given the extent to which individual differences and contextual cues can shape these effects. In other words, researchers should clearly document their affective recipes.

Concluding Remarks

To answer the questions posed in the introductory paragraph: Yes, it might be easier to persuade a person in a happy mood. No, sad moods do not necessarily foster creativity. And, yes, anger does seem to increase reliance on derogatory stereotypes. However, the likelihood of finding these effects depends on the context. Affective states are basic ingredients that can have a wide number of effects. This feature

makes them adaptive, versatile, and highly functional – but also can make their influence tricky to predict. At this point, researchers have developed some sound basic principles for understanding these effects: (a) affect provides information, (b) this information must be experienced as relevant to the task, and (c) individual, situational, and task characteristics can change the meaning of this information. These principles form a foundational recipe that people can use as a basis for understanding a range of different ways to approach this work. To move forward, researchers need to refine their affective recipes by asking questions that better assess and highlight the complex, interactive effects that affective states can have on information processing.

Footnotes

[1]This review focuses on the effects of mild, everyday feelings, not on clinical affective reactions (e.g. depression, mania, etc.). Everyday feelings sometimes produce effects akin to those found in clinical populations, but sometimes they do not.

[2]When people think about the message, moods can also influence persuasion by increasing the confidence people have in their thoughts (Briñol, Petty, & Barden, 2007; Petty, Briñol, & Tormala, 2002).

[3]In addition, there are many other individual and cultural factors that can shape how affect is experienced and interpreted, which in turn influences how affect functions (see: Avnet, Pham, & Stephen, 2012; Gasper & Bramesfeld, 2006; Gasper & Clore, 2000; George & Zhou, 2002; Kashdan, Barrett, & McKnight, 2015; Tamir, 2009; Tamir, Bigman, Rhodes, Salerno, & Schreier, 2014).

Abstract

Whether people can sustainably change their level of happiness has been a topic of much debate in the psychological literature, with some researchers suggesting that happiness change is futile and others suggesting that it is quite possible, even if challenging. The current chapter reviews the literature on the major sources of happiness including genetics, life circumstances, and intentional activities, pointing to evidence of both stability and malleability in happiness over time. Although happiness is stable over time, evidence suggests that changes in certain life circumstances and the effortful practice of intentional happiness-increasing activities can shift happiness. Research also suggests that increases in happiness are not only valuable because they make life more pleasurable, but also because they trigger successful outcomes in other important life domains (e.g., improved relationships, work, and physical health). Although research on the potential downsides of over-valuing happiness serves as a warning for the excessive pursuit of happiness, research on prioritizing positivity paints a healthier version of happiness-seekers who organize their daily lives around opportunities for greater happiness. Finally, intentional happiness-increasing activities—often called Positive Psychological Interventions—are discussed, including their mechanisms, moderators, and areas for future research. In sum, the research suggests that happiness change is possible, but not easy. Through persistent effort directed toward efficacious interventions, people can intentionally boost their happiness.

Keywords: happiness change, happiness stability, hedonic adaptation, happiness interventions, positive psychological interventions

Happiness is not something ready-made. It comes from your own actions – His Holiness the 14 th Dalai Lama of Tibet

It may be that trying to be happier is as futile as trying to be taller and therefore is counterproductive – Lykken & Tellegen, 1996

The two quotes above represent two schools of thought on the malleability of happiness. The first quote, from the Dalai Lama, asserts that happiness is a result of people's actions, providing hope that happiness is as changeable as behavior. In contrast, the second quote, from two authors of a classic paper on the genetic basis of happiness, asserts that trying to change people's happiness is as futile as trying to change their physical characteristics. A deep dive into the research on the various sources of happiness (e.g., genetics, life circumstances, intentional activities) provides support for both perspectives. That is, evidence suggests that happiness can change but that this change requires sustained effort and is difficult to maintain over time. Nevertheless, the prognosis on the malleability of happiness does not seem quite as grim as Lykken and Tellegen (1996) presumed. That said, even if people can become happier, questions remain about whether and how they should pursue this happiness. Thus, recent research has sought not only to answer the question "can people become happier?" but also "should people pursue happiness?" and, if so, "how can people effectively increase their happiness?"

Can People Become Happier?

Researchers cite many different types of evidence to answer the larger question of whether people's happiness can change. First and foremost, researchers explored whether genetics influence happiness (i.e., is happiness heritable?). The short answer is yes, but the longer and more nuanced answer is covered below. Secondly, researchers explored whether life circumstances (e.g., being rich, being male, or being married) are related to happiness. The resounding conclusion is that these types of circumstances are related to happiness, but not as much as conventional wisdom might suggest. People tend to adapt to emotionally evocative situations in their lives such that positive or negative events in people's lives elicit less intense positive or negative emotions, respectively over time, making any one event or circumstance less likely to permanently affect happiness (i.e., hedonic adaptation). Of course, there are variations on this theme that are discussed below. Even though genetics and life circumstances explain some differences in happiness across people, they do not explain the total variance, leaving room for other explanations that might be more under people's control (i.e., intentional activities).

Genetics

Most of the evidence pertaining to the genetic influence on happiness comes from behavioral genetics studies. The most common design is one in which researchers calculate the correlation in happiness scores between identical (monozygotic) twins reared together (those who share 100% of their genes) and between fraternal (dizygotic) twins reared together (those who share about 50% of their genes). If identical twins have a higher correlation in happiness scores than fraternal twins, a genetic influence of happiness can be inferred (i.e., happiness is considered to be heritable). The twin designs and associated analyses can be much more complex than the design just described and can yield more detailed information, but they all rely on comparisons of correlations between twins or siblings who share a certain amount of genes (see Genetics and Heritability chapters in this Handbook).

Across multiple studies in multiple samples, using multiple different measures of well-being, researchers have consistently estimated that happiness is about 40 to 50% heritable (e.g., Bartels & Boomsma, 2009; Røysamb, Tambs, Reichborn-Kjennerud, Neale, & Harris, 2003; Stubbe, Posthuma, Boomsma, & de Geus, 2005). That is, after correcting for unreliability, about 40 to 50% of individual differences in happiness across a population are due to genetics. Importantly, heritability is not deterministic. In one illustrative example, Røysamb, Nes, and Vittersø (2014) calculated difference scores between identical twins on an 11-point subjective well-being index. The absolute mean difference was 1.28, with 51.4% of twin pairs having at least a one point difference. This indicates that even two people with an identical genotype can still vary substantially in happiness.

The aforementioned studies measured one's global level of happiness at one time point and calculated heritability estimates at that time point. Other studies measured happiness across time, up to 10 years apart and found a strong correlation between individual's scores from time 1 to time 2 (.50 to .67, depending on the age of the sample with the older sample being more stable). Across three samples, researchers found that the stability of happiness (how correlated scores were from time 1 to time 2) was highly heritable—80% was accounted for by genetics (Lykken & Tellegen, 1996; Nes, Røysamb, Tambs, Harris, & Reichborn-Kjennerud, 2006). This stability could be interpreted to mean that any short-term changes in happiness due to life events or intentional activities will be short-lived, as one will return to their original happiness level over time (i.e., their "set-point"; e.g., Lykken & Tellegen, 1996). Notably, however, a quarter of people do substantially change in well-being over time (Fujita & Diener, 2005) and, despite the high genetic influence on the stability that does exist, there are still substantial within-twin-pair differences across time (Røysamb et al., 2014). For example, Røysamb and colleagues (2014) isolated one member of an identical twin pair who scored high (above 8.5 on a scale from 0 to 10) at time 1 and at time 2 six years later (showing stably high well-being). The means across this group of twins were 9.25 and 9.22 at time 1 and time 2, respectively. The means for their co-twins were 8.4 and 8.34, respectively. Thus, at some point, an environmental influence had set these twin pairs on stable yet different well-being paths.

In sum, given the heritability estimates of happiness, there is empirical evidence to support the contention that some people are born happier than others. That said, this so-called genetic "set-point" is not deterministic and there are environmental factors or perhaps intentional behaviors that can set people on different well-being trajectories. For example, Haworth and colleagues (2016) administered a multi-week positive psychological intervention in a sample of identical and fraternal twins and found that average well-being across the sample improved even though estimates of genetic effects remained consistent across time points. Future intervention studies with genetically sensitive designs would continue to illuminate the interaction effects between genes and environments on happiness.

Life Circumstances

If genetics do not completely predetermine happiness levels, environmental factors are likely at play. Conventional wisdom may suggest that people who are younger, richer, and more attractive would be far happier than those who are older, poorer, and uglier. Extensive research has explored how much stable life circumstances (e.g., income, age, physical attractiveness, or marital status) are related to well-being. Generally, these life circumstances do not explain as much of the individual differences in happiness as people might expect—researchers typically find that about 10-15% of individual differences in happiness are explained by their combined life circumstances (Diener, Suh, Lucas, & Smith, 1999). Notably, the estimate may depend on what type of well-being is being measured. For example, in a worldwide sample, 24% of the variance in life satisfaction, but only 5% of the variance in affect, was attributable to country-level differences (Tay, Chan, & Diener, 2014; Tay & Diener, 2011). Although people might consider 5 or 10% to be a nominal amount, it is not.

Correlations are difficult to interpret practically, and even small correlations can lead to meaningful differences in happiness across people (see Rosenthal & Rubin, 1982). For example, the within-country correlation between personal happiness and personal income is .17 (Lucas & Schimmack, 2009). Although this may seem small, Lucas and Schimmack (2009) noted that this yields a difference in happiness of about

0.75 standard deviations between people making $200,000 versus people making $10,000 a year and people making $200,000 were still at least 0.50 standard deviations happier than those making about $55,000 (the average income in the sample). Thus, although life circumstances do not explain as much of the variance in individual differences in happiness as people might expect, that does not mean that they do not meaningfully relate to happiness. In addition, much of the research is conducted on people who are meeting basic needs and thus we likely do not have a good estimate of how much changing income from poverty to subsistence may change someone's well-being. Indeed, in developing countries with the lowest incomes, the relationship between income and well-being is higher than it is in developed countries or even in developing countries with higher incomes, indicating that the lower your income, the more income increases will matter for your well-being (Howell & Howell, 2008). Likewise, we likely do not have a good estimate on how much marriage could change the well-being of someone who was utterly lonely before meeting their life partner. Thus, the effect of life circumstances likely varies across people and situations.

Another piece of evidence to support the importance of life circumstances in explaining well-being are consistent between-country differences in happiness ratings. If life circumstances did not matter much for well-being, researchers would not find such vast differences in well-being between countries like Denmark (high happiness) and Sierra Leone (low happiness; Diener, Ng, Harter, & Arora, 2010). Indeed, even after controlling for individual income, societal levels of income predicted happiness in a sample of 132 countries, indicating that there may be something about a nation's wealth beyond individual prosperity that contributes to a sense of well-being (Diener et al., 2010). In time-series data, researchers found that happiness rose in 45 of the 52 countries they studied and these increases were explained by the degree to which a society allowed free choice (Inglehart, Foa, Peterson, & Welzel, 2008). Over time, countries that became democratized, developed economically, and increased in social tolerance also showed increases in their residents' perceptions of free choice, which in turn fed into increased well-being (Inglehart et al., 2008).

Notably, estimates of heritability largely come from twin samples within economically stable and democratic countries (e.g., U.S., Netherlands, England, and Norway), thus do not have the cross-country variety like Inglehart and colleagues' (2008) sample included. With less variance in environmental factors that may affect well-being, heritability (versus environmental) estimates may be over-estimated in these samples. Similarly, the relative stability in well-being among people over time could be because the research largely draws from countries in which the types of environmental factors that affect well-being remain relatively stable. That said, even within the U.S., income inequality is related to lower happiness, indicating that shifting circumstances within stable countries can also relate to well-being (Oishi, Kesebir, & Diener, 2011). Specifically, in years with greater income inequality, happiness is lower in the U.S and these changes are mediated by lower perceptions of fairness and trust in people.

Thus, life circumstances do contribute to well-being. That said, as many researchers have noted, they do not contribute as much as we might expect. Most researchers explain the relatively low percentage of the variance attributable to life circumstances as a result of the natural process of adapting to our environments—hedonic adaptation.

Hedonic Adaptation

Hedonic adaptation is the process by which people adapt to the emotionally salient events or circumstances in their lives—both negative and positive—such that they do not feel the emotions as intensely over time as they did when the event or circumstance first occurred (Brickman & Campbell, 1971; Frederick & Loewenstein, 1999; Lyubomirsky, 2011; see also Luhmann & Intelisano, 2017 in this e-Handbook for a comprehensive review of theories and empirical evidence related to hedonic adaptation and set-point theory). The process of hedonic adaptation is often used to explain why people fluctuate around a stable level of well-being (i.e., a set-point or set-range; see Diener, Lucas, & Scollon, 2006 for a review). Although there is evidence that people adapt to life events, there is also evidence that people vary in the degree to which they adapt, that people vary in their rate of adaptation, and that different events have different rates of adaptation (Diener et al., 2006; Lucas, Dyrenforth, & Diener, 2008).

The best way to investigate hedonic adaptation is with large panel studies that track individuals, their life events, and their happiness levels over time. Fortunately, a few such panel studies exist, allowing for this type of investigation. An oft-cited finding is that people experience a boost to their well-being when they get married, but then return to pre-event levels of well-being about two years post-marriage (Lucas, Clark, Georgellis, & Diener, 2003; Yap, Anusic, & Lucas, 2012). Notably, however, Lucas and colleagues (2003) found substantial variability in adaptation to marriage with some people adapting more or less quickly than the average two years, and some people never adapting. They concluded that although on average there was evidence of adaptation to marriage, adaptation should not be viewed as an inevitable

process as it did not happen for all and rates and trajectories of change varied across people.

Anusic, Yap, and Lucas (2014) offered yet another perspective to the puzzle of hedonic adaptation in marriage when they compared changes in well-being over time to those who had been married to those who had never been married. They found an age-related dip in well-being over time in the never-been-married group and noted that marriage actually seemed to slow this dip. Thus, it is possible that the declines in well-being seen after marriage are not due to hedonic adaptation to marriage, but just normative age-related declines in well-being during mid-life as responsibilities ramp up.

Although adaptation seems to occur on average to positive events like marriage (see also childbirth; Dyrdal & Lucas, 2013; Yap et al, 2012; Anusic et al., 2014 and job change; Boswell, Boudreu, & Tichy, 2005), adaptation to negative events is not as complete. Researchers have found that people do not adapt as quickly or at all to negative events such as widowhood (Lucas et al., 2003; Yap et al., 2012), divorce (Lucas, 2005), disability (Lucas, 2007), or unemployment (Lucas, Clark, Georgellis, & Diener, 2004; Yap et al., 2012; but see Anusic et al., 2014 for normative age-related changes comparison). It is evolutionarily adaptive for negative events to grab people's attention so that they can address threat and promote survival and it is likely also adaptive to remember the threat vividly as to avoid it in the future (Baumeister, Bratslavsky, Finkeneauer, & Vohs, 2001). Thus, adaptation to positive and negative events is asymmetrical —on average, people are quicker to adapt to positive than negative events.

Because adaptation varies across people and is often incomplete for negative events, there may be characteristics of the events or how people handle them that could make people less likely to fully adapt to positive events, therefore extracting greater well-being over time. Although negative events and the memory of them naturally hold people's attention, there could be intentional ways in which people forestall their adaptation to positive events. Sheldon and Lyubomirsky (2012) note that as time passes, positive events provide fewer positive emotions (see also Lyubomirsky, 2011). At the same time, people's aspirations for their lives increase, undermining happiness. In their Hedonic Adaptation Prevention model, Sheldon and Lyubomirsky (2012) suggest that hedonic adaptation to positive events can be forestalled if people actively focus on appreciating the positive events or experiences (therefore keeping them at the forefront of the mind just like negative events are more naturally) and also infusing them with variety so that positive events and experiences can stay fresh over time. For example, a marriage may cease giving as much pleasure as the partnership gets more routine and less exciting over time. In addition, people may come to expect that their partner will do certain things for them (e.g., wash the dishes) and may have increasing aspirations for what they thing constitutes good partner behavior. The Hedonic Adaptation Prevention model suggests that people should actively appreciate their partners and put effort into doing new and exciting things with their partner, just as they would have in the beginning of the relationship. These activities may slow hedonic adaptation or at least give much needed boosts of positivity into the relationship along the way, allowing for marriage to be a continual source of well-being.

Intentional Activities

Suggesting ways in which people can intentionally forestall hedonic adaptation leads directly into a discussion of ways in which people can intentionally increase their happiness in general—not only in response to a positive life events or experiences. As mentioned before, research suggests that about 50% of individual differences in happiness are likely due to genetics and about 10-15% are likely due to people's life circumstances. As Lyubomirsky, Sheldon, and Schkade (2005) pointed out, this leaves a great deal of individual differences in happiness unexplained. They suggested that these unexplained differences may be due to how people respond to the events in their lives and the activities that they choose to engage in. Although behavior change is not easy by any means, intentional activities meant to boost happiness provide a more optimistic route to sustained happiness change than genetics and life circumstances. Furthermore, as noted above, intentional activities could also positively affect the degree to which life circumstances explains individual differences in happiness, helping people extract more positivity out of the favorable aspects of their lives. Thus, although the percentages of how each source of happiness affects well-being (genetics, circumstances, and intentional activities) are not set in stone, the likelihood remains that at least part of well-being can be alterable via intentional activities. Furthermore, heritability estimates do not address the possibility that an entire population's well-being could be raised by societal factors like free choice or individual intentional happiness practices. I will address more about activities to intentionally boost happiness later in this chapter, but I would be remiss not to mention them as evidence that happiness can change. Two meta-analyses of dozens of randomized controlled studies concluded that intentional activities can increase people's happiness (Bolier et al., 2013; Sin & Lyubomirsky, 2009) and more evidence is accumulating each year about what factors make these intentional activities most likely to improve well-being.

Happiness Can Change Over Time

Lastly, and perhaps most persuasively, we know that happiness can change over time because it has changed for some people. Lykken and Tellegen (1996) asserted that they did not think happiness could sustainably change, but they found that happiness scores in their sample across time were correlated at .50. Although this is a strong correlation, it accounts for only about a quarter of the variance in happiness scores over time, leaving room for the interpretation of substantial change. Part of the variance in happiness scores over time could be attributed to measurement error, but the fact remains that real changes in happiness in their sample are plausible. Indeed, in a separate study, Fujita and Diener (2005) found that 24% of people in their sample changed in life satisfaction significantly over 17 years and 9% changed by two standard deviations or more. One may argue (correctly) that Fujita and Diener's (2005) findings indicate that over half of respondents did not change in life satisfaction over the 17 years, providing strong evidence of the stability of life satisfaction. Although this is true, exploring the lives of the quarter of people who did change could provide insight into what factors lead to sustainable shifts in happiness. Furthermore, this sample was not engaged in any sort of intentional practice to shift well-being—they were just going about their daily lives. Even then, some people showed meaningful change, indicating that it is possible.

Should People Intentionally Pursue Happiness?

The evidence reviewed thus far demonstrates that changing one's happiness is possible yet challenging, but the question still remains whether pursuing greater happiness is worth the effort. For example, are increases in happiness only for their own sake (i.e., greater positivity for the individual experiencing greater happiness) or might they also stimulate better outcomes in a variety of ways—for individuals, those close to them, and societies? If increases in happiness were only for greater pleasantness of an individual's life, the effort expended by the individual might be deemed selfish by some. However, if greater happiness caused greater success for the individual in other ways, and better lives for those around them, then pursuing greater happiness could be seen as a public good. In contrast, another possibility is that pursuing happiness could undermine well-being by directing attention inward rather than outward to things that may promote happiness (e.g., relationships or nature). Thus, researchers set out to explore what good happiness can bring and whether intentional happiness pursuit could be detrimental.

Happiness and Success

The broaden-and-build theory of positive emotions sets out a strong, empirically supported, argument that positive emotions promote many desirable outcomes beyond simply feeling good (Fredrickson, 1998, 2001, 2013). As opposed to negative emotions, which are meant to narrow attention to handle an immediate threat, Fredrickson argues that positive emotions signal to people that they are safe to explore and expand their horizons. In a positive state, people are free to be curious and engage in approach-oriented behaviors like meeting new people or learning something new that can potentially affect their lives positively in the long-term via reciprocal processes (i.e., upward spirals).

Thus, although positive states are fleeting, they broaden people's thinking and attention, allowing them to take steps that might build durable cognitive, social, physical, or psychological resources (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008). In one empirical test of this process, participants engaged in a loving-kindness meditation training which boosted positive emotions, which in turn improved important resources (e.g., mindfulness, social support, physical health; Fredrickson et al., 2008). These personal resources also predicted greater life satisfaction, which will theoretically feed back into greater positive emotions over time, setting Fredrickson's proposed upward spiral into effect. Thus, positive emotions provide an emotional backdrop that allows people to improve themselves in a variety of ways.

Corroborating the findings from the broaden-and-build theory, a meta-analysis of over 300 findings sought to answer whether happiness leads to success (Lyubomirsky, King, & Diener, 2005; see also De Neve, Diener, Tay, & Xuereb, 2013). The findings overwhelmingly supported that happiness was not only related to success cross-sectionally, but also preceded success in longitudinal studies, and caused success when manipulated in the laboratory. The authors included many different indicators of success across work, physical health, and social domains, finding that happy people performed better at work (both in terms of productivity and social relationships), were physically healthier, had better relationships with others, and were more likely to engage in community service. Collectively, these findings point to happiness having benefits for the individual beyond simply feeling good, and also benefits for the people close to them and their communities.

Potential Negative Consequences of Happiness Pursuit

Although successful increases in one's happiness can hold benefits for the individual and their community, it is still possible that actively pursuing happiness could be detrimental for some. Research has demonstrated that people who value happiness may actually be less happy in positive situations because they are more likely to feel disappointed if a situation does not match their high happiness expectations (Mauss, Tamir, Anderson, & Savino, 2011). Indeed, in one study, participants who valued happiness

relatively more, and were under relatively low life stress, reported less happiness than their counterparts who either did not value happiness as much or did value happiness, but were under relatively higher stress (Mauss et al., 2011). Furthermore, in a separate paper, Mauss and colleagues (2012) found that the more people valued happiness, the lonelier they felt. Thus, the authors concluded that valuing happiness can have some surprisingly negative consequences.

Importantly, Mauss and colleagues' (2011) measure of valuing happiness does not explicitly measure the pursuit of happiness, but rather valuing happiness to an extreme degree. Questions include participants' level of agreement with statements like "How happy I am at any given moment says a lot about how worthwhile my life is," "If I don't feel happy, maybe there is something wrong with me," and "I am concerned about my happiness even when I feel happy." Thus, their measure of valuing happiness may be tapping into an unrealistic and possibly pathological valuing of happiness. Indeed, the valuing happiness scale is related to depression and bipolar disorder (Ford, Mauss, & Gruber, 2015; Ford, Shallcross, Mauss, Floerke, & Gruber, 2014). In a test of the psychometric properties of the valuing happiness scale, Luhmann, Necka, Schönbrodt, and Hawkley (2016) found that only two of the items are meaningfully related to lower well-being: "If I don't feel happy, maybe there is something wrong with me," and "I am concerned about my happiness even when I feel happy." These items demonstrate a worry about being unhappy that undermines people's happiness. Luhmann and colleagues (2016) found that the rest of the items either did not relate to well-being or related positively, suggesting that only the excessive focus on happiness or fear of unhappiness is related to lower well-being.

In contrast, Catalino, Algoe, and Fredrickson (2014) created the prioritizing positivity scale which more directly measures the intentional pursuit of happiness. Specifically, they assess the degree to which people organize their daily lives around opportunities for positive emotions by asking participants to rate how much they agree with statements like "A priority for me is experiencing happiness in everyday life," "What I decide to do with my time outside of work is influenced by how much I might experience positive emotions," and "My major decisions in life (e.g., the job I choose, the house I buy) are influenced by how much I might experience positive emotions." This type of prioritizing positivity is related to higher positive emotions, lower depression, and greater resources like self-compassion and ego-resilience (Catalino et al., 2014). Importantly, Catalino and colleagues (2014) also explored Mauss and colleagues (2011) valuing happiness scale and found that, although prioritizing positivity and valuing happiness were related ($r = .25$), they had distinct relationships with positive affect, negative affect, and life satisfaction. Specifically, as mentioned, prioritizing positivity was related to higher well-being and, replicating Mauss and colleagues (2011) work, valuing happiness was negatively related to well-being.

People Should Pursue Happiness (Thoughtfully)

In sum, organizing your life around increased happiness is not inherently a bad thing (as evidenced by the prioritizing positivity findings), but if you take it too far, it could have detrimental outcomes (as evidenced by the valuing happiness findings). Other work supports the idea that the type of intentional activities people engage in to become happier has implications on whether their happiness pursuit will be successful. Specifically, if people are going to pursue happiness, they need to do it in ways that feel authentic to them (i.e., person-activity fit; Lyubomirsky & Layous, 2013). In addition, most of the work on the intentional pursuit of happiness has included relatively mentally healthy samples (i.e., not clinical samples) and people who are having more severe issues would likely be better off with the professional help of a clinician than with a self-guided pursuit of happiness (see Sin & Lyubomirsky, 2009). Lastly, how happy one may seek to become may depend on their goals. For example, people at the very highest level of happiness have the most satisfying relationships and engage in the most community service, but those who are happy, but just below the highest level, are the most successful at work and school and more politically engaged, suggesting that they need a little room to grow to keep that drive (Oishi, Diener, & Lucas, 2007).

How Can People Effectively Increase Their Happiness?

After Lyubomirsky, Sheldon, and Schkade's (2005) seminal paper outlining the persuasive argument that happiness can change, research on happiness interventions exploded. Early pioneers had already provided some evidence that happiness could change in response to certain activities (Fordyce, 1977, 1983) and gratitude interventions as a path to happiness were just taking off in the literature (Emmons & McCullough, 2003), but Lyubomirsky and colleagues' (2005) paper provided the theoretical basis for research on happiness interventions that helped the field expand. Given the processes of hedonic adaptation outlined earlier, Lyubomirsky and colleagues (2005) stipulated that the best route to sustained happiness change would be through intentional and effortful activities rather than changing life circumstances. Of course the processes of hedonic adaptation can apply to intentional activities as well as to life circumstances, but intentional activities lend themselves more readily to variety that can help sustain positive changes in well-being (Sheldon & Lyubomirsky, 2006).

Positive Psychological Interventions

Positive Psychological Intervention (PPI) is an umbrella term used to describe a treatment method or activity designed to foster happiness. PPIs can be directed by a therapist or coach in an individual or group session or self-guided. Lyubomirsky and Layous (2013) have also used the term positive activity intervention (PAI) to exclusively focus on the self-guided type of PPI or simply "positive activity" to refer to happiness-increasing activities practiced in daily life (i.e., not as part of a randomized controlled intervention). Before testing PPIs in randomly controlled interventions, researchers sought to explore the behaviors of happy people to answer the question—what do happy people do that might reinforce their happiness? For example, across multiple studies, researchers found that happy people are grateful (McCullough, Emmons, & Tsang, 2002), prosocial (Krueger, Hicks, & McGue, 2001), and optimistic (Lucas, Diener, & Suh, 1996). Thus, researchers started designing studies to explore whether the intentional practice of gratitude (e.g., writing a gratitude letter or counting one's blessings), prosociality (performing acts of kindness), or optimism (visualizing one's best possible self) could boost happiness. Research has now accumulated to demonstrate that intentionally engaging in the activities of happy people boosts well-being (Bolier et al., 2013; Sin & Lyubomirsky, 2009).

PPIs can be viewed as a type of emotion regulation strategy in which one seeks to upregulate positive emotions. Thus, Quoidbach, Mïkolajczak, and Gross (2015) wrote a helpful review of positive interventions, integrating the different types of PPIs with the extant emotional regulation literature by categorizing them according to the process model of emotion regulation (i.e., into the strategies of situation selection, situation modification, attentional deployment, cognitive change, and response modulation; Gross, 1998) and demonstrating how they may be applied before, during, and after positive emotional events to enhance their effect. In addition, the review covered which PPIs have the most empirical support and during what time frame, pointing toward areas of opportunity for further research within the field.

How Positive Psychological Interventions Increase Well-Being

As described by the positive activity model (Lyubomirsky & Layous, 2013; see also Layous & Lyubomirsky, 2014), PPIs increase global well-being via increases in positive emotions, positive thoughts, positive behaviors, and psychological need satisfaction (i.e., autonomy, competence, and relatedness; Ryan & Deci, 2000). Although much research is still needed to support these mechanisms, they do have some preliminary support. For example, a loving-kindness meditation intervention boosted positive emotions, which in turn improved personal resources such as social relationships and physical health, which in turn improved life satisfaction (Fredrickson et al., 2008). In another study, people who expressed gratitude and optimism rated their weekly experiences as more satisfying over time even though independent coders rated them as consistently satisfying over time (Dickerhoof, 2007). Thus, people engaging in the PPI construed the events in their lives more positively over time even though they did not objectively change. PPIs can also stimulate the performance of positive behaviors unrelated to the specific PPI. For example, in one study, participants assigned to record their blessings (i.e., express gratitude) engaged in more exercise over time than those assigned to record their hassles (Emmons & McCullough, 2003). Finally, students assigned to imagine their time as scarce in their college town (a savoring manipulation) reported increases in psychological need satisfaction, which in turn predicted increases in subjective well-being (Layous, Kurtz, Chancellor, & Lyubomirsky, 2017). Thus, the positive activity model has preliminary support, but much research is needed to explore when and under what conditions these interventions may work, as well as other mechanisms that may be at play.

Moderators of the Success of Positive Psychology Interventions

The positive activity model (Lyubomirsky & Layous, 2013) posits some features of the PPI itself that may increase its efficacy, some features of the person engaging in the PPI that might make them more likely to benefit, and finally, the importance of matching the activity to the person (i.e., person-activity fit) to optimize successful increases in happiness. For example, research has demonstrated that timing and dosage of a PPI can affect its efficacy (Lyubomirsky, Sheldon, et al., 2005), as can the variety with which its practiced (Sheldon, Boehm, & Lyubomirsky, 2012), and whether it is other- or self-focused (Nelson, Layous, Cole, & Lyubomirsky, 2016). For example, participants prompted to perform kind acts for others or for the world reported higher levels of flourishing than those who were prompted to be kind to themselves (Nelson et al., 2016).

Research has also revealed that people who are more motivated to engage in PPIs and put more effort into their practice have greater increases in well-being (e.g., Lyubomirsky, Dickerhoof, Boehm, & Sheldon, 2011). In one study, people who self-selected into a happiness intervention study reported greater gains in well-being over the 8-week intervention period than those who self-selected to "test cognitive exercises" (Lyubomirsky et al., 2011). These gains were the highest for self-selected participants who were assigned to the intervention conditions (i.e., gratitude and optimism) versus the control condition indicating

that participants not only need motivation to improve their happiness, but also an appropriate PPI (i.e., a will and a way; Lyubomirsky et al., 2011; see also Sin & Lyubomirsky, 2009). Lyubomirsky and colleagues (2011) also found that participants who put more effort into completing the intervention conditions, but not the control condition, saw greater increases in well-being. Thus, participant motivation and effort, coupled with the efficacy of the activity, predict greater increases in well-being.

Although studying main effects of certain features of the activity or happiness-seeker on intervention efficacy provides valuable information, perhaps most importantly, researchers should be exploring the optimal fit between the activity and the person (i.e., person-activity fit). Indeed, in one study, people who indicated that they enjoyed the activity, benefitted from it, and did not find it difficult, were more likely to complete the activity and showed greater boosts in well-being (Schueller, 2010). Similarly, in one study, people who responded that they liked the exercise, benefitted from it, completed the exercise as instructed, showed early reactivity (i.e., change in well-being during the one-week intervention period), and continued to practice the activity post-intervention, were more likely to sustain well-being benefits out to the 3.5 year follow-up (Proyer, Wellenzohn, Gander, & Rush, 2015). Corroborating this finding, another study found that people who showed early reactivity to the intervention were more likely to continue practicing the intervention after the intervention period had ended, which was predictive of sustained increases in positive emotions at a 15-month follow-up (Cohn & Fredrickson, 2010). These researchers took their participants' preference for the activity, early reactivity, and continued practice post-intervention to be evidence of person-activity fit. In addition, evidence suggests that people show a pattern of preference toward certain activities (e.g., activities that focus on the present versus the past; Schueller, 2010), and thus researchers may be able to look for these fit patterns and assign PPIs accordingly. Much research needed regarding this more fine-tuned administration of PPIs, but early evidence suggests that better matching of person and activity can stimulate long-term rewards in well-being.

Future Directions in Research on Intentional Happiness Pursuit

As PPIs become widely used, it becomes even more important to understand their boundary conditions, including how to maximize the efficacy of the activity and how to ensure that people are not engaging in an activity that does not fit them and their needs. For example, some evidence suggests that specific types of PPIs do not work equally well across cultures. In one study, both gratitude and kindness activities boosted well-being over the control group when exploring across the U.S. and South Korean samples. However, the effect of the gratitude condition was moderated by culture such that people in the U.S. benefited from practicing gratitude, but people in South Korea did not (Layous, Lee, Choi, & Lyubomirsky, 2013). The researchers reasoned that maybe gratitude was not additionally beneficial for South Koreans because they had already expressed gratitude and obtained some sort of well-being benefit or perhaps because the gratitude exercise was a reminder that they had put someone out and perhaps upset a delicate social harmony that is extremely valued in collectivistic societies. Furthermore, it is quite possible that the appeal of happiness-increasing activities is a western—or even a U.S.—notion as not all cultures pursue positivity like people in the U.S. (e.g., Tsai, 2007, but see Diener, 2000). Thus, future research needs to explore culture-activity fit in the pursuit of person-activity fit and also continue to explore how actively different cultures intentionally pursue happiness.

Another person-activity fit issue includes whether people with certain levels of well-being might actually be harmed by practicing PPIs. Evidence suggests that PPIs can decrease depressive symptoms (Fava & Ruini, 2003; Seligman, Rashid, & Parks, 2006; Sin & Lyubomirsky, 2009), but one study found that listening to neutral music (a distracter activity) was more effective in decreasing depressive symptoms than a gratitude letter writing activity among mildly depressed participants (Sin, Della Porta, & Lyubomirsky, 2011). Importantly, many of the self-guided PPIs have not been tested in clinical samples. Given that approximately half of happiness-seekers on the internet would qualify as clinically depressed (Parks, Della Porta, Pierce, Zilca, & Lyubomirsky, 2012), more research needs to investigate whether there are certain types of activities that could backfire among clinical samples. Likewise, given that most people are above the midpoint on happiness (Diener, Kanazawa, Suh, & Oishi, 2015), it may be futile for some people to pursue greater happiness if they are already at the top of the scale. Furthermore, depending on someone's goals (e.g., political or career) they may benefit from being slightly less happy than their most happy peers (e.g., Oishi et al., 2007)

In addition, the sustainability of intentional happiness change needs to continue to be explored. As researchers in the field of psychology well know, behavior change is difficult and making intentional behavior change habitual requires great effort and persistence (Lally, van Jaarsveld, Potts, & Wardle, 2010; Wood & Neal, 2007). Evidence across multiple studies suggests that well-being at a three to six month follow-up is still significantly higher in the intervention group than the control group (Bolier et al., 2013), but few notable exceptions explore a lengthier follow-up (e.g., Cohn & Fredrickson, 2010; Proyer et al., 2015). Proyer and colleagues (2015) have the longest follow-up of a PPI to my knowledge (3.5 years) and

unfortunately, they did not have enough retained participants in the control group to make between-condition comparisons. That said, they were able to explore within-intervention components that sustained effects (e.g., continued practice, early reactivity, enjoyment of the intervention, and effort) and future researchers would do well to continue exploring what factors promote sustained happiness after the inevitable completion of the prescribed intervention period. For example, possibly the happiness intervention teaches the participant a happiness-enhancing skill (e.g., keeping a gratitude journal), and the continued practice of that skill is what sustains boosts in well-being (see Kushlev et al., 2017).

Finally, studies are starting to explore how changes in well-being as a result of PPIs affect other downstream consequences like social relationships, productivity, and physical health (e.g., Fredrickson et al., 2008; Moskowitz et al., 2017) and more such studies are needed to demonstrate not only that happiness can be increased, but that increasing happiness has other positive benefits. One example is the Enduring Happiness and Continued Self-Enhancement (ENHANCE) program, a comprehensive intervention program that seeks to develop multiple happiness-enhancing skills to boost happiness and, in turn, trigger positive changes in other domains of life (e.g., relationships and physical health; Kushlev et al., 2017). A randomized controlled trial of ENHANCE is currently under way and preliminary results are quite promising regarding ENHANCE's ability to improve well-being and stimulate other positive benefits.

Conclusion

Borrowing another quote from the Dalai Lama, the research can be summarized as follows: "Although bringing about inner change is difficult, it is absolutely worthwhile to try" (His Holiness the 14th Dalai Lama tweeted this on May 30, 2017). As Lykken and Tellegen (1996) noted, it is undoubtedly easier for people who are born relatively happier than others to engage in behaviors that reinforce their happiness. That said, over the past two decades, a great deal of evidence has accumulated demonstrating that people can increase their own happiness through intentional and effortful practices like expressing gratitude and performing kind acts. Thus, although challenging, increasing one's happiness is possible and the science of well-being is continually advancing to offer people more efficacious ways of doing so.

Abstract

A corpus of literature has documented the benefits of physical activity to well-being and quality of life in older adults. However, this relationship has frequently been studied in the context of health-related quality of life (HRQL), as opposed to global quality of life, and in clinical populations. While meta-analyses in this area provide strong evidence of a positive effect of physical activity on HRQL in these populations, systematic evidence is lacking in relation to well-being and global quality of life in healthy older adults. A small number of randomized controlled trials suggest physical activity benefits global quality of life; however, additional research using the global conceptualization of well-being is needed to confirm these findings. There is strong evidence, on the other hand, of a positive influence of physical activity on the proposed antecedents of HRQL and global well-being, including self-related function, or psychological states (i.e., depression, anxiety, self-esteem, positive affect, self-efficacy), and cognitive function (e.g., executive function, working memory) in older adults. Despite this, less is known about the: (1) modes and doses of physical activity that most effectively improve self-related function, cognitive function, HRQL, and well-being; (2) mechanisms of change in well-being outcomes due to increased physical activity; and (3) mediating roles of self-related function, cognitive function, and HRQL in the broader relationship between physical activity and well-being. In this chapter, we present current evidence of physical activity's effects on well-being and its correlates, HRQL, self-related function, and cognitive function. We also highlight limitations in this evidence base and provide recommendations for future research.

Keywords: Physical activity, subjective well-being, quality of life, older adults

There has been a rapid shift in the demographic landscape of the United States in the last few decades, a result of adults now living longer than ever before (Vincent & Velkoff, 2010). However, older adulthood is a period often fraught with the onset of comorbid conditions and disability, which can lead to impaired well-being and quality of life (QoL; Ward, Schiller, & Goodman, 2012). Defined as an affective cognitive judgment of one's satisfaction with life, QoL is a global construct often used interchangeably with subjective well-being and considered a significant predictor of long-term survival (Diener, Emmons, Larsen, & Griffin, 1985). Thus, it has become an important priority for researchers and clinicians to identify low-cost, effective methods of maintaining older adults' well-being and QoL and to protect against age-related health decline.

Physical activity may be an effective vehicle for improving well-being and QoL with increased age. In this chapter we focus on physical activity's effects on the psychological (e.g., satisfaction with life, anxiety, esteem, affect, cognition) rather than the physical (e.g., functional performance, activities of daily living) components of well-being. We also focus on QoL as a global judgement of well-being. However, the physical activity literature has given limited attention to QoL following this definition. Rather, this literature has focused primarily on health status, or health-related quality of life (HRQL), while operationalizing it as QoL (Chou, Hwang, & Wu, 2012; Gillison, Skevington, Sato, Standage, & Evangelidou, 2009; Motl & Gosney, 2008).

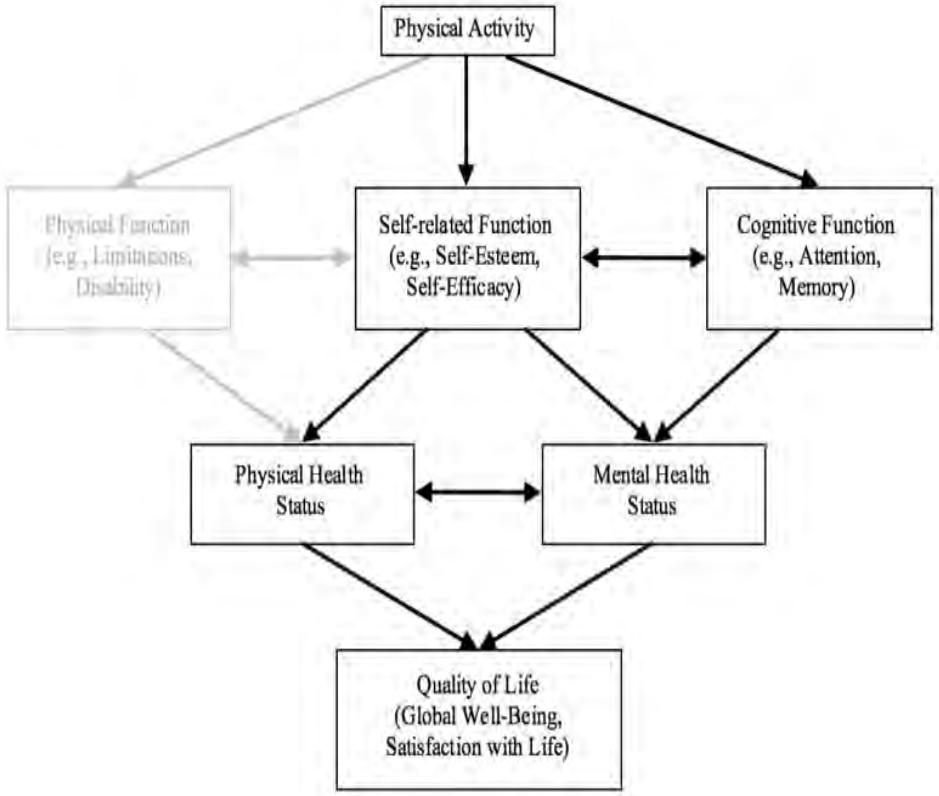
HRQL is a construct derived from behavioral medicine and biomedical science and is comprised of physical and mental health domains (Ware Jr. & Sherbourne, 1992). It is distinct from well-being and QoL and considered by some researchers to be a proximal outcome along the pathway between physical activity and well-being. For example, McAuley and Morris (2007) proposed that physical activity has a direct impact on self-related function (self-esteem, self-efficacy, affect), cognitive function, and physical function, which impact HRQL (physical and mental health domains). In turn, improved HRQL directly influences global QoL (Figure 1). As this follows theoretical suppositions of subjective well-being (Diener, 1984; Rejeski & Mihalko, 2001), our discussion herein is guided by this framework.

A compelling body of evidence has demonstrated the effectiveness of physical activity interventions for improving health status, reducing negative psychological states (e.g., depression, anxiety), and

increasing positive psychological states (e.g., self-esteem; Arent, Landers, & Etnier, 2000; Barbour, Edenfield, & Blumenthal, 2007; Clarke et al., 2005; Ensari, Greenlee, Motl, & Petruzzello, 2015). Likewise, a number of studies have identified the efficacy of physical activity interventions for improving cognitive health (Northey et al., 2017; Smith et al., 2010), a key component of successful aging and well-being in older adults (Diener, 1984; Fiocco & Yaffe, 2010; Lehnert, Sudeck, & Conzelmann, et al., 2012). Despite this, the final path to well-being and global QoL has rarely been tested in accordance with McAuley and Morris's (2007; see Figure 1) hypothesized model. In this chapter we present current evidence relative to subjective well-being in the context of global QoL and HRQL, self-related function (i.e., psychological states), and cognitive function; identify strengths and shortcomings (relative to design in particular, theoretical underpinnings, measurement, mode and dose of activity, potential mechanisms and moderators); and make recommendations for future research directions.

Figure 1. A conceptual model of the physical activity and quality-of-life relationship*

***Adapted from McAuley and Morris (2007)**



Note: Physical function is presented in gray as it is included in the original model proposed by McAuley and Morris (2007), but is not the focus of this book chapter.

Global Well-Being

A small number of randomized controlled trials (RCTs) have shown that aerobic and non-aerobic modes of physical activity may improve subjective well-being (Awick et al., 2015, 2017b; Li et al., 2001). Unfortunately, this limited literature, in addition to inconsistent conceptualizations of well-being, make it difficult to synthesize findings across studies and conclude whether physical activity interventions improve well-being in older adults (Rejeski & Mihalko, 2001). As such, meta-analytic studies and systematic reviews examining older adults' physical activity and well-being from the global perspective are scarce in the literature. A further limitation of this evidence is that it has focused primarily on clinical populations, thus making generalizations to healthy older adults difficult. In this section we discuss: the effects of physical activity on HRQL; the small body of evidence focusing on global QoL; and future directions to better understand the influence of physical activity on these constructs in older adults.

Physical Activity and Health-related Quality of Life

As noted above, physical activity and HRQL have largely been studied from the perspective of clinical populations (Chou et al., 2012; Ferrer, Huedo-Medina, Johnson, Ryan, & Pescatello, 2011; Motl & Gosney, 2008). To the best of our knowledge, only one meta-analysis has focused on healthy populations and included adults aged 18 to 65+ years (Gillison et al., 2009). Motl and Gosney (2008) observed a small to moderate effect (d =.34) of short-term (<3 months), aerobic physical activity interventions on HRQL in individuals with multiple sclerosis (MS). Longer interventions and non-aerobic (i.e., yoga, resistance training) or combined programs did not yield the same benefits. Ferrer and colleagues (2011) also observed increases in cancer survivors' HRQL after participation in aerobic physical activity interventions; however, they found that studies of longer duration (>6 months) had a greater influence on HRQL, and these improvements were maintained ~4.5 months after the interventions ended.

Gillison and colleagues (2009) also found that short-term (3-6 months) physical activity interventions yielded significant, albeit small, improvements in the physical and mental domains of HRQL in healthy adults, (d = 0.22, 0.21, respectively). Interestingly, the mental domain of HRQL improved more after engaging in light intensity activity, whereas the physical domain improved only with moderate intensity activity (Gillison et al., 2009). This suggests the HRQL domains may be differentially impacted by physical activity intensities. This may be due in part to recruitment of healthy, yet unfit and inactive individuals who may have perceived light physical activity as more achievable and enjoyable, thereby improving the mental HRQL domain. While results from these meta-analyses suggest aerobic activity may be a viable mode for increasing HRQL in clinical and healthy populations, more studies are warranted.

The implications of these findings are restricted by a number of limitations. First, the focus on clinical populations and HRQL limits broad understanding of physical activity's effects on well-being in older adults. For example, in the meta-analysis in MS patients by Motl and Gosney (2008), the effect of physical activity on HRQL was statistically significant when using MS-specific HRQL measures, but non-significant when using broad measures such as the Medical Outcomes Study 36-item Short Form Survey (Motl & Gosney, 2008; Ware Jr. & Sherbourne, 1992). Moreover, the effect of physical activity on HRQL and well-being may be greater in clinical populations when compared with the general older adult population (Ferrer et al., 2011; Gillison et al., 2009). It is also possible that physical activity impacts clinical populations differently or may work along different underlying pathways. Similarly, HRQL is a proximal outcome of physical activity and thought to be more of an indicator of health status (Stewart & King, 1991). As such, more research with a focus on global QoL and well-being in clinical and general older adult populations may enable us to better quantify the effects of physical activity on subjective well-being.

Additionally, more details are needed on the intervention characteristics, such as mode, frequency, intensity, duration, and settings that are most effective for improving HRQL in older adults. The extant literature suggests shorter interventions and light intensity exercise may have larger effects on HRQL, but further research should be conducted to confirm these findings. Finally, HRQL domains may be differentially sensitive to the effects of physical activity (Chou et al., 2012; Gillison et al., 2009); therefore, research is needed to explain relationships among physical activity, physical and mental HRQL, and global QoL. A few studies in the older adult literature have aimed to reduce these knowledge gaps (see below); however, more work in this area is warranted.

Physical Activity and Global Quality of Life

A smaller, yet important body of literature has assessed the impact of physical activity on global QoL and well-being, using satisfaction with life as the proxy measure. For example, Awick and colleagues (2015) examined the effects of a walking intervention compared with a stretching/toning control intervention on satisfaction with life in low-active older adults at mid-intervention (6 months) and post-intervention (12 months). Both groups reported increases in life satisfaction at 6 months; however, the walking intervention continued to improve their life satisfaction throughout the 12 months, while the stretching/toning group declined from months 6 to 12. Li and colleagues (2001) also observed a large effect (d =.93) on satisfaction with life in older adults who participated in a 6-month Tai Chi intervention compared to a no-treatment control group. Findings from these studies suggest aerobic and non-aerobic (stretching, toning, alternative exercise) exercise modalities have the capacity to improve subjective well-being in older adults, but aerobic activity may have a greater, long-lasting impact. Notably, participants of both interventions were generally healthy, suggesting the benefits of physical activity programs to well-being are not restricted to clinical populations or those with compromised HRQL or QoL.

Contrary to these findings, a meta-analysis that included satisfaction with life as an outcome of QoL reported no significant differences between physical activity groups and controls (Netz, Wu, Becker, & Tenenbaum, 2005). However, this meta-analysis had several limitations to be considered. For example, a table of study characteristics was not included, methodological quality was not evaluated, and specific

measures used to assess global QoL were not reported in the meta-analysis, thus making interpretation of these findings difficult.

In keeping with the theoretical conceptualization of well-being as a global, distal outcome of physical activity (Figure 1), researchers have also tested the indirect effect of physical activity. For instance, in a prospective study of older women, McAuley and colleagues (2008) found that changes in physical activity were associated with changes in self-efficacy, which was in turn significantly associated with changes in HRQL. Changes in mental health status were then significantly associated with changes in satisfaction with life. The authors suggested that lack of findings in the physical health domain may be due to the observational design, as individuals are more likely to improve physical function (e.g., strength, flexibility) within the context of an intervention. A cross-sectional study by Mudrak and colleagues (2016) also found that increased participation in physical activity was associated with greater self-efficacy in 546 older Czech adults. Greater self-efficacy was associated with better HRQL, and HRQL was associated with higher satisfaction with life. Together, these findings provide support for proposed relationships between physical activity and global QoL. However, as our interpretations are limited by the study designs (prospective and cross-sectional), further research in the context of an RCT is needed to test the directionality and causality of the relationships. Despite this, a robust literature provides strong evidence in support of physical activity's benefits to proximal outcomes associated with well-being, such as HRQL, self-related function, and cognitive function.

Self-related Function

A considerable body of literature has highlighted the positive influence of physical activity interventions on psychological outcomes in older adults, specifically for reducing negative symptomology (i.e., depression, anxiety) and improving positive psychological states (i.e., esteem, positive affect; Arent et al., 2000; Barbour et al., 2007; Clarke et al., 2005; Ensari et al., 2015). These effects have remained relatively consistent across levels of exercise supervision (e.g., center- v. home-based) and mode (e.g., aerobic v. non-aerobic). However, the mechanisms underlying physical activity's influence on these factors, as well as their concurrent influence on the larger relationship between physical activity and subjective well-being are still unclear. In this section, we present evidence of the influence of physical activity on negative and positive psychological states in older adults, including findings related to dose-response and mode of exercise.

Negative Psychological States

Negative psychological states are important concerns for older adults and have been consistently associated with increased risk of morbidity and mortality when left untreated (Blake, Mo, Malik, & Thomas, 2009). Although McAuley and Morris (2007) defined self-related function in terms of positive psychological states only, negative affective outcomes are an important component of subjective well-being (Diener, 1984) and a robust literature provides evidence in support of physical activity interventions for improving negative psychological symptoms (Arent et al., 2000; Barbour & Blumenthal, 2005; Blake et al., 2009; Herring et al., 2010; Penedo & Dahn, 2005; Rosenbaum et al., 2011). Barbour and Blumenthal (2005) reported physical activity to be more effective for reducing depressive symptoms when compared with wait-list and social contact controls and antidepressant medications. Conn (2010) corroborated these findings in a meta-analysis and noted that both supervised and unsupervised physical activity interventions in older adults were comparable in reducing depressive symptoms. The magnitude of physical activity's effect on depression across studies was moderate (*d*s ~0.38).

Exercise interventions have also been shown to reduce anxiety levels in older adults (Arent et al., 2000; Herring et al., 2010; Penedo & Dahn, 2005). In an update to a previous comprehensive review of the anxiety-reducing influence of acute and regular exercise (Petruzzello, Landers, & Hatfield, 1991), Ensari and colleagues (2015) confirmed the small, but significant, beneficial effect of acute bouts of physical activity on anxiety. Indeed, some of the most robust effects of physical activity on psychological well-being in older adults have been on anxiety symptoms (Netz et al., 2005). While more recent evidence examining the influence of regular physical activity on anxiety is needed, the extant literature overall unequivocally supports a beneficial effect of physical activity on negative affect in older adults. However, as the effects are not entirely uniform, there are several considerations for maximizing the benefits of physical activity in future trials. Specifically, further exploration of physical activity dose, mode, and underlying mechanisms is warranted. This is further discussed later in the chapter in the Future Directions section.

Positive Psychological States

Other important determinants of health in old age are factors associated with positive psychological states, such as self-esteem, self-efficacy, and positive affect. Self-esteem, one's affective evaluation of his/her worth, and self-efficacy, one's situation-specific self-confidence, are two constructs that have been associated with successful aging (Orth, Robins, & Roberts, 2008; Orth, Robins, & Widaman, 2012; Rejeski

& Mihalko, 2001). Although meta-analytic reviews have consistently revealed significant, but small improvements in self-esteem, self-efficacy, and positive affect with exercise training (*d*s =.16-.57; standardized mean difference [SMD] = .50; (Ashford, Edmunds, & French, 2010; Ekeland, Heian, Hagen, & Coren, 2005; Reed & Buck, 2009; Spence, Mcgannon, & Poon, 2005; Wiese, Kuykendall, & Tay, in press), most have failed to include individuals over the age of 60. As there is a paucity of systematic evidence focused on positive psychological states in older adults specifically, we focus here instead on exemplar RCTs. For example, older adults randomized to a 12-month walking group versus flexibility-toning-balance control group reported similar improvements in physical self-worth, a domain of self-esteem (Gothe et al., 2011). Similarly, Awick and colleagues (2017a) found that a home-based, DVD-delivered flexibility/toning/balance exercise program helped older adults improve and maintain their physical self-worth immediately post-intervention (6 months) and after a one year, no-contact follow-up period.

There is a demonstrative body of evidence highlighting the reciprocal relationship between physical activity and self-efficacy in older adults, such that self-efficacy acts as both a determinant and outcome of physical activity behavior (Anderson, Winett, Wojcik, & Williams, 2010; Bandura, 1997; Chase, 2013; McAuley & Blissmer, 2000). As such, self-efficacy has become widely recognized as an important intervention target in numerous physical activity studies in older adults (Amireault, Godin, & Vézina-Im, 2013; Heath et al., 2012). In a meta-analysis by Ashford et al. (2010), the largest effects for increased self-efficacy were evidenced in physical activity interventions that included a greater emphasis on vicarious experience and performance feedback, making these important considerations for future interventions. Elavsky and colleagues (2005) reported that, among individuals randomized to a 6-month exercise intervention, those who remained more physically active at one-year follow-up reported higher levels of self-efficacy, self-esteem, and positive affect. It should be noted that these effects were maintained at 5-year follow-up for self-esteem and positive affect, further suggesting that physical activity interventions can provide long-lasting improvements in positive psychological states responses.

Cognitive Health

Cognition and brain health have increasingly been recognized as important factors of successful aging and may be considered significant components of older adults' subjective well-being (Fiocco & Yaffe, 2010; Kramer & Erickson, 2007; Lehnert et al., 2012; McAuley & Morris, 2007; Rowe & Kahn, 1997). A small number of studies have linked cognition with well-being (Gerstorf, Lövdén, Röcke, Smith, & Lindenberger, 2007), and several have connected it with well-being correlates, including depression, anxiety, self-esteem, and self-efficacy (Agroskin, Klackl, Jonas, Downs, & Caspi, 2014; Birch et al., 2016; McAuley et al., 2011). A large body of research has provided evidence in support of regular physical activity for slowing cognitive decline, improving brain health and cognitive function with advancing age, and reducing risk of dementia and Alzheimer's disease (Bherer, Erickson, & Liu-Ambrose, 2013; Blondell, Hammersley-Mather, & Veerman, 2014; Colcombe & Kramer, 2003; Smith et al., 2010). While a smaller number of studies have questioned the overall effectiveness of physical activity for preserving cognitive function in older adults (Kirk-Sanchez & McGough, 2013; Young, Angevaren, Rusted, & Tabet, 2015), physical activity is generally accepted as protective against age-related cognitive decline. It is less clear which dimensions of activity (i.e., frequency, intensity, duration, mode) most effectively ameliorate cognitive decline, mechanisms by which physical activity influences cognitive function, and the effects of cognitive function on well-being. In this section, we review evidence of the effects of physical activity on cognitive function in older adults and emphasize important areas of further scientific investigation.

A number of meta-analyses and systematic reviews have attempted to quantify the effects of physical activity on cognitive function in older adults, with most focusing on aerobic exercise. In an early meta-analysis of 18 randomized aerobic exercise trials, Colcombe and Kramer (2003) reported that aerobic exercise was moderately effective for improving cognitive function in older adults (Hedge's $g = 0.48$), and these benefits were greatest for executive control processes (e.g., cognitive flexibility, inhibition, planning; $g = 0.68$). More recent meta-analyses and reviews have corroborated these findings, but suggest aerobic exercise's effects on cognitive function may be somewhat smaller. Smith and colleagues (2010) found, across 29 aerobic interventions in adults aged 18 years and older, that aerobic exercise consistently led to modest improvements in attention and processing speed ($g = 0.16$), executive function ($g = 0.12$), and memory ($g = 0.13$). In the most recent meta-analysis, aerobic exercise (k=18) in adults aged 50 years and older was associated with improvements in cognition compared with controls (SMD = 0.24; Northey et al., 2017). Like Smith et al. (2010), the effects were similar across cognitive domains (i.e., attention, executive function, memory, working memory; SMDs = 0.27-0.36; Northey et al., 2017). Despite these positive findings, the most recent Cochrane review reported no evidence of an association among aerobic exercise (compared to non-aerobic exercise or no intervention), cardiorespiratory fitness, and cognitive function in cognitively intact older adults aged 55 years and older (Young et al., 2015). This is also in contrast to previous studies suggesting improvements in cardiorespiratory fitness brought about by increases in aerobic

physical activity may at least partially explain enhancements in cognitive function among older adults (Erickson et al., 2011; McAuley, Kramer, & Colcombe, 2004).

It is important to note the limitations in this evidence base, particularly in relation to study design, risk of bias, and poor reporting of methods (Colcombe & Kramer, 2003; Fiocco & Yaffe, 2010; Northey et al., 2017; Young et al., 2015). In the Cochrane review, Young and colleagues (2015) acknowledged a preponderance of cross-sectional and observational studies, unclear randomization schemes in RCTs, lack of participant and trainer blinding to exercise protocols, per-protocol analytic procedures, limited number of published protocols, poor reporting of attrition, no assessment of contamination bias, and limited discussion of ceiling effects. These factors may have contributed to the small or null effects observed across studies.

Although most studies have provided evidence of a positive main effect of aerobic exercise on cognitive function, results of moderator analyses have been mixed. For example, Colcombe and Kramer (2003) observed varied relationships with cognitive performance across dimensions of fitness including trial length and bout duration. Long-term training programs (6+ months; $g = 0.67$) and bout durations of 31-45 minutes ($g = 0.61$) were associated with better cognitive performance. Contrary to this, Smith et al. (2010) and Northey et al. (2017) observed similar cognitive effects across trials of varying lengths (Smith et al. (2010): range 8-72 weeks; Northey et al. (2017) categorized: 4-12 weeks, 13-26 weeks, >26 weeks). Additionally, the effect of exercise bout duration on cognitive function followed a quadratic trend in which only medium duration exercise bouts (i.e., >45 to $\leq$60 minutes) led to improvements in cognitive functioning (Northey et al., 2017).

A growing body of evidence also suggests the cognitive benefits of exercise are not restricted to aerobic exercise. Combined aerobic exercise + strength training programs, while comprising only a small number of studies examined by Colcombe and Kramer (2003), had greater effects on cognitive function when compared with aerobic exercise only ($g = 0.59$ v. 0.41). The cognitive effects observed by Smith and colleagues (2010) were evident regardless of training received (i.e., aerobic v. aerobic + strength). Likewise, Northey and colleagues (2017) observed similar improvements in cognitive function across 41 exercise interventions of different modes (aerobic exercise [SMD = 0.24], resistance training [SMD = 0.29], combined training [SMD = 0.33], tai chi [SMD = 0.52]). Although much additional work is needed, the evidence to date indicates cognition should be fundamental to the discussion of physical activity's effects on subjective well-being in older adults.

Future Directions

The extant literature suggests further research in a number of areas in order to better understand the roles of physical activity and proximal outcomes, such as psychological health, cognitive health, and HRQL, in improving subjective well-being in older adults. Research areas of particular interest include examination of (a) alternate modes of physical activity; (b) dose-response relationships; and (c) the mechanisms and moderators of change in these outcomes. In this section we detail recommendations for future research, in addition to practical considerations (e.g., study design) for the examination of physical activity's effects on well-being.

Alternate Modes of Physical Activity

Although aerobic exercise interventions comprise the majority of studies included in meta-analyses and systematic reviews of physical activity's effects on psychological and cognitive health, results of a growing number of non-aerobic exercise interventions (e.g., strength and flexibility training, Tai Chi) suggest examination of alternate modes of physical activity is warranted. For example, meta-analyses have suggested that resistance-based exercise may result in the largest reductions in depressive and anxiety symptoms (Arent et al., 2000; Conn, 2010). In the cognitive literature, meta-analyses and RCTs have observed cognitive benefits of non-aerobic exercise modes similar to those of aerobic exercise (Colcombe & Kramer, 2003; Northey et al., 2017). For example, Voss and colleagues (2010) observed improvements in brain functional connectivity and older adults' performance on executive function tasks after 6 and 12 months of training in a non-aerobic, stretching and toning group.

Interventions targeting positive psychological states also suggest similar effects of aerobic (i.e., walking) and resistance training (i.e., toning/flexibility/stretching) programs on self-efficacy and physical self-worth (Elavsky et al., 2005; Gothe et al., 2011). However, the physical self-esteem subdomains (i.e., physical condition, body attractiveness, physical strength esteem) may be differentially influenced by physical activity modality. Gothe and colleagues (2011) noted that individuals randomized to a flexibility/toning group reported greater improvements in body attractiveness and physical strength esteem, likely due to the nature of the program and subsequent improvements in muscular strength. Individuals assigned to the walking group reported improvements in the physical condition and strength esteem. Despite these variations between groups, older adults in both conditions reported improvements in overall

physical self-worth, suggesting various exercise modes may contribute similarly to more global perceptions of physical self-esteem.

The effects of complementary exercise, such as yoga or Tai Chi, have also increasingly been explored. Patel, Newstead, and Ferrer (2012) documented greater effects of yoga practice compared with conventional exercise on mental health status (SMD = 0.65) across 18 studies (*N*=649 adults aged 60+ years). Although a non-significant effect of yoga was observed for depression (SMD = -0.57), findings across the studies included in the review were mixed. Elavsky and McAuley (2007) also provided preliminary evidence that yoga may be effective in enhancing certain aspects of self-esteem in post-menopausal women. Women assigned to a walking condition reported improvements in physical condition, strength, and body attractiveness esteem, and women in the yoga group reported improvements in body attractiveness esteem after the 4-month intervention compared to a control condition. However, no increases in global self-esteem or physical self-worth were observed in either group.

In in a meta-analysis on cognitive health by Gothe and McAuley (2015), yoga practice led to improvements in attention, processing speed, executive function, and memory across 15 RCTs (g = 0.33) and 7 acute bout studies (g = 0.56). Further, effects sizes were similar to those reported in relation to aerobic exercise (Smith et al., 2010). In older adults specifically, Gothe and colleagues (2014; 2013) observed greater improvements in working memory and executive function after an acute bout of yoga, compared to aerobic exercise, and after 8 weeks of yoga practice, compared to a stretching-strengthening control. Likewise, Eyre and colleagues (2016) observed improvements in brain functional connectivity and visuospatial memory in a small sample of older adults assigned to 12 weeks of hatha yoga compared to a memory enhancement training control. Taylor-Piliae and colleagues (2010) also provided evidence suggesting Tai Chi may lead to greater improvements in cognitive functioning in older adults compared with aerobic exercise. These findings have been supported by Northey and colleagues (2017) who observed significant effects of Tai Chi on cognitive function across four studies included in their meta-analysis. As findings are preliminary and generally diverse, researchers acknowledge that larger, prospective studies examining the effects of alternative exercise modalities on correlates of subjective well-being in older adults are needed.

Dose-Response

While dose-response relationships of exercise on negative psychological states and cognitive function have been examined, findings are equivocal. In relation to depression and anxiety, evidence suggests programs that are shorter in length (i.e., 3-12 weeks) and lower in intensity may have the largest effects compared with longer programs (i.e., 12+ weeks) and those of moderate and vigorous intensities. Barbour and Blumenthal (2005) found that in individuals aged 20-45 years, activity at a lower energy expenditure failed to provide significant reductions in depressive symptoms. However, researchers contend that older adults may respond differently to physical activity interventions compared to their younger counterparts (Arent et al., 2000; Herring et al., 2010). Thus, exercise trials of low intensity and short duration may be leveraged to provide the greatest reductions in negative symptomology in late life. While it remains unclear as to why shorter and lower intensity programs may elicit larger improvements in older adults' negative symptomology, it is possible that adherence is higher (Herring et al., 2010). Studies have also proposed that improvements may be due to participants being low-fit and previously sedentary, making low intensity physical activity more enjoyable and a more achievable goal. However, maintenance of these effects beyond the end of the intervention is unknown. Studies comparing the effects of various doses of exercise on negative states and including long-term follow-up assessments after program cessation may reduce these knowledge gaps.

Observational studies have consistently described a dose-response relationship between total volume of physical activity and cognitive function in older adults (Blondell et al., 2014; Xu et al., 2011). Fanning and colleagues (2017), using isotemporal substitution models, found that replacing 30 minutes of sedentary time with 30 minutes of moderate-to-vigorous physical activity resulted in improvements in performance on working memory and executive function tasks across 247 older adults. However, replacing sedentary time with light intensity activity did not confer the same cognitive benefits. Meta-analyses have provided more details on dose-response; however, findings have been mixed and are limited by design issues across RCTs. Northey and colleagues (2017) provided important evidence in support of the comprehensive physical activity guidelines including both aerobic exercise and resistance training. Findings also indicated that exercise sessions of a moderate duration (i.e., >45 to $\leq$60 minutes) and moderate or vigorous intensity may be most beneficial to older adults' cognitive functioning. Smith and colleagues (2010), on the other hand, observed positive cognitive outcomes across physical activity intensity levels. These preliminary and contrasting findings across studies indicate the need for further research examining the effects of exercise duration and intensity on older adults' cognitive functioning.

Moreover, Voss and colleagues (2014) have argued that daily moderate-to-vigorous physical activity may not offset the negative impacts of prolonged sedentary behavior on brain health and cognitive function. In this review, the authors provide compelling evidence of a common mechanistic pathway of cognition between moderate-to-vigorous physical activity and sedentary behavior. Certainly, more research examining the independent effects of sedentary behavior and interactive effects with light and moderate-to-vigorous physical activity is warranted. The conclusions drawn by Voss and colleagues (2014) suggest that neither sedentary time replacement nor increased physical activity should be promoted in isolation, but that combined efforts targeting the entire physical activity spectrum (e.g., light activity, moderate-to-vigorous physical activity, breaking up sedentary time) may most effectively benefit older adults' cognitive function. Findings across these studies indicate a need for additional RCTs investigating how various doses of physical activity are associated with different levels of cognitive function and, in turn, well-being.

As there has been little investigation of dose-response relationships between physical activity, positive psychological states, HRQL, and subjective well-being more research in these areas is needed. Studies have suggested that shorter interventions and light intensity exercise may have larger effects on HRQL (Gillison et al., 2009; McAuley et al., 2008). Likewise, Martin and colleagues (2009), in one of the few RCTs to examine the dose-dependent effects of exercise on HRQL, observed greater improvements in mental health status among participants assigned to the lowest dose of exercise when compared with the control group. However, more evidence is needed to verify the effects of lower volumes of physical activity on psychological health and HRQL, as this study also observed increases in physical and mental health status among participants in the highest dose group (i.e., exceeding physical activity recommendations). Taken together, the evidence across the literature suggests the effects of various doses of physical activity may differ across domains of well-being. Studies that aim to identify the physical activity dose or combination of doses (i.e., intensity + bout duration + mode + trial length) that optimize psychological, cognitive, and HRQL responses, and thereby subjective well-being, are need to reconcile these differential effects.

Mechanisms and Moderators

Studies have tested a number of mechanisms thought to explain the effects of physical activity on psychological states and cognitive function. Cardiorespiratory fitness is arguably the most studied mediator in older adults, partially due to a focus on aerobic physical activity that predominates the literature (Blake et al., 2009; McAuley et al., 2004; Prakash, Voss, Erickson, & Kramer, 2015). However, findings suggest that change in cardiorespiratory fitness is an unlikely mechanism of exercise's effects on well-being responses.

Other potential physiological mechanisms of the physical activity—self-related function relationship include physical activity-induced changes in neurotransmitters of the brain and endogenous opioids that are known to be associated with depression, anxiety and other mood constructs (Antunes, Stella, Santos, Bueno, & Mello, 2005; Morgan & O'Connor, 1988). While there is preliminary evidence for these mediators in younger individuals and within the context of acute physical activity (Antunes et al., 2005; Brosse, Sheets, Lett, & Blumenthal, 2002; Dinas, Koutedakis, & Flouris, 2011; Janal, Colt, Clark, & Glusman, 1984), it remains unclear as to how these biomarkers relate to the influence of regular exercise on psychological health in older adults.

Consistent with the model proposed by McAuley and Morris (2007), there is a body of evidence that indicators of self-related function may themselves be mediators of the more distal relationship between physical activity and subjective well-being (Awick et al., 2017b; Elavsky et al., 2005; McAuley et al., 2006; Mudrak et al., 2016; Rejeski & Mihalko, 2001). Awick and colleagues (2017b) found that previously sedentary older adults who increased their levels of moderate-to-vigorous physical activity after a 6-month exercise program reported significant reductions in a latent conceptualization of psychological distress (i.e., depression, anxiety, stress, sleep disturbance). Reduced distress was in turn significantly associated with improvements in satisfaction with life.

In relation to positive psychological states, Arent and colleagues (2000) discussed the use of physical activity as a mastery experience through which individuals may increase their exercise self-efficacy which, in turn, may contribute to more effective coping and better mood. Elavsky and colleagues (2005) reported that increased physical activity was positively associated with physical self-worth, self-efficacy, and positive affect in older adults 6 months after completing a 6-month physical activity intervention. Increased self-efficacy and positive affect were, in turn, significantly associated with greater satisfaction with life. Further, after a 4-year follow-up period (5 years from baseline), increases in physical activity were related to improvements in physical self-worth and positive affect, and these improvements in positive affect observed were directly associated with increased satisfaction with life. Importantly, the direct effect of physical activity on satisfaction with life was not significant at either time point. Thus,

positive psychological states may at least partially mediate the influence of physical activity on QoL, and these effects may be maintained years after programs end. In the context of public health, these findings not only highlight the capacity of exercise interventions for improving a host of negative and positive components of self-related function, but also suggest these improvements may be at least partially responsible for lasting improvements in subjective well-being and life satisfaction.

Mechanisms of cognitive change frequently explored include brain volume, brain activity and connectivity, and neurogenesis (Bherer et al., 2013; Erickson & Kramer, 2008). Specifically, these mechanisms are: white and gray matter volumes, structural integrity, synaptic plasticity, growth factors (e.g., brain-derived neurotrophic factor [BDNF], insulin-like growth factor [IGF-1]), brain vasculature, inflammation, and neuroendocrine function (Voss et al., 2014). For example, Erickson and colleagues (2011) provided evidence relative to the effects of aerobic exercise and cardiorespiratory fitness on brain volume, neurogenesis, and cognitive functioning. Hippocampal volumes after a one-year RCT increased in older adults assigned to a walking program and decreased among those assigned to a stretching control group. Further, increases in cardiorespiratory fitness (as measured by a maximal graded exercise test) and serum BDNF were correlated with these increases in hippocampal volume. Although fitness and BDNF were not associated with participants' performance on a spatial memory task across the intervention, increases in hippocampal volume in the walking condition were associated with improvements in performance on the memory task.

Likewise, Voss and colleagues (2010) observed increased functional connectivity, which, was correlated with improved executive function in older adults participating in 12-month walking and stretching/toning programs. While these studies represent some of the few to comprehensively examine relationships among exercise training, neural mechanisms, and cognitive function, findings represent correlated change. The literature is rich with studies investigating causal relationships between physical activity and brain structure and function (Prakash et al., 2015); yet, few have extended Erickson et al. (2011) and Voss et al.'s (2010) findings using structural tests of mediation of the causal pathway from exercise training to brain structure and function to cognitive function.

Despite growing knowledge of mediators along the pathway between physical activity and subjective well-being, less is known about the moderators. In this chapter, we have suggested that intervention (e.g., program length, activity mode) and population (i.e., healthy v. clinical) characteristics may modify the effects of physical activity on well-being outcomes in older adults. However, less research has focused on person-level moderators, such as gender, age, personality, and baseline well-being. Netz and colleagues (2005) observed greater improvements in well-being in young-old adults (d = 0.20) when compared with old-old adults (d = 0.11) across 36 studies. As fewer well-being outcomes were tested in old-old adults (13 v. 159 in young-old), further investigation of physical activity's effects on well-being in the oldest old is critical. Although studies have provided evidence of physical activity's effects on well-being in older women and men separately (McAuley et al., 2008; Vallance, Eurich, Lavallee, & Johnson, 2012), the differential effects of physical activity on well-being by gender are equivocal (Netz et al., 2005). Research has also shown that personality traits (e.g., neuroticism, extroversion, agreeableness) may predict satisfaction with life, happiness, negative affect, positive affect, and physical activity (Artese, Ehley, Sutin, & Terracciano, 2017; DeNeve & Cooper, 1998). Yet, how personality and physical activity may interact in effecting change in well-being is unknown. We also might expect that individuals with lower levels of well-being or physical activity at the beginning of an exercise intervention may stand to benefit most. For example, Reed and Buck (2009) reported that improvements in positive affect across 105 aerobic exercise studies was greatest in individuals with the lowest levels of positive affect at program initiation (d = 0.81 [lowest tertile] v. d = 0.26 [highest tertile]). Similarly, Netz and colleagues (2005) reported greater increases in well-being in sedentary versus non-sedentary adults (d = 0.35, 0.17, respectively). Unfortunately, most of these studies have not focused on moderators within older adults specifically even though aging researchers have stressed that modifying factors, such as baseline perceptions, may be more important in older adults compared with younger adults (Lehnert et al., 2012).

Other Considerations

In addition to the areas detailed above, there are other practical considerations for research investigating relationships among physical activity, psychological health, cognition, and well-being. First, studies suggest a positive relationship between physical activity and global well-being; however, due to a lack of experimental studies, few meta-analyses and systematic reviews have focused on well-being or global QoL in older adults. Therefore, more RCTs and reviews are warranted to provide more evidence of physical activity's influence on subjective well-being. Future research in this area should be explicit in their definitions of well-being and QoL, and, as such, carefully consider the measures utilized.

Similarly, design limitations noted across meta-analyses and reviews in psychological and

cognitive health warrant additional RCTs. For negative psychological states, it has become a challenge for researchers to design adequate placebo/attentional control groups given that center-based exercise programs may include other factors that facilitate reductions in negative symptomology (Hawley-Hague et al., 2014; Hawley-Hague, Horne, Skelton, & Todd, 2015). For example, the level of social support inherent in many exercise training interventions may be effective in and of itself for improving negative affective responses (Ehlers et al., 2017; McAuley & Blissmer, 2000); therefore, it will be important to identify the individual role of physical activity for improving psychological states independent of other psychosocial elements. While previous research has demonstrated that a home-based (i.e., non-social) physical activity program is capable of improving positive affect (Awick et al., 2017a), further comparisons of social vs. non-social programs are warranted.

In relation to cognitive health, RCTs that test the effects of exercise against an active control condition may be needed to provide more definitive evidence of physical activity's effects on cognition (Northey et al., 2017; Young et al., 2015). While some RCTs have observed positive effects of exercise training compared to an active control (Kramer et al., 1999), Northey and colleagues (2017) found that exercise training only improved cognitive functioning when compared with education and no contact control conditions. No differences were observed when exercise was compared with active or social control conditions. RCTs may also help us to better understand interactions among physical activity, self-related function, cognition, health status, and well-being in older adults and to expand our knowledge of potential mediators, as recommended by Etnier, Nowell, Landers, and Sibley (2006).

Further, as subjective well-being is in part a cognitive assessment of one's life satisfaction (Diener, Oishi, & Lucas, 2003; Rejeski & Mihalko, 2001), understanding well-being perceptions among older adults with cognitive impairment or compromised health status represents a significant challenge (Logsdon, Gibbons, McCurry, & Teri, 2002). Deficits in attention, memory, and communication, in addition to psychological health symptoms such as depression and anxiety, can affect older adults' ability to understand questionnaire items and effectively communicate subjective states (Logsdon et al., 2002). The development of measures that validly assess well-being in individuals with cognitive impairment and dementia is needed (Thorgrimsen et al., 2003). Finally, although the temporal order of effects relative to self-related function and well-being is well-established, the directionality of the association between cognition and well-being is equivocal. Some studies suggest positive well-being is protective against age-related cognitive decline, while others argue the relationship may be reciprocal (Goveas et al., 2016). Therefore, the question remains—does greater life satisfaction lead to preserved cognitive function with aging, or does maintained cognitive function lead to greater perceptions of life satisfaction among older adults? Studies that investigate interactions among demographic (e.g., education, income), clinical (e.g., disease states), psychological, and cognitive correlates along the pathway between physical activity and well-being in older adults may help to answer this question, in addition to others relative to exercise mode, dose-response, and mediators of change (Chodosh, Kado, Seeman, & Karlamangla, 2007; Goveas et al., 2016; McAuley & Morris, 2007).

Similarly, evidence has suggested a bidirectional relationship between physical activity and the psychological, cognitive, and global aspects of well-being. For example, although individuals who are regularly active may be less likely to report depressive symptoms over time, individuals reporting fewer depressive and anxiety symptoms may also be more likely to participate in regular physical activity (Steinmo, Hagger-Johnson, & Shahab, 2014). Moreover, while a robust literature supports exercise in ameliorating cognitive decline in older adults, McAuley and colleagues (2011) also found that older adults' baseline self-regulation and executive function were predictive of their adherence to a randomized exercise trial. Finally, the framework proposed by McAuley and Morris (2007) posits well-being as a distal outcome of physical activity; yet, empirical studies have suggested that individuals with greater life satisfaction may also be more likely to engage in health behaviors such as physical activity (Diener & Chan, 2011). Unfortunately, most studies investigating these reciprocal interactions between physical activity and subjective well-being have been conducted in the context of observational designs and in younger adult cohorts. RCTs in older adults are needed to better understand the temporal nature of the relationship between physical activity and well-being in this population.

Conclusion

The literature on physical activity and QoL, self-related function, and cognition provides a compelling argument in support of physical activity for improving subjective well-being in older adults. However, systematic, empirical evidence is lacking. Several factors outlined in this chapter have contributed to a lack of synthesis in the evidence on well-being in older adults. First, there is a need to better operationalize well-being and QoL in the context of physical activity interventions, as an array of definitions and measures have been used when referring to well-being (e.g., HRQL). We further contend that QoL and health status (i.e., HRQL) are distinct constructs and should, therefore, be measured and

interpreted as such.

Next, a robust literature has evidenced the effectiveness of physical activity for improving self-related function and cognitive health, but few studies have linked these outcomes with well-being in older adults. Studies examining the pathway of changes in physical activity to mediators (e.g., self-related function and cognitive health) and global QoL in the context of RCTs are needed. The conceptual model proposed by McAuley and Morris (2007) provides a useful framework for filling this knowledge gap. Specifically, further scientific investigation in this area may help researchers to (1) define exercise prescriptions that optimize well-being in older adults; (2) clarify the temporal order of effects along this path; (3) better understand the mechanisms of change in well-being due to increased physical activity; and (4) identify for whom and under what conditions subjective well-being is most amenable to physical activity. Such knowledge may improve the design of interventions, programs, and health policies aimed at increasing well-being and QoL in older adults.

Both the psychological health and cognition literatures suggest aerobic and non-aerobic exercise programs may benefit well-being in older adults. The HRQL and psychological health literatures indicate that lower intensity programs may result in larger improvements in negative and positive psychological states. Findings within the cognition literature, on the other hand, suggest moderate-to-vigorous intensity exercise may be needed to elicit meaningful improvements in older adults' cognitive function. Additional research aimed at identifying the doses of physical activity that most effectively improve self-related function, cognition, health status, and well-being is needed. This includes further examination of trial length and type (e.g., home- v. center-based) and activity intensity, mode, and duration. Findings also suggest that less studied biological mechanisms (e.g., neurotransmitters, brain structure), in addition to cardiorespiratory fitness, warrant further investigation. Finally, although psychological factors, such as depression and self-efficacy, are generally accepted as proximal outcomes of physical activity, less is known about the temporal interaction between cognition and well-being (Goveas et al., 2016).

As medical technologies advance and the population continues to age, it is imperative to preserve the quality of extended years of life. Physical activity has emerged as an effective and attainable method for improving a number of important factors associated with well-being. While more research is needed to improve our understanding of lifestyle behaviors and well-being with advanced age, it is clear physical activity can be leveraged to improve subjective well-being in older adults.

Abstract

Positive Psychological Interventions are activities that have been demonstrated to cause a positive change in a population by increasing a positive variable (e.g., optimism). Although these activities come in a variety of forms and focus on a wide range of positive variables, researchers tend to concentrate their efforts on seven popular and well-researched categories of PPIs that are as follows: meaning, gratitude, strengths, savoring, optimism, empathy, and kindness. Collectively, the PPIs in these domains have been shown to alleviate depressive symptoms, increase pro-social spending and social connectedness, reduce suicidal ideation, increase subjective well-being or happiness, and many other positive changes across diverse populations. Still, there are many questions that warrant discussion for future research such as sex and cultural differences, long-term effects, and antithetical or unexpected reactions to activities. Along with examining these benefits and critiques of PPIs, we discuss the background and state of replicability for each domain.

Keywords: Positive Psychological Interventions, Subjective Well-being, Self-Help

The relatively new field of Positive Psychology has produced a great deal of clinically applicable research through the study of Positive Psychological Interventions (PPIs). In both self-help, research, and clinical practice, well-researched domains such as gratitude, savoring, and kindness encourage individuals to shift their focus away from negative experiences, traits, and circumstances towards the positive (Parks & Biswas-Diener, 2013). The idea of this approach is to strengthen the non-psychopathological qualities of an individual so that one is less susceptible to future psychopathology, and so that distressing symptoms become more manageable. PPIs have been designed and tested for those who are suffering from severe mental or physical ailments (e.g., schizophrenia; cancer), but also for subclinical psychological symptoms (e.g., mild levels of depression and anxiety; management of chronic conditions) and normally occurring problems (e.g., bereavement, vocational anxiety, interpersonal conflict). Furthermore, PPIs enhance individual's lives that are not experiencing a problem (Seligman & Csikszentmihalyi, 2000). Essentially, unlike other more traditional psychological interventions (e.g., cognitive-behavioral therapy), PPIs are designed to benefit anyone who uses them, regardless of one's mental state or circumstance.

Parks and Biswas-Diener (2013) proposed a set of criteria to determine which interventions fall under the umbrella of "PPI." First, the activity must target some positive variable (e.g., positive affect). Thus, researchers typically design PPIs to serve a function through the targeting of a positive variable. For example, some PPIs seek to improve happiness among those who are depressed. The second criterion is that the intervention observably affects that positive variable through experimentation. This second criterion distinguishes between interventions with an empirical basis and those disseminated without research vetting (for example, certain self-help books and programs whose "evidence base" comes from testimonials and public acclaim rather than data). Lastly, there must be empirical evidence that a positive change in the tested population was caused by a change in the positive variable targeted by the intervention. For example, if one were to aim to increase hope in employees who hold high-stress jobs, there must be some evidence that increasing hope actually improves the ability of those employees to persevere at work, reduce their stress, perform better, and so on.

PPIs designed to increase an individual's happiness and wellbeing generally fall into seven well-researched domains. There are many other areas, such as creativity, courage, patience, and humor (see Parks & Schueller, 2014 for chapters on these emerging areas and others), which have some research basis, but less than those featured in this chapter. In no particular order, the well-researched domains are meaning, gratitude, strengths, savoring, optimism, empathy, and kindness. In this chapter, we examine the theoretical framework, as well as an overview of the interventions, limitations, and future directions, for each of these domains with a particular emphasis on their effect on subjective well-being and happiness.

Meaning

Meaning-oriented interventions focus on clarifying an individual's sense of purpose – that which gives one's life importance. Research suggests that life is generally pretty meaningful and that having

meaning may be an important element of good functioning (Heintzelman & King, 2014; Steger, 2012). Due to the complex nature of the construct, there is debate within the field as to which approach, either reductionist (e.g., measuring a single "meaning") or multidimensional (e.g., measuring various aspects that sum to make "meaning"), is appropriate. Many opt for the multidimensional approach consisting of two parts; although, many people have broken it down further (Martela & Steger, 2016; Leontiev, 2006; Reker & Wong, 1988). The first component is purpose, which is the aspirations or goals an individual possesses. This first component applies to multiple meaning-oriented ideas such as reasons for being in certain relationships or vocational ambitions. The second part is coherence – one's comprehension about one's life. This second part relates to the consistency one feels when assigning meaning to one's lives (i.e., prescribing circumstances and behaviors to one's bigger picture). Writing in meaning-oriented activities promotes this coherence aspect of meaning in life.

As previously mentioned, an individual can find meaning by examining one's relationships. In other words, one can find meaning by defining reasons one is in a relationship. Furthermore, one can find meaning within one's work life through a calling. A calling is a sense of having a religious purpose or devotion to one's vocation. The difference between a career and a calling is that when someone possesses a calling they experience motivation that is spiritual and does not solely come from the desire to earn money or do a good job. Moreover, Dobrow-Riza & Heller (2015) found in a longitudinal study that individuals who had a stronger early musical career calling were more likely to perceive their abilities as better, which resulted in them pursuing musical careers. Perhaps, this sense of direction in one's career may lead to well-being.

Consequently, there is evidence to support the claim that there are many psychological benefits to finding and practicing meaning in life. Duffy & Dik (2013) found that developing an understanding of one's calling leads to higher levels of career maturity. Career maturity deals with one's ability to process and make difficult vocational decisions. This benefit ultimately leads to better and more fulfilling work outcomes. In a study done by Bassi, Bacher, Negri, and Delle (2013) a successful and a failing insurance company were compared in terms of life satisfaction, well-being, and job-meaning scores. Interestingly, job-meaning scores did not differ between the companies, suggesting that the success of the organization one works at is independent from one's vocational purpose. However, those at the thriving company experienced higher levels of meaning, life satisfaction, environmental mastery, and autonomy at an organizational level.

An example of a meaning-based PPI is goal-setting (Parks & Layous, 2015). In this activity, individuals set up goals they plan on achieving along with a timeline of when to accomplish those goals. This planning strengthens the purpose aspect of finding meaning in life by determining precise motivations and steps towards progress. Another common meaning-based intervention is reflecting on one's life as a whole (e.g. Pennebaker's writing paradigm; see Niles, Haltom, Mulyenna, Lieberman, & Stanton, 2014 for a review). This activity can be used to focus on some of the more unexplainable or negative aspects of one's life (e.g., getting a divorce) by filling in or explaining the negative or confusing times with meaning.

Still, some argue that having a calling may not be beneficial to one's subjective well-being. This antithetical effect may be explained by the distress individuals feel if they do not live up to their calling; which in some circumstances is probable if one's career aspirations are particularly unrealistic or challenging to accomplish. Future research should examine the long-term effects of meaning-based interventions using longitudinal designs. A majority of studies on meaning-based interventions focus on the immediate effects or cross-sectional, and thus concurrent, effects instead of the long term. Lastly, gender differences may explain differences in how individuals feel towards their calling. Researchers should seek to differentiate the psychological effects and benefits of having a calling between the genders.

Gratitude

The domain of gratitude consists of activities in which an individual exercises one's appreciation for the altruistic acts of another individual or individuals. Originally, the sociobiologist Trivers (1971) proposed that the emotion of gratitude is dependent on the cost to benefit ratio one experiences in a relationship. He argued that gratitude is a means of regulating the generous acts from the benefactor so that the natural sensitivity to feeling cheated is controlled. Specifically, he proposed that there is system between individuals called *reciprocal altruism*. This concept suggests that there are two types of behaviors when giving and taking in a relationship. The first type comprises behaviors of altruism and the second type are behaviors of cheating. He suggests that humans have the tendency to perform both types of behaviors. If either one of these behaviors significantly exceed the other than an individual who is giving more may feel that one is being taken advantage of, which adds tension to the relationship. However, other variables play into controlling this dynamic such as, "friendship, dislike, moralistic aggression, gratitude, sympathy, trust, suspicion, trustworthiness, aspects of guilt, and some forms of dishonesty and hypocrisy"

(p. 35). Therefore, gratitude from the individual displaying cheating behaviors may reduce the altruistic individual's feelings of being cheated.

More recent studies argue that gratitude plays a more critical and complex role than merely regulating the cost-benefit ratio between two individuals. Algoe, Haidt, & Gable (2008)'s *Find-Bind-and-Remind Theory* proposes that gratitude may also be a reaction to the kind acts of another individual; not just to mediate the relationship. The reaction may occur because acts of altruism stand out in comparison to other more common social interactions. This theory stands apart from traditional theories because the duration and intensity of the relationship between the benefactor and the recipient may not affect the expression of gratitude. This theory recognizes that the experience of gratitude can happen outside of established relationships, where mediating the give-take ratio would be less important than in established relationships.

With the role of gratitude for relationship success in mind, one of the most popular gratitude-based intervention is the gratitude letter exercise. In this activity, individuals write a letter to someone who they are very grateful for, even though they may have never fully expressed their gratitude to that individual. When writing the letter for an appropriate amount of time and length, those taking part in this activity demonstrated an increase in well-being after just ten minutes. Additionally, the benefits of writing a gratitude letter occur regardless of whether the letter is delivered to its intended recipient (Seligman, Steen, Park, & Peterson, 2005) or if it remains undelivered (Boehm, Lyubomirsky, & Sheldon, 2011; Lyubomirsky, Dickerhoof, Boehm, & Sheldon, 2011). Moreover, expressing gratitude is common outside of relationships where individuals are not necessarily grateful for other individuals rather, they are grateful for positive circumstances and situations. One can exercise this kind of gratitude through the three good things activity. In this intervention, individuals write or think about three good things that have happened to them recently or during that same day. Along with being convenient and easy to do daily, this intervention can decrease an individual's negative affect after just two weeks.

Furthermore, gratitude may decrease stress and depressive symptoms while encouraging higher perceived social support (Wood, Maltby, Gillett, Linley, & Joseph, 2008). This finding supports the idea that practicing gratitude in clinical settings may be helpful in treating some depressive and anxiety disorders. Additionally, gratitude promotes prosocial behaviors to strangers more than general positive affect (Bartlett & Desteno, 2006). These helping behaviors may lead to other benefits typically experienced from kindness and empathy interventions. In addition, Vieselmeyer, Holguin, and Mezulis (2017) found that expressing gratitude after a school shooting (Seattle Pacific University) lead to a decrease in post-traumatic stress symptoms and an increase in post-traumatic growth. This finding suggests that gratitude may be an effective protective and coping mechanism for trauma-related disorders in clinical settings. Lastly, Emmons and McCullough (2003) found that gratitude was able to increase one's subjective well-being on many on numerous psychological and physical measures.

There is some concern in the literature on the effects one's cultural background has on the potential benefits of the gratitude interventions. Boehm, Lyubomirsky, & Sheldon (2011) found that Anglo Americans demonstrated a larger increase in life satisfaction than that of the Asian Americans completing the same gratitude-based intervention. In addition, Layous, Lee, Choi, and Lyubomirsky (2013) presented evidence that Koreans may benefit even less from these kinds of interventions. These findings suggest that one's cultural values affect the outcome of gratitude interventions. Some have also proposed that certain depressive styles affect gratitude interventions. According to Sergeant and Mongrain (2011) self-critics received more benefits from the gratitude intervention than needy individuals. In fact, the gratitude intervention for needy individuals had a negative impact on their self-esteem.

Future research should examine whether or not gratitude affects one's social support system. There is debate as to whether having strong social support creates gratitude in an individual or if gratitude in an individual causes more people to join one's social network. Regardless, gratitude may increase perceived social support (Wood, Maltby, Gillett, Linley, & Joseph, 2008). Lastly, researchers should focus on the role of gender in the style of expressing gratitude (e.g., are women more likely to express gratitude? Are men and women more likely to express gratitude to certain individuals?)

Strengths

An essential virtue of PPIs is focusing on the positive instead of the negative. Likewise, focusing on one's strengths, instead of one's weaknesses, is an important area of research for PPIs. Researchers have separated strengths into two types. The first kind are strengths of character (e.g., empathetic, kind, and determined), which are qualities individuals possess as character traits or temperament. The second type of strengths are talents (e.g., good friend or parent, exceptional football player, and natural musicianship) which are qualities individuals possess as aptitude or skills (Park, Peterson & Seligman, 2004). Strength-based PPIs effectively use both types of strengths, although researchers tend to focus more on character

strengths.

The general structure of strength-based interventions is a strength-based assessment brings awareness to one's strengths, and then a counselor or therapist will explore those findings with the client, although the latter is not necessary. These interventions work by giving an individual feedback and guidance to use those strengths more often, in a novel manner, or as a means of replacing negative or harmful behaviors (Parks & Layous, 2015). For example, strengths assessments may reveal that someone is an exceptionally caring person. One could take this information and try to focus one's efforts on exercising one's caring demeanor by doing more volunteer work or taking care of family and friends through small acts of kindness. Similarly, a strengths assessment may reveal that one is remarkably good at considering the different perspectives of others. One may exercise this strength by serving on a college judicial board, or volunteering to help with evaluating applications hiring in one's department.

Importantly, using one's talents and character attributes in a positive or novel manner is associated with many benefits. A study by Seligman, Steen, Park and Peterson (2005) demonstrated that strength-based interventions are effective at increasing happiness and decreasing depressive symptoms after just one month. These effects remained present for the 6-month follow-up. Moreover, Park, Peterson, and Seligman (2004) found that certain types of character strengths (e.g., creativity or love of learning) were associated with higher levels of subjective well-being. Generally, agreeableness and extraversion are positively associated with life satisfaction. Similarly, character strengths have been found to be a more potent promoter of resilience than positive affect, self-efficacy, optimism, social support, self-esteem, and life satisfaction (Martínez-Martí & Ruch, 2017). However, an important caveat to strength-based interventions is that one must actually use the identified strengths. Seligman et al. (2005) found that the group in which participant's strengths were only identified yielded very similar results to the control group. Taking an assessment and talking about one's strengths does not yield the same benefits as using those strengths – particularly in a novel manner.

A potential downfall to using strength-based interventions is that the participants may be inclined to feel as if the strengths are permanent, and therefore unchangeable (Biswas-Diener, Kashdan, & Minhas, 2011). This can be discouraging to individuals because they may believe that pursuing the strengths serves no purpose because they are immutable. This defeating idea renders the strength assessment ineffective because one must actively pursue and believe that they are able to grow the strengths to receive the benefits. Moreover, there is concern over the inappropriate use of strengths, which may lead individuals into harmful or dangerous situations. For instance, if some individuals discover they have the strength of "zest," they may apply their enthusiasm to maladaptive behaviors, or they may pursue stimulation-seeking or substances in order to enhance their experience of zest.

One other concern regarding strengths has to do with strengths assessment, which is typically lengthy and cumbersome. Although many real-world settings use more time-efficient workarounds to strengths assessment such as a patient-endorsed checklist, research has not demonstrated whether this type of assessment approach is equally valid. Research should examine the benefits of patient identified strengths instead of assessment or clinician identified strengths. Some have suggested that there may be benefits to simply having an individual assess oneself.

Savoring

When individuals choose to savor, they focus on neglected or forgotten details and experiences. Savoring-based interventions direct individuals to focus on these details (e.g., the intricate tastes of food or the way the air smells). Researchers divide savoring activities into four types. *Sharpening perception* occurs when an individual focuses on sensory experiences, which can involve all of the senses. *Memory building* occurs when an individual focuses on significant moments, which may work by inducing an appreciation of the fleeting nature of the present moment (Kurtz & Lyubomirsky, 2012). *Reminiscence* involves savoring non-sensual experiences (e.g., ridding a fun roller coaster in the past). Lastly, the fourth type of savoring, related to gratitude, involves relishing the healthy aspects of one's relationships (Borelli et al., 2014).

There are many other benefits to savoring mentioned in the literature. First, Bryant, Smart, and King (2005) found that a reminiscing intervention lead to greater levels of positive affect when compared to the control group after one week post-study. Furthermore, savoring imaginary future positive experiences (mental time travel) daily for a period of two weeks heightened levels of happiness when compared to savoring negative or neutral imaginary future experiences (Quoidbach, Wood, & Hansenne, 2009). Some research also suggests that certain aspects of savoring (e.g., mindfulness, reappraisal, & meaning) can be a potent buffer against stress (Bryant, 2003). Still, naturally savoring events (i.e., outside of clinical interventions) may be effective. Gentzler, Palmer, and Ramsey (2016) demonstrated that naturally savoring positive events was associated with a higher perception of one's ability to savor and an

increase in subjective well-being.

One of the most popular savoring-based PPIs is a slow and attentive experience of the senses (i.e., sharpening perception). This intervention involves consuming a certain food (e.g., a cookie) slowly and with high levels of focus on the senses. Instead of eating the cookie at a normal rate, an individual performing this intervention might start by smelling and inspecting the textures of the food before taking a bite. Black & Areni (2016) demonstrated that this activity can decrease one's appetite – filling people up faster with smaller proportions of food. Another activity that uses savoring is focusing on the positive memories an individual has shared with others. This activity involves a slow and concerted effort to remember all the details by mentally re-experiencing the memory as if it were happening again. This type of reminiscing activity may lead to higher overall relationship-satisfaction as well as an increase in positive affect. This effect was particularly present in those whose baseline overall relationship-satisfaction was naturally elevated (Borelli, Rasmussen, Burkhart, & Sbarra, 2015).

Future research should examine the role of everyday savoring on the efficacy of reminiscing-based activities. Essentially, if one habitually savors during any given moment, then one's recollection of that moment would be more intense and detailed when compared to someone who was paying less attention.

Optimism

Optimism-based activities focus on developing a positive outlook of the future instead of a negative one (Scheier & Carver, 1985). One way in which optimism may affect an individual is by creating a desire to work towards predicted or expected positive outcomes. An important distinction is that optimism and pessimism may not exist on a continuum to form a unidimensional trait. Segerstrom, Evans, and Eisenlohr-Moul (2011) found that optimism and pessimism may be separate constructs; it is possible to be both optimistic and pessimistic at the same time.

Optimism may also work by assisting an individual in forming a positive coherent life narrative (different from a meaning-based coherent life narrative, which is not necessarily positive). Some suggest that optimism creates an illusion of control for an individual in which one feels more secure about one's ability to control one's life. In fact, Alloy and Abramson (1979) found that nondepressed individuals tend to overestimate the control they have over their lives whereas depressed individuals tend accurately estimate their control. This finding suggests that optimism may be linked to an overestimation of one's control over one's life, which is an essential component to healthy functioning. Additionally, optimism may increase positive and healthy self-serving biases in individuals, whereas depression and pessimism may lead to negative biases (e.g., discounting positive character strengths) (Alloy & Ahrens, 1987).

Arguably, the most notable activity that captures the idea of forming a coherent positive life narrative is the Best Possible Selves (BPS) activity. In this activity, participants write about a future in which they fulfill every expectation and aspiration they desire. The benefits of this activity are effective when completed twenty minutes a day over the course of four days (King, 2001). Another optimism-based intervention is the Life Summary. In this intervention, individuals write about an ideal future in which everything turns out as planned – or better. When combined, these interventions focus on creating a positive coherent life narrative.

A known benefit of optimism-based interventions is an increase in positive affect and positive future expectations, accompanied by a decrease in negative expectations (Enrique, Bretón-López, Molinari, Baños, & Botella, 2017). Peters, Flink, Boersma, & Linton (2010) found that less catastrophizing is associated with a decrease in pain sensitivity and an increase in one's ability to adjust to painful stimuli. Moreover, there is an association between high levels of optimism and a faster recovery from serious surgeries along with a lower likelihood of recurring illnesses (Balck, Lippmann, Jeszen, Klaus-Peter, & Kirschner, 2016). A proposed explanation for this health-related benefit is that individuals who are high in optimism tend to address their health concerns in a more constructive way. Furthermore, optimism is likely to increase one's desire to protect one's health, higher levels of engagement and coping, lower levels of avoidance and disengagement, and better relationships (Carver, Scheier, & Segerstorm, 2010). One can attribute this finding to optimism's effects on preparing an individual to expect positive, instead of negative, outcomes. Lastly, optimism may promote subjective well-being by minimizing the distress an individual experiences over events and decreasing depressive symptoms (e.g., as measured in women with postpartum depression) (Carver & Gaines, 1987).

Nonetheless, there is some concern over the malleability of optimism. When examining the benefits of optimism, one has to consider the difference between state and trait optimism. If some individuals are predisposed to optimistic thinking, then there is a possibility that those people may not benefit as much as someone with less dispositional optimism. Likewise, for those less inclined to thinking optimistically, practicing optimism through interventions may feel less natural. A distinction between the effects of state optimism affected by trait optimism (a possible moderator variable) need to be further

addressed in the literature. Second, researchers should further examine the effects and benefits of little optimism compared to big optimism. Little optimism has to do with fleeting situational attitudes (e.g., "I am going to make it to work on time!"). Whereas big optimism focuses on large-scale situations (e.g., "The economy is about to flourish!"). Making an important distinction between these types of optimism could be beneficial to future research (Peterson, 2000). Lastly, the literature on optimism-based interventions is lacking in strong longitudinal studies where several interventions occur. As a result, researchers should focus on the long-term effects of practicing optimism.

Empathy

Empathy-based interventions focus on taking another person's perspective in order to develop a deeper understanding of the feelings another is experiencing. There is a consensus that empathy is multidimensional and composed of both an affective and cognitive component (Decety & Jackson, 2004). The affective component has to do with the sensitivity one has towards experiencing other's emotional states, whereas the cognitive component has to do with the extent to which one is aware of the flexibility and intricacy of others' thoughts.

Cultivating empathy is beneficial on both an intimate and a professional level. Arriaga & Rusbault (1998) demonstrated that accurately taking a partner's perspective during a conflict leads to a better resolution of that conflict. Additionally, Sadri, Weber, & Gentry (2011) found that, in the workplace, employers who exercised more empathy were more likely to receive positive evaluations and higher productivity from employees. Lastly, in the book "Video Interaction Guidance", authors Kennedy, Landor, and Todd (2011) explain the benefit of increased well-being from practicing empathy through a relationship-based intervention. A relationship-based intervention focuses on the quality of an individual's relationship with others as a measure and a means of promoting one's subjective well-being and overall happiness.

An example of an empathy-based PPI is loving-kindness meditation (LKM). LKM is similar to mindfulness meditation; however, the focus is on building a strong love for others instead of awareness. The love practiced in LKM is one that has no conditions and is not restricted to friends and family, but extends to all living beings. The idea behind LKM is that anyone can practice to attain this particular idealistic feeling of love for others. Additionally, LKM reliably increases subjective well-being (Galante, Galante, Bekkers, & Gallacher, 2014; Hofmann, Grossman, & Hinton, 2011; Shonin, Gordon, Compare, Zangeneh, & Griffiths, 2015). Another empathy-based PPI is self-affirmations – or having empathy for oneself. Self-affirmations fall into two categories (Armitage & Rowe, 2011). The first is attribute self-affirmations which emphasis an individual's positive attributes and skills. The second type is value self-affirmations which emphasize an individual's morals. Both type of self-affirmations may promote positive behaviors (e.g., increased fruit intake and cessation of indoor tanning) (Fielden, Little, Sillence, & Harris, 2016; Mays & Zhao, 2016) and increase feelings of self-worth (Dijk, Koningbruggen, Ouwererk, & Wessling, 2011).

Nonetheless, there are concerns within the field that need further investigation on how and when perspective taking and empathy are not always positive. Hodges, Clark, and Myers (2011) discuss how perspective taking when in a competitive environment where resources are limited might cause an adverse reaction for both the empathizer and the target of the empathy. First, when an individual attempts to empathize with someone considered a competitor, one may use that information to figure out the individuals plans instead of trying to form a genuine connection. This misuse of empathy could lead to increased aggression and selfishness if the empathizer finds that the targets perceived plans are threatening (Caruso, Eply, & Bazerman 2006). Second, when a perceived competitor attempts to empathize with an individual the actions of the empathizer may seem disingenuous and manipulative which increases mistrust and competitiveness (Caruso, Epley, & Bazerman, 2007).

Kindness

Kindness interventions aim to promote altruistic behaviors towards others with the intention of fostering positive emotions in the benefactor. One PPI that promotes kindness is prosocial spending – the act of spending money to benefit others. Generally, those with more money tend to be happier than those with less money; however, science on prosocial spending is revealing that how you spend your money also affects happiness. Still, there are times when spending money on others does not increase happiness. Dunn, Aknin, and Norton (2008) suggest that three criteria that allow prosocial spending to be beneficial. The first is relatedness, in which the act of prosocial spending results in a feeling of being close to another individual. This need satisfies individuals' desires of acceptance and love from others. The second criterion is competence, which deals with others knowing that the act of prosocial spending results in some positive outcome. Essentially, the powerful benefits of prosocial spending are most potent when the benefits to the receiving party are apparent to others. For example, donating to a charity fulfills this requirement well since

there is a clear positive outcome that is universally accepted. Lastly, one must feel autonomous in one's actions. The individual cannot feel as if they were coerced or forced to prosocially spend. If one fulfills these three conditions, prosocial spending may increase happiness and well-being (Dunn, Ashton-James, Hanson, & Aknin, 2010).

There are other guidelines to ensure that practicing acts of kindness is beneficial. First, Lyubomirsky, Sheldon, & Schkade (2005) found that the amount of time in between the acts of kindness affects the benefits to one's emotional health and well-being. When participants performed single acts of kindness once a day across a week, the benefits were not as strong as when participants performed five acts of kindness in a single day. These activities have little to do with the behavior itself, rather, the reflection of the behavior post-act (Parks & Biswas-Diener, 2013). Additionally, the acts of kindness must have an element of novelty involved. For example, an individual who always holds the door for others would not significantly benefit from holding the door for several people in a single day. However, if an individual who does not hold the door for others suddenly held the door open for everyone they encounter in a single day, they would experience the benefits of acts of kindness to well-being more intensely than the former individual.

Acts of altruism may increase both the giver and receiver's well-being. Pressman, Kraft, and Cross (2014) concluded that acts of altruism were responsible for a significant increase in positive affect and a decrease in negative affect among the givers in their study. Moreover, Windsor, Anstey, & Rogers (2008) found an inverted U shape between hours spent volunteering and life satisfaction. Individuals who spent little and too much time volunteering reported similar low levels of well-being. Whereas, individual who reported a moderate amount of time volunteering reported the highest levels of well-being. Lastly, a study by Schwartz, Keyl, Marcum, and Bode (2009) found that helping others within a person's family was associated with benefits to health and subjective well-being.

Nonetheless, there is argument within the field over the need for authenticity when helping others and how the motivation affects the benefits. Future research should examine if having intrinsic motivation is more potent than extrinsic motivation. Additionally, there are several other concerns when studying the benefits of acts of kindness. First, studies should examine if knowing the individual, as opposed to performing the acts of altruism on strangers, affect the benefits. Second, individuals should examine if planned acts of kindness have a different effect than random acts of kindness. Lastly, future research should examine if seeing the individual respond to the acts of kindness affect the benefits.

Conclusion

The study of PPIs has resulted in a wide breadth of scientific knowledge on what is involved in promoting subjective well-being, happiness, and life satisfaction. Despite great strides in the science of increasing subjective well-being – the specific techniques that improve subjective well-being and the key features of interventions such as variability and dosage that result in optimal outcomes – researchers still know little about the underlying theoretical mechanisms that drive well-being interventions. Although for a variety of interventions, many have proposed positive emotion as a mechanism, conversations with other researchers in the field indicate to the second author that more often than not, well-being interventions affect variables like depression with much larger effects than for positive emotion, if there is an effect on positive emotion at all. Other potential mechanisms should be tested and considered such as hope, self-efficacy, and attention towards positive stimuli. Furthermore, it may be that the idea of a single mechanism that underlies well-being interventions is a misnomer, because different techniques operate by different mechanisms. Although seminal work by Fredrickson and colleagues on the *Broaden-and-Build Model of Positive Emotions* provides an important foundation for understanding how it is beneficial to improve subjective well-being, the search for other mechanisms should also continue.

There are a few other domains that are becoming popular areas of interest among researchers worth mentioning, though they were beyond the scope of this chapter. First, forgiveness interventions are that which focus on the decision to let go of the negative feelings of anger, resentment, and hurt towards another individual for behaving in a way that was perceived as offensive (DiBlasio, 1998). Forgiveness-based interventions may reduce negative thoughts and feelings and increase positive thoughts and feelings about a transgressor, increase forgiveness self-efficacy (i.e., forgiving without external pressure), and even increase the likelihood that forgiveness will generalize to new situations (Harris et al., 2006). Additionally, forgiveness-based interventions may be effective in helping females who have survived abuse (Freedman & Enright, 2017) and students who experience emotional breakdowns (Mohammadi & HajiAlizadeh, 2017). Secondly, hope interventions and Hope Intervention Programs (HIP) focus on decreasing an individual's feelings of helplessness, powerlessness, and despair while increasing feelings of self-esteem (Shin & Park, 2007). Hope interventions may increase sexual satisfaction and perceived body image in men who suffer from addiction (Koolaee, Eslamei, & Mohammadi, 2017) and increase the effectiveness of

self-care instructional programs for those suffering from multiple sclerosis (Anderson, Turner, & Clyne, 2017). Lastly, Chamodraka, Fitzpatrick, and Janzen (2016) focused on the effectiveness of hope in a therapeutic setting and found that a good match between a client's preferences and a clinician's hope-based input can result in a client having increased faith in the therapeutic process, which leads to an increase in hope as a positive outcome. Overall, these domains of hope and forgiveness need much more research to be on par with the other previously mentioned domains.

Finally, one rising area of interest among researchers and clinicians is the dissemination of PPIs in these aforementioned domains. Although providing clients with worksheets and homework in a therapeutic environment similar to Cognitive Behavioral Therapy (CBT) or Dialectal Behavioral Therapy (DBT) would work, some are opting for a more user-friendly method of delivery to individuals who are not receiving treatment from a licensed professional. This can be done using mobile technology (i.e., smart phone applications), but new methodological considerations arise when conducting interventions over the internet (see Parks, 2014). Nevertheless, technology is a promising avenue for the dissemination of well-being interventions to scale.

In conclusion, PPIs have both theoretical value for the study of how human happiness works as well as practical applications for both therapeutic settings and the general population. Although scientists already have a good depth of knowledge on PPIs, the field is only getting started and has many questions that will guide future research, especially when it comes to realistic dissemination.

Abstract

Research and practice in mental health has a long history of focusing on what is wrong with people. By contrast, relatively little work has examined how to raise subjective well-being. This chapter provides a general overview of some therapies and interventions shown to increase well-being. An underlying theme is that despite recent progress, more work is needed to understand what therapies increase well-being and the putative mechanisms involved. Well-being researchers should learn from the lessons of clinical psychology, such as thinking carefully about issues regarding reach and accessibility.

Keywords: Clinical psychology, Subjective well-being, Therapies, Mental health

Dominic has struggled with debilitating anxiety for as long as he can remember. Over the years, he has figured out ways to compensate for his extreme fears and negative thoughts. For example, he is good at blending into the background at work and avoids eye contact with people he sees on his street. However, Dominic recently decided that he wanted more out of life, so he sought out a local psychotherapist who could provide anxiety treatment. Over the past three months, Dominic has acquired a set of skills to manage his fears and negative thoughts. However, despite experiencing some relief from his symptoms, Dominic feels his overall quality of life is not where he would like it to be. While he feels more at ease contributing to projects at work and interacting with people in his neighborhood, Dominic does not experience optimism in his day-to-day life, nor is he on the path to deep and fulfilling personal growth. Unfortunately, Dominic's experience is common for those who receive psychotherapy. Researchers are recognizing that therapies delivered in clinical settings are focused on decreasing symptoms rather than increasing subjective well-being (e.g., Seligman, 2002; Sin & Lyubomirsky, 2009). In the case of Dominic, while anxiety treatment has allowed him to lead a less symptomatic lifestyle, the likelihood that his anxiety symptoms will surface in the future remains relatively high (full remission occurs in a minority of patients). Most importantly, anxiety treatment has not given Dominic the skills he needs to grow and flourish.

Most theory and research in clinical psychology has focused on what is wrong with people. For example, prominent theories and research in depression and anxiety highlight the cognitive, emotional, and behavioral factors that contribute to the development and maintenance of symptoms (Beck, 1974; Clark & Watson, 1991). For example, much research has examined the role of negative cognitive biases in the development and maintenance of anxiety symptoms (Dodge & Frame, 1982; Foa, Franklin, Perry, & Herbert, 1996; Mathews, Mackintosh, & Fulcher, 1997; Mineka & Sutton, 1992). By contrast, relatively little work has examined psychological therapies that *promote* subjective well-being. Thus, the focus of this chapter is on providing a brief overview of psychological interventions and therapies that increase subjective well-being. This chapter begins by briefly discussing some historical trends in how mental health is conceptualized, as well as how a dysfunction model of mental health contrasts with models of well-being promotion. Next is a discussion of traditional and third wave cognitive behavioral therapies, with an emphasis on components that have been empirically shown to raise subjective well-being. There is also a brief discussion of humanistic therapies and how they relate to modern day well-being interventions. Finally, the conclusion of this chapter will focus on some critical unanswered questions and recommendations for future work.

Well-Being and Mental Health

The history of mental health is marked by efforts to identify weaknesses in people (Szasz, 1974). For example, some of the earliest attempts to assess mental status in the United States led to discriminative and exclusionary practices against refugees trying to enter the country (e.g., those labeled as "Undesirables"). This early focus on people's perceived shortcomings has had far-reaching implications for how mental health is conceptualized and researched. For example, the Diagnostic and Statistical Manual of Mental Disorders (DSM), now in its fifth revision, and the International Classification of Diseases (ICD), currently in its tenth revision, are the two widely used classification systems that influence

how we view mental health status. Both systems rely on symptom checklists to classify individuals based on perceived weaknesses. This method of classifying mental health status has dominated the way researchers and the public perceive mental health, which is to view mental health from a lens of harm and dysfunction (Wakefield, 1992). This systematic bias has, in part, led to the vast majority of mental health research being focused on how to alleviate distress rather than promote well-being.

Many prominent psychologists have questioned psychology's focus on the negative aspects of life. For example, influential figures such as Carl Rogers and Abraham Maslow argued that people should be seen as more than the sum of their symptoms, and that individuals should strive to achieve their full potential (these ideas would serve as the basis for humanistic therapies and an impetus for the positive psychology movement, discussed later in this chapter). More recently, the field of positive psychology (Seligman & Csikszentmihalyi, 2000) is focused on how to cultivate people's strengths in order to achieve greater life meaning and fulfillment.[1] Although seemingly nuanced, the difference between models of stress reduction and well-being promotion has far-reaching implications. Chief among them is the notion that acquiring skills for symptom reduction is not a sufficient replacement for those needed to develop and maintain healthy levels of social and emotional well-being. A tacit assumption among many mental health providers is that focusing on symptom reduction will necessarily translate into higher levels of well-being. However, a burgeoning area of research is proving this assumption to be misguided, as researchers are developing interventions that specifically target well-being promotion (e.g., Seligman, Steen, Park, & Peterson, 2005).

How people think and feel about their lives are core components of subjective well-being (Diener, Lucas, & Oishi, 2002; for a more thorough discussion of definitions and components of well-being, the reader is encouraged to visit the corresponding section and chapters "Introduction/Theory/Measurement" in this handbook). Importantly, a high level of positive affect alone is not sufficient for a high level of subjective well-being, as researchers have stressed the importance of conceptualizing subjective well-being as a general area of scientific interest rather than as a single construct (Diener, Suh, Lucas, & Smith, 1999). Thus, as discussed further below, therapies that raise well-being commonly target how people think, feel, and behave in everyday life.

It is important to note that despite clinical psychology's focus on mental disorders, much work has been dedicated to understanding factors relevant to well-being. For example, literature on resilience has uncovered a great deal regarding how people adapt to stressors in their environments (e.g., Betancourt & Khan, 2008; Davydov, Stewart, Ritchie, & Chaudieu, 2010). Although psychologists interested in pleasurable emotions have most frequently studied joy or happiness, researchers have uncovered numerous discrete (or highly similar) pleasant emotions, such as joy, contentment, interest, pride, and love (e.g., Berenbaum, 2002; Berenbaum, Chow, Schoenleber, & Flores, 2016; Shiota, Neufeld, Yeung, Moser, & Perea, 2011). Likewise, studies have found that how people think about different types of pleasurable emotions, such as happiness and appreciation/gratitude, is linked to a range of important outcomes (e.g., Chow & Berenbaum, 2015; Mauss, Tamir, Anderson, & Savino, 2011). Although most studies on cognitive biases have focused on negative or threat related biases, studies have also examined how positive cognitive biases contribute to life satisfaction (e.g., Cummins & Nistico, 2002; Peeters, 1971). Importantly, continued research on these types of psychological factors will enhance our ability to understand the putative mechanisms through which therapies increase subjective well-being.

Cognitive Behavioral Therapies and Emerging Third Wave Therapies

Cognitive behavioral therapy (CBT) is based on a wealth of empirical research demonstrating strong connections between cognitive, emotional, and behavioral processes (Butler, Chapman, Forman, & Beck, 2006). Thus, CBT[2] is a goal-oriented approach that targets the ways people think, feel, and/or behave. For example, CBT changes maladaptive thoughts (e.g., "I am such a loser") that cause emotional distress (e.g., sadness) and interpersonal dysfunction (e.g., excessive reassurance seeking from peers). CBT is typically conducted through face-to-face therapy sessions. A key component of CBT is homework, focused on skill acquisition through repetition, that clients are expected to complete between sessions. Compared to other types of psychotherapy (e.g., psychoanalysis), the length of CBT is usually shorter on a scale of weeks. CBT is best thought of as a family of interventions rather than as a solitary treatment, and therapists will tailor treatments depending on the patient's background as well as the specific skills the patient needs to acquire. Among all therapies, CBT is among the most effective in treating a range of mood and anxiety disorders (Barlow, Gorman, Shear, & Woods, 2000; Covin, Ouimet, Seeds, & Dozois, 2008; Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012).

Although CBT is typically employed in clinical populations, where the primary focus is on reducing psychological distress, an undercurrent of research suggests that interventions targeting the way people think and behave can also increase aspects of well-being. For example, a robust body of literature on

gratitude interventions suggest that increasing the experience of gratitude influences well-being by targeting the way people think (e.g., Emmons & McCullough, 2003; McCullough, Emmons, & Tsang, 2002; Wood, Froh, & Geraghty, 2010; Wood, Maltby, Gillet, Linley, & Joseph, 2008). These interventions often involve engaging in some type of repetitive activity, such as counting one's blessings or recalling positive memories, which promotes positive thinking, feeling states, and prosocial behaviors.

Behavioral activation (BA) is another type of CBT intervention that is based on models of behavior (for a review, see Jacobson, Martell, & Dimidjian, 2001). BA draws upon foundational learning principles, whereby individuals are taught to understand how their environmental responses are linked to the way they think and feel. Individuals are typically asked to schedule activities (e.g., starting up a conversation with a stranger, exercising) that allow for reinforcement and introspection to occur. Importantly, because a key component of BA is positive reinforcement, some of the first studies demonstrated that BA not only reduced depressive symptoms, but also increased the frequency of both pleasurable activities and prosocial interactions (Lewinsohn, Biglan, & Zeiss, 1976). Further, engaging in behavioral activities has also been found to lead to an increase in positive affect (e.g., Jacobson & Gortner, 2000; Martell, Addis, & Jacobson, 2001).

Although CBT is one of the most widely studied therapies, more research is needed before concluding that it can raise subjective well-being. One reason is that studies of CBT almost exclusively focus on symptom reduction in clinical populations. In these studies, a between-groups design is usually employed where one group receives CBT and the other receives either no treatment or a placebo. Participants in these studies often have high symptom levels (e.g., depression, anxiety, alcohol use) and are desperate for relief. Thus, the outcome of interest is almost always symptom level rather than variables linked to well-being. Although CBT packages could be useful in boosting well-being among the general population, such as cultivating an optimistic thinking patterns and behaviors that foster strong interpersonal relationships, these issues require more attention from researchers.

A "third wave" (also referred to as "new wave", "next generation", and "third generation") of CBT has increasingly caught the attention of researchers and clinicians. While there is ongoing debate regarding what qualifies as a third wave therapy (Hofmann, Sawyer, & Fang, 2010), newer therapies such as acceptance and commitment therapy (ACT; Hayes, Luoma, Bond, Masuda, & Lillis, 2006) and mindfulness based treatments (Segal, Williams, & Teasdale, 2002) largely aim to change how people respond to events, rather than changing the events themselves. For example, third wave acceptance-based therapies encourage individuals to develop a meta-awareness of recurring thoughts and feelings. With enough practice, individuals learn to objectify their subjective experiences and to monitor their reactions. This allows people to effectively distinguish between what is real and what is imagined. By contrast, traditional CBT aims to teach skills that change the content of thoughts. Through repeated practice, individuals learn to identify maladaptive thoughts and generate alternative, healthier thinking patterns.

Despite their shift in focus, third wave therapies have much in common with traditional CBT approaches. A central component of all CBT approaches is a shared focus on how cognitive processes relate to affective experiences and behavior. For example, as discussed further below, an important mechanism of mindfulness is cultivating awareness and attention to experiences in the present moment. Thus, mindfulness practice leads to desired outcomes by restructuring how people respond to the automatic thoughts and feelings that arise in response to events (e.g., accepting and describing a thought or feeling, rather than pushing it away). This is similar to a more traditional CBT approach that might target thoughts (and their underlying connections with emotions and behavior) by identifying and untwisting distorted thoughts that give rise to maladaptive feelings and behavior (e.g., the distorted thought of "I'm terrible at everything" gives rise to the alternative thought of "I know I'm a responsible husband and father"). Therefore, third wave CBT approaches can be seen as largely building on a traditional CBT framework.

Mindfulness is a third wave therapy that has received considerable attention in recent years (for reviews, see: Chiesa & Serretti, 2009; Grossman, Niemann, Schmidt, & Walach, 2004; Hoffman, Sawyer, Witt, & Oh, 2010; Hoffman et al., 2012; Khoury et al., 2013; Piet & Hougaard, 2011). In scientific literature, mindfulness is thought of both as a trait, or a characteristic that varies between individuals and that is relatively stable, as well as a skill that can be acquired through practice. Most studies examining the effectiveness of mindfulness practice conceptualize it as the latter. As a skill, mindfulness involves the capacity to purposefully attend to one's present experiences while taking a nonjudgmental stance (Kabat-Zinn, 2003).[3] Relative to other therapies, a strong body of research supports the notion that mindfulness not only decreases symptoms, but conveys numerous benefits to well-being (e.g., Brown & Ryan, 2003; Carmody & Baer, 2008) and use of adaptive coping strategies (e.g., Weinstein, Brown, & Ryan, 2009). As mindfulness was originally developed to promote spiritual growth in Buddhism (Shonin, Van Gordon, & Griffiths, 2014), relative to traditional CBT considerably more mindfulness research has been focused on

how mindfulness practice develops strengths rather than shores up weaknesses.

An emphasis of mindfulness interventions is on cultivating attention and awareness to present moment experiences. Thus, in contrast to the many automatic behaviors (e.g., accepting thoughts as one's reality, dwelling on past mistakes or future threats, daydreaming) that prevent people from fully living their day-to-day lives, practicing mindfulness leads to an enhanced vividness, clarity, and appreciation of the present. Individuals learn to be an observer of their own lives, developing a capacity to self-regulate and weigh options. For example, mindfulness is consistent with self-determination theory (Deci & Ryan, 2000), whereby increasing awareness of the present leads to enhanced feelings of autonomy, competence, and relatedness. Along these lines, cognitive researchers theorize that mindfulness may directly impact well-being by allowing for more intense pleasure through connection with present moment experiences (for a review of mindfulness and theories of well-being, see Brown & Ryan, 2003). Not surprisingly, mindfulness overlaps with constructs such as emotional intelligence (i.e., clarity and attention to one's emotional states; Salovey, Mayer, Goldman, Turvey, & Palfai, 1995), self-consciousness (e.g., Fenigstein, Scheier, & Buss, 1975), and the personality trait dimension of openness to experience (Costa & McCrae, 1992).

Although studies examining mindfulness have been around for decades (e.g., Kabat-Zinn, Lipworth, & Burney, 1985), recent years have seen a proliferation in research demonstrating that practicing mindfulness[4] leads to increases in factors of well-being. Noted increases in well-being have also been documented in studies focused on symptom reduction. For example, short-term meditation training has been found to increase levels of empathy and spirituality in medical students (Shapiro, Schwartz, & Bonner, 1998) and levels of well-being in adults (Carmody & Baer, 2008). Research also indicates that mindfulness training has other benefits, such as increasing positive affect and frequency of positive thoughts (Garland, Geschwind, Peeters, & Wichers, 2015), job-related affect (e.g., optimism and self-efficacy; Malinowski & Lim, 2015), and use of adaptive emotion regulation strategies (Hülsheger, Alberts, Feinholdt, & Lang, 2013; Teper, Segal, & Inzlicht, 2013).

Meta-analyses have found that mindfulness practice leads to positive outcomes, in part, by increasing levels of mindfulness and decreasing cognitive and emotional reactivity, as well as repetitive negative thinking (Gu, Strauss, Bond, & Cavanagh, 2015). For example, researchers theorize that mindfulness training leads to changes in thought processes and the ability to shift one's perspective (for a review, see Shapiro, Carlson, Astin, & Freedman, 2006). This in turn allows individuals to achieve a degree of objectivity regarding their internal experiences, which is consistent with models of personal growth outlined by developmental psychologists (e.g., Deikman, 1982; Kegan, 1982). Taken together, among all empirically supported therapies, mindfulness-based therapies are some of the strongest ones found to increase well-being.

Like literature on CBT, a drawback of mindfulness effectiveness literature, including meta-analyses of mindfulness studies, is that the focus has primarily been on treating mental disorders in clinical populations and settings, or symptom reduction rather than promotion of well-being (e.g., Khoury et al., 2013; Brown & Ryan, 2003). Thus, despite an accumulation of studies demonstrating that mindfulness training can enhance well-being, this issue has received relatively little attention. In addition, precisely *which* factors of well-being (e.g., positive affect, positive appraisals) are most reliably influenced by mindfulness-based interventions is still an open question.

Acceptance and commitment therapy (ACT; Hayes, Strosahl, & Wilson, 1999), a therapy that counts mindfulness as one of its core components, has also received considerable attention from researchers in recent years. ACT extends traditional behavioral models (for a more detailed discussion, see Hayes, Luoma, Bond, Masuda, & Lillis, 2006), and is largely based on Relational Frame Theory (RFT; Hayes, Barnes-Holmes, & Roche, 2001). RFT focuses on how people use language to relate to events. For example, subjective experiences (e.g., thoughts) can cause distress because of the language that is used to relate to them. Thus, a notable difference from traditional CBT is that ACT views cognitions as a type of behavior, and seeks to change the function of those behaviors rather than the content. ACT teaches people to accept their thoughts and feelings, rather than judging their acceptability, and to understand the functionality of their responses. Another notable difference from traditional CBT approaches is that, like mindfulness, ACT emphasizes contextual and experiential strategies to generate change, but only after accepting one's subjective experiences.

A primary aim of ACT is psychological flexibility, which encompasses an ability to connect with the present moment as well as the ability to regulate one's behavior in line with one's values. This is done through exercises focused on: acceptance, cognitive defusion (seeing thoughts as what they are, not as what they say they are), being present, understanding the self as context (that we are more than the sum of our subjective experiences), identifying and pursuing values, and committed actions (goals in accordance with one's values; for a more thorough review, see Hayes et al., 2006). Indeed, several of these domains are

highly overlapping with core principles of mindfulness, such as those that involve cultivating acceptance, objectivity, and present-oriented awareness. ACT also incorporates striving for values and goal-oriented behaviors, components commonly found in traditional CBT. In addition, despite their different approaches, like CBT, a core function of ACT is to address experiential avoidance, or attempts to avoid unpleasant thoughts, feelings, and sensations, that contribute to long-term suffering.

Some research suggests that ACT can enhance aspects of well-being, although the bulk of this literature highlights the importance of mindfulness-related components of ACT. For example, fostering acceptance of thoughts, feelings, and sensations leads to enhanced ability to regulate one's affect and physiological response to events (e.g., Bishop, Duncan, & Lawrence, 2004; Kabat-Zinn, 2003). Other active components of ACT, such as cognitive defusion, are usually centered on unpleasant subjective experiences and therefore applications to raising subjective well-being have been largely ignored by researchers. Given that research and meta-analyses focusing on ACT is relatively new (the bulk of meta-analyses have occurred in the last decade), and the vast majority of research has been limited to examining effectiveness of symptom reduction in clinical populations (Öst, 2008; Powers, Vording, & Emmelkamp, 2009), whereas direct applications of ACT on increasing subjective well-being is relatively unknown.

Humanistic Therapies

When evaluating the landscape of therapies that raise subjective well-being, it would be remiss to not include humanistic therapies. Humanistic therapies have a rich history in the field of clinical intervention, and prominent psychologists such as Abraham Maslow, Otto Rank, and Carl Rogers have had a profound impact on how therapy is conducted in the present day. For example, common factors in psychotherapy such as therapeutic alliance, understanding the client's perspective, and positive regard for client experiences are among the most robust predictors of therapy success (Ackerman & Hilsenroth, 2003; Duncan, Miller, Wampold, & Hubble, 2010; Krupnick et al., 1996). At its core, humanistic approaches treat the whole person, rather than reducing individuals to their symptoms. An emphasis is placed on understanding the individual's subjective experience, such as how they perceive and interpret events, and an overriding assumption is that people are generally good and have a basic need for growth. However, early humanists were skeptical of quantitative methods and chose instead to use approaches such as unstructured interviews. However, it is generally accepted that humanistic psychology was a precursor to the now burgeoning field of positive psychology, although considerable tension between these fields has focused on the precise role humanism has played in positive psychology (see Friedman & Robbins, 2012; Seligman & Csikszentmihalyi, 2000; Waterman, 2013). This is not surprising given that humanists were among the first to advocate seeing people as composed of strengths and potential, whereas positive psychology emerged out of concerns that clinical psychology was only concerned with amelioration of distress. Using principles of humanism as a building block, positive psychology studies therefore have been instrumental to understanding how to encourage growth, flourishing, and well-being. Mounting evidence supports positive psychology interventions (for reviews, see Bolier et al., 2013 and Sin & Lyubomirsky, 2009), such as gratitude interventions (e.g., Emmons & McCullough, 2003; Wood et al., 2010) and well-being therapy (e.g., Fava & Ruini, 2003) in increasing well-being. For example, ENHANCE is a 12-week positive psychology program that targets knowledge and skills acquisition to improve subjective well-being in generally health community samples, with encouraging early findings (Kushlev et al., 2017). What makes ENHANCE different from most other positive psychology interventions is its use of a multi-pronged approach that targets ten principles of happiness (e.g., values and roles, goals, gratitude, prosocial behavior) organized around themes of building the *core self*, *experiential self*, and *social self*. As a sustainable intervention package, programs like ENHANCE will continue to bridge the divide between research and application. In order to understand the modern day influence of humanistic theories and models on well-being, the reader is encouraged to review the chapter on positive psychology interventions in this handbook (Parks, 2018).

Effectiveness of Clinical Therapies on Subjective Well-Being

This chapter only covers some of the therapies employed in real-world settings, though careful consideration was made to present therapies that had at least some empirical support. Major scientific and government organizations are striving to set guidelines regarding what constitutes an evidence-based therapy. For example, Division 12 of the American Psychological Association (www.psychologicaltreatments.org), SAMHSA (www.nrepp.samhsa.gov), and the National Institute for Health and Care Excellence have all compiled such lists. However, it is important to note that these efforts are primarily based on literature concerned with ameliorating distress (Cloninger, 2006). This is largely driven by clinical psychology's traditional focus on discrete categories of mental disorders. For example, it is still rare to come across subjective well-being as a primary outcome in CBT studies. Instead, research tends to focus on a mental disorder type, such as depression, anxiety, and alcohol dependence. By contrast, literature focused on therapies that increase subjective well-being is relatively sparse, although early

reviews are promising (e.g., Bolier et al., 2013; Goyal et al., 2014; Sin & Lyubomirsky, 2009). Thus, while it is likely that at some point organizations will compile lists of empirically supported therapies that raise subjective well-being, more work is needed.

Unanswered Questions

This is an exciting time for researchers and clinicians interested in raising subjective well-being. This is a burgeoning area of research and many unanswered questions remain. This section will focus on important issues that still need to be fully addressed by therapy and well-being researchers.

One critical issue is whether effectiveness of well-being interventions differs as a function of the population in question. Much theory and research in clinical psychology has focused on cultural considerations in therapeutic settings (e.g., Lin & Cheung, 1999; Helms & Cook, 1999; Sue & Zane, 2009), trying to take into consideration a client's cultural background when tailoring a treatment approach. However, despite significant progress, serious concerns remain (e.g., Sue & Zane, 2009). For example, there is confusion regarding to what degree one should factor in a client's cultural background, since studies have shown a large amount of variation within cultural groups. In addition, many guidelines for tailoring interventions are overly vague and lack the degree of specificity necessary to be useful to treatment providers. To date, very little research has focused on how to tailor interventions that raise subjective well-being. For example, some studies suggest that gratitude interventions are less impactful among East Asians than among Americans (Layous, Lee, Choi, & Lyubomirsky, 2013), and researchers are increasingly targeting well-being interventions towards specific populations and settings (e.g., Hamar, Coberley, Pope, & Rula, 2015; Siu, Cooper, & Phillips, 2014). However, this body of work is still relatively new and it will be important for researchers to pursue this line of inquiry.

Another issue pertains to the precise mechanisms involved in therapies that raise subjective well-being. While some evidence suggests that the average effect sizes of well-being interventions is comparable to psychotherapy interventions targeting mental disorders (Sin & Lyubomirsky, 2009), the putative mechanisms involved in well-being interventions are not well understood. Some reviews have identified candidate factors in raising well-being. For example, Layous and Lyubomirsky (2012) proposed four mediating variables (positive emotions, positive thoughts, positive behaviors, and need satisfaction) and two moderating variables (characteristics of the activity and the person) in the link between positive activity interventions and well-being. In a review of mindfulness-based studies, Gu and colleagues (2015) found strong support for the mediating variables of cognitive and emotional reactivity, and moderate evidence for mindfulness, rumination, and worry (as well as preliminary support for self-compassion and psychological flexibility). Importantly, the authors found that many studies had key methodological shortcomings that limited the conclusions that could be made. This highlights the importance of conducting methodologically sound studies that can be connected to the broader literature. Efforts should be made to standardize paradigms and measures. In addition, future studies should systematically isolate mechanisms thought to play a role in well-being interventions. These efforts will allow for more reviews and meta-analyses that are instrumental to understanding how and why well-being interventions work (and for whom).

There is a great deal of overlap between well-being interventions and clinical psychology interventions aimed at attenuating distress. For example, both types of interventions typically involve changing underlying cognitive processes tied to emotions and behavior. Thus, it would appear that these interventions could be used in tandem—while clinical interventions can be used to decrease distress, well-being interventions could be used to promote thriving and a healthy lifestyle. To date, the vast majority of studies have focused on either clinical interventions to alleviate distress *or* interventions designed to raise well-being. Thus, it will be important for future work to understand how these approaches can be integrated, ideally in single treatment packages. One way to facilitate this effort is for researchers to include outcome measures assessing psychopathology *and* well-being. This will enhance understanding of how an intervention or therapy can be used in the service of decreasing symptoms or increasing well-being. From a systematic perspective, it may also be useful for graduate programs to include well-being interventions in their standard training packages, since most programs (e.g., clinical psychology, social work) exclusively focus on training students to assess and alleviate psychological distress.

Prominent models and theories of well-being should continue to play a key role in developing and evaluating therapies that target well-being. Virtually all influential models of well-being identify subcomponents that can be targeted through intervention. For example, hedonic models of subjective well-being highlight the importance of increasing positive affect and minimizing negative affect. According to Ryff's model of eudaimonic well-being (Ryff, 1989), an effective intervention should seek to increase at least one of multiple factors (self-acceptance, personal growth, life purpose, positive relationships, environmental mastery, autonomy), in order to allow individuals to strive to reach their full potential.

However, the existence of competing models of well-being may cause confusion among therapy researchers and practitioners. Future work should focus on how to integrate different models of well-being (e.g., Gallagher, Lopez, & Preacher, 2009) so that connections between interventions can be made more readily.

An important issue is how to deliver well-being interventions in everyday life. It is noteworthy that evidence-based psychological treatments for mental disorders have come under scrutiny for their lack of reach (for reviews, see Barlow, Bullis, Comer, & Ametaj, 2013, and Harvey & Gumport, 2015) and standardization in real-world settings (Chow, Wagner, Lüdtke, Trautwein, & Roberts, 2017. Despite yearly increases in the prevalence of mental disorders, roughly half of individuals who need treatment do not have access to adequate treatment (Kessler et al., 2003). Thus, despite solid empirical work showing that evidence-based psychological treatments can be effective in attenuating psychological distress (Chambless & Ollendick, 2001; Layard & Clark, 2014), therapies targeting well-being will need to overcome the same barriers to treatment dissemination and standardization. Technology offers one potential solution. Many therapies that were once limited to the clinician's office can now be delivered remotely online, with many online therapies having comparable effect sizes to those delivered face-to-face (e.g., Barak, Hen, Boniel-Nissim, & Shapira, 2008; White et al., 2010). For example, there is emerging empirical support for the *Happify* app (www.happify.com) for increasing positive affect, which delivers a mindfulness-based intervention via people's personal smartphones (Howells, Ivtzan, & Eiroa-Orosa, 2016). Other apps such as *JOOL Health* (www.joolhealth.com) target well-being by creating personalized plans through predictive modeling, although the effectiveness of these apps are still being examined. Compared to face-to-face therapy, technology delivered interventions are more cost-effective, are capable of reaching a wider audience, and can be delivered where and when they are most needed (e.g., Nahum-Shani, Hekler, & Spruijt-Metz, 2015; Ritterband & Tate, 2009). For example, research leveraging mobile technology is enhancing our understanding of everyday life processes in psychopathology (e.g., Chow et al., 2017; Saeb et al., 2015) so that researchers can begin developing interventions that are woven into people's routines. Similar efforts are being made to understand processes important to well-being (e.g., Bentley & Tollmar, 2013). Such work is critical to personalizing well-being interventions (e.g., dynamically adapting an intervention to people's changing states) and understanding where, when, and how to deliver them. For example, traditional face-to-face CBT usually involves once a week hourly sessions. Thus, clinicians have little understanding of how their clients are doing outside the therapy office. Technology based approaches can allow therapists to monitor their client's well-being, as well as deliver an intervention (e.g., using a smartphone application) at critical times (e.g., when the client is alone) and locations (e.g., when the client is at home). However, the majority of technology based work (and works in mobile technology, in particular) is being done by engineers who have limited training in mental health models. Given the ubiquity of technology in modern society, it is therefore imperative for well-being researchers to bridge the divide in order to explore cutting-edge solutions to intervention development and dissemination.

Conclusion

The therapies and interventions covered in this chapter do not comprise an exhaustive list. A primary aim of this chapter was to provide a general scope of therapies that can raise subjective well-being. Although more work needs to focus on therapies and interventions that raise subjective well-being, this is an exciting field that holds great promise for enhancing the lives of both clinical populations and the general population. Ideally, well-being researchers can learn from the trials and successes of clinical researchers, as individuals from these seemingly disparate fields continue to work towards a unifying field that focuses on improving people's lives.

Footnotes

[1]Because this book contains a separate chapter dedicated to positive psychology, interventions and therapies directly relevant to positive psychology will not be discussed in this chapter.

[2]There are several therapies with strong empirical support that are based on a CBT framework, such as Dialectical Behavior Therapy (DBT; Linehan, 2014), although those will not be discussed in this chapter. Relative to CBT, DBT emphasizes the relational aspects of psychopathology through skills training in a group format. People learn skills of interpersonal effectiveness, distress tolerance, emotion regulation, and mindfulness.

[3]In literature, mindfulness has been examined as both a unidimensional and a multidimensional construct (i.e., as a general factor versus one composed of several interrelated facets, respectively). As researchers have become increasingly interested in examining how mindfulness is associated with various outcomes, this has necessitated examination of mindfulness at the facet level (e.g., Baer et al., 2008; Desrosiers, Vine, Curtiss, & Klemanski, 2014). Research shows that mindfulness can be separated into five factors, which

are *describing* and labeling one's experiences, *acting with awareness* and attending to one's activities in the present moment, *non-judging* of inner experiences, *observing* and noticing one's experiences, and *non-reacting* to unpleasant stimuli (for a review, see Baer, Smith, Hopkins, Krietemeyer, & Toney, 2006). For simplicity, mindfulness is presented as a single construct in the current chapter.

[4]There have been several mindfulness-based programs developed, such as mindfulness-based stress reduction (MBSR; Kabat-Zinn, 1990) and mindfulness-based cognitive therapy (MBCT; Teasdale, Segal, & Williams,1995), that are all based on the foundational principles of cultivating attention and awareness to present moment experiences.

Abstract

In this chapter we provide an overview of stress management interventions (SMI) and review the evidence for their effects on employee stress and well-being. We start by setting out a typology of SMI that classes SMI according to level (i.e., the individual-level or organisation-level) and focus (i.e., a 'primary' focus on altering the causes of stress or a 'secondary' or 'tertiary' focus on reducing stress itself). We then use this typology to describe key types of SMI, after which we review the evidence for those SMI with the most extensive evidence bases, namely secondary individual-level SMI that seek to reduce stress in employees (e.g., relaxation techniques, cognitive-behavioral therapy, mindfulness training) and primary organisational-level SMI that seek to remove the causes of stress by changing organisational practices (e.g., job redesign, changes to working time schedules). We conclude by suggesting that there is convincing evidence for both of these SMI approaches. However, the evidence base needs strengthening through more robust methodological designs (e.g., randomised control trials, broad based evaluations of intervention processes) and a better understanding of the contexts and individuals in which SMIs are most effective, how the implementation of SMIs affects outcomes, and the long-term impacts of SMIs.[1]

Keywords: stress management interventions, evaluation, review, cognitive-behavioral therapy, mindfulness training, job redesign

Improving employee well-being and reducing stress can have a number of benefits for organizations, from increasing performance, improving relationships, to reducing sickness and absenteeism rates (De Neve, Diener, Tay & Xuereb, 2013; Warr, 2003). Stress management interventions refer to a class of activities that are used by organizations to improve employee well-being and reduce stress, principally by either addressing the causes of stress or by reducing the impact of stress on an individual. The aim of this chapter is to review the literature on stress management interventions to establish what we know about the effectiveness of different interventions in improving psychological well-being. It is split into three main sections. First, we introduce a typology of stress management interventions (SMI) and provide examples of the different types of intervention. Second, we discuss the evidence concerning the effectiveness of SMI, although before this we will briefly discuss methodological considerations used when evaluating interventions to provide the reader with some grounds for understanding the quality of evidence in this area. Finally, we conclude the chapter with an overview of what works best.

When reviewing the literature, we use a broad definition of subjective psychological well-being which enables us to include studies on burnout, anxiety, and depression, for example, as well as studies focusing directly on positive psychological well-being. Furthermore, as we are interested in psychological well-being we do not include studies that have looked at physical health or job attitudes, or those on well-being related outcomes at the organizational-level such as sickness and absenteeism. However, it is worth noting that these outcomes are related such that improvements in psychological well-being can lead to improvements in health, job satisfaction and absenteeism rates.

Stress Management Interventions: A Typology and Description

The stress management literature typically classifies interventions according to the 'focus' of stress management and according to the 'level' at which the intervention takes place (DeFrank & Cooper, 1987; de Jonge & Dollard, 2002). With regard to the focus of stress management, interventions are categorized as primary, secondary or tertiary. The aim of *primary interventions* is to prevent stress from occurring by removing the sources of stress and enhancing the causes of well-being. *Secondary interventions* aim to reduce the severity or duration of stress once it has occurred and to prevent the level of stress becoming problematic. *Tertiary interventions* seek to rehabilitate and maximize functioning for those who are already experiencing or suffering from psychological ill-health.

With regard to the level of an intervention, a common and simple distinction is between individual and organizational levels. As the name suggests, *individual-level interventions* focus on helping employees to develop skills to manage, cope with and reduce stress, whereas *organizational-level interventions* make more systemic changes to organizational practices that either target all employees or a

specific group of workers. A third category, individual-organizational level interventions, is used in some classifications. Such interventions are thought to differ from others in that they focus on changing the relationship between the individual and organization, e.g., peer support groups. However, as the distinction between organizational and individual-organizational level interventions is not always clear cut, we use the more parsimonious categorization of individual-level and organizational-level interventions.

Classifying stress management interventions (SMI) according to their focus and level implies that both individual and organizational-level interventions can be primary, secondary and tertiary in nature. This is illustrated in Table 1, along with examples of the different types of intervention in each category. Throughout the remainder of the chapter we describe the different types of SMI according to this classification.

Table 1. A Typology of Stress Management Interventions

Intervention type	***Individual***	***Organisational***
Primary	Selection & Assessment Pre-employment medical examination	Job Redesign Working time and schedules Management training, e.g. mentoring
Secondary	Mindfulness training Health promotion, e.g., exercise Cognitive behavioral therapy Relaxation Meditation Personal and interpersonal skill training Acceptance and commitment therapy Psychosocial intervention training Coping skills training Resilience training	Improving communication and decision making Conflict management Peer support groups Coaching & career planning
Tertiary	Employee Assistance Programmes Counselling Posttraumatic stress assistance Disability management	Vocational rehabilitation Outplacement

Individual-Level Interventions

The aim of a primary individual-level intervention is to prevent stress from occurring in an employee. One means of achieving this is through selection and assessment procedures that select applicants who have the skills and abilities to manage the demands of the job and to screen out those who might be susceptible to experiencing stress in the target role, particularly in highly-stressful occupations (Bartone, Roland, Picano & Williams, 2008). Although such interventions are one way of managing stress and promoting well-being, they are rarely used (Giga, Cooper & Faragher, 2003).

Secondary individual-level interventions seek to equip employees with the skills and abilities to manage stress and promote well-being, and to provide employees with opportunities to engage in stress-reducing activities. They include techniques such as relaxation, meditation, cognitive behavioural therapy, mindfulness training, and exercise programmes, as well as other techniques such as education and interpersonal skill development. Drawing on the emotion regulation literature (Gross, 1998), these techniques can be understood as promoting antecedent-focused emotion regulation strategies that seek to reduce or remove the causes of stress, or response-focused emotion regulation strategies that seek to reduce the level of stress experienced by individuals. It can also be noted that some individual-level interventions are multimodal, e.g., a combination of relaxation, CBT and mindfulness exercises. Such an approach might be used in the expectation that it will increase the likelihood of beneficial outcomes for both the individual and organization, as it can enable employees to develop a wide set of skills that can be used across different circumstances, provide employees with the opportunity to develop both antecedent and response-focused emotion regulation strategies, and increase the chance of meeting employees' needs. As secondary

individual interventions are one of the more commonly used SMI, and there is a stronger evidence base for their effectiveness (which we outline later), we now detail the more widely used techniques.

Relaxation techniques are based on the assumption that states of relaxation and stress (i.e., highly-aroused negative states of well-being such as anxiety, tension and anger) are antithetical (Russell, 1979). In other words, you cannot be both relaxed and stressed at the same time, such that increasing levels of relaxation will necessarily entail lower levels of stress. Various methods are used to induce relaxation but all can be considered as response-focused emotion regulation strategies as they focus on reducing the symptoms of stress. Progressive muscle relaxation involves tensing and then relaxing different muscles throughout the body in a prescribed order. For example, a person might start by clenching and unclenching one hand then the other, then focus on the muscles in one forearm and then the other, and so on. The length, duration and range of muscles covered can vary but with practice employees can induce a deep state of muscle relaxation in minutes (Murphy, 2003). Meditation is another relaxation technique but one that focuses on a mental rather than physical process. Techniques typically involve sitting in a quiet place and repeating a word or sound while maintaining a passive mental state that excludes intrusive thoughts. Although meditation has its roots in religious practice, secular and standardized methods appropriate for clinical trials have been developed (Carrington et al., 1980). Muscle relaxation and meditation can also involve breathing techniques that focus on the inhalation and exhalation of breath as an additional means of achieving relaxation, although some interventions use breathing techniques alone.

Cognitive behavioral therapies (CBT) assume that maladaptive cognitions contribute to the maintenance of psychological distress and problematic behavioral responses to stress. CBT addresses this by helping the person to identify misconceptions about the nature and causes of stress, to test the validity of existing thoughts and understandings, and to develop new conceptions about stress. In addition, the behavioral element of CBT encourages the person to develop new behavioral responses to stressful events. CBT is thought to work by promoting antecedent-focused emotion strategies that help the person to reappraise and restructure their understanding of stress and stressful events (Hofmann & Asmundson, 2008). For example, Cecil and Forman (1990) conducted an intervention amongst teachers based on a method of CBT called stress inoculation training (Meichenbaum, 1977) that consists of three phases: education about stress and its causes; acquisition and rehearsal of skills in cognitive restructuring (e.g., identifying irrational thoughts and replacing them with rational thoughts); and developing and practising new cognitive, emotional and behavioral 'scripts' for responding to stressful events. Their evaluation revealed that the CBT intervention decreased stress to a greater extent than a peer support group and a passive listening group.

Mindfulness training is an increasingly popular SMI that aims to promote states of mindfulness (i.e., paying attention to the experiences, thoughts and emotions occurring in the present moment in a non-judgmental, compassionate, accepting and non-reactive way) and new adaptive responses to negative thoughts and emotions (Kuyken et al., 2010). Mindfulness is thought to foster psychological well-being by primarily helping the person to dissociate negative thoughts and emotions from maladaptive behavioral and emotional responses. Mindfulness training can therefore be understood as a method that develops response-focused emotion regulation strategies. But mindfulness training has key differences from other methods that also encourage response-focused emotion regulation strategies, such as relaxation and meditation. In particular, in mindfulness training, negative thoughts and experiences are not avoided or suppressed (which can have negative consequences for well-being, Richards & Gross, 1999) and there is an emphasis on developing new and more adaptive responses.

Mindfulness therapies include acceptance and commitment therapy (Hayes, Luoma, Bond, Masuda, & Lillis, 2004) and mindfulness-based cognitive therapy (MBCT) (Segal, Williams & Teasdale, 2002). MBCT, for example, uses a range of methods, often conducted in groups with a trainer, such as body scanning, yoga and meditation exercises. The initial emphasis in MBCT is cultivating states of mindfulness. At later stages, the emphasis moves towards identifying how negative thoughts trigger maladaptive responses, helping the person to accept those feelings, and encouraging the choice of more adaptive responses. Although mindfulness training has grown in popularity, few empirical studies have been conducted in organizational settings. An exception is a study by Hülsheger and colleagues who conducted a two-week, self-directed mindfulness intervention, based on MBCT protocols, with employees from a range of occupations. Their evaluation, using data collected from daily diaries completed by participants, showed that employees in the mindfulness training condition reported higher levels of daily mindfulness and lower levels of daily emotional exhaustion that those in a control group (Hülsheger, Alberts, Feinholdt & Lang, 2013).

Other types of secondary individual-level interventions have also been developed. Two popular initiatives include educational programmes that inform employees about stress and how it can be managed, and health promotion initiatives that are based on the assumption that a healthier lifestyle (e.g., more

exercise, better diet) will improve well-being (Anger et al., 2015; Rongen, Robroek, van Lenthe, & Burdorf, 2013). In addition, personal skill development training in communication, goal setting and time management all aim to reduce stress by helping employees to prevent stressful situations from occurring, e.g., conflict, high workloads.

Lastly, tertiary individual-level interventions focus on individuals who are experiencing high or chronic levels of stress that may be impairing their ability to work. For example, employee assistance programmes (EAP) provide counselling and advice to those experiencing high-levels of stress or mental health problems, whether these issues are related to work or not (Bhagat, Steverson & Segovis, 2007; Csiernik, 2011; McLeod, 2008).

Organizational-Level Interventions

Primary organizational-level interventions aim to remove the causes of stress in organizations by changing organizational practices and policies, such as those concerned with leadership, working time, and occupational health and safety (Anger et al., 2015). The majority of primary organizational-level interventions reported in the literature are job redesign interventions that aim to modify job characteristics (e.g., job discretion, workload, ergonomic design) as a means of enhancing employee well-being, and they have a strong theoretical and empirical grounding in studies of job design that show job characteristics to be key antecedents of employee stress and well-being (Humphrey, Nahrgang & Morgeson, 2007; Demerouti, Bakker, Nachreiner & Schaufeli, 2001). Job redesign interventions typically differ in scale, with some seeking to change one job characteristic, such as job discretion (Bond & Bunce, 2001), whereas others seek to change multiple job characteristics in the expectation that this will produce larger changes in well-being (Holman & Axtell, 2016).

Secondary organizational-level interventions aim to make organizational-wide changes that help employees cope better with stressful experiences. Such interventions include the introduction of peer support groups that enable employees to discuss the difficulties they face (Peterson, Bergstrom, Samuelsson, Asberg, & Nygren, 2008) and communication skills training courses that seek to improve the ability of all employees to manage stressful situations through, for instance, improved conflict management (Ghazavi, Lohrasbi, & Mehrabi, 2010; Leiter, Laschinger, Day & Oore, 2011). However, in practice, there is not always a clear distinction between primary and secondary organizational level interventions, particularly with regard to social support interventions which can remove a potential source of stress (i.e., a lack of social support) whilst also improving the ability of employees to cope with stressful events.

Implementing organizational-level interventions can be difficult and complex. This means that an important part of organizational-level interventions, particularly primary interventions that seek to change organizational practice, is the efficacy of the implementation process. In particular, reviews suggest that successful organizational-level interventions involve four key activities: *preparation*, i.e., securing support; *screening*, i.e., identifying the psychosocial risks; *action planning*, i.e., developing change initiatives; and *implementation*, i.e., embedding change initiatives within the organization (Nielsen, Randall, Holten & González, 2010). Another important characteristic of organizational-level interventions is the level of employee participation. For example, in a job redesign intervention conducted by Morgeson et al. (2006), only managers and external consultants were involved in developing and implementing job redesign changes. In contrast, in a job redesign intervention among knowledge workers in Denmark (Sørensen & Holman, 2014), employees participated throughout the intervention process by identifying, developing and implementing job redesign initiatives to reduce workload and modify work procedures. Employee participation is thought to be advantageous as it can improve the quality of change initiatives by drawing on employees' expertise to make them more contextually appropriate, and because it can increase commitment to implementing change initiatives, as employees have a greater sense of ownership of those change initiatives (LaMontagne, Keegel, Louie, Ostry, & Landsbergis, 2007). Participation can also increase the sense of job control and responsibility, which is beneficial for well-being in its own right (Mikkelsen & Saksvik, 1998). But participation is not without risk: it can increase complexity by involving a wider range of stakeholders who may have competing ideas and motivations, increase frustration with the intervention process if employees are not experienced or skilled in participation, and raise costs by removing front-line employees from their jobs.

Some multimodal SMI combine individual- and organizational-level interventions. For example, 'total worker health interventions' integrate organizational-level health and safety programmes with individual level health promotion programmes (see Anger et al., 2015 for a review). An advantage of this approach is that the organizational-level intervention can reduce the causes of stress, while the individual-level intervention can enhance employees' ability to deal with stress. Such an approach can be particularly important for employees exposed to higher demands, as they also tend to engage in more high-risk health behaviors (Anger et al., 2015). Other multimodal interventions occur just at the organizational level. For

example, job redesign interventions have been implemented alongside changes to other organizational practices, in the expectation that this will augment the effects of the job redesign intervention (Daniels, Gedikli, Watson, Semkina, & Vaughn, 2017). Potential disadvantages of multimodal approaches are an increase in implementation complexity and that one intervention may reduce the effectiveness of the other.

What Works? Evaluating the Effectiveness of Stress Management Interventions

When selecting SMI it is clearly important to consider the evidence for their effectiveness in reducing stress and promoting well-being. In this section, we review the findings for those SMI that have a more substantial evidence base, namely secondary individual-level and primary organizational-level interventions[2]. But before we do this, it is important to touch on the issues concerned with how best to evaluate interventions, as this provides a better understanding of the nature and quality of evidence available.

Based on the natural science paradigm, randomised control trial (RCT) designs are traditionally considered to be the optimal methodology for evaluating interventions. RCTs randomly allocate participants to experimental and control groups and then introduce the intervention to the experimental group. Change in the focal outcome is measured in both groups before and after the intervention. Randomization is used to control for the effects of context and participant differences, such that when change in the outcome in the experimental group is significantly different to that in the control group, the change is assumed to be caused by the intervention. RCTs are therefore thought to provide stronger evidence for the causal effects of an intervention than methodological designs that do not randomize individuals to groups, that do not have a control group, and those that do not have pre-intervention measurement.

In addition to the evaluation of individual studies, meta-analyses are used to provide a quantitative overview of multiple studies. A meta-analysis produces an overall effect size based on the individual studies selected for review. More confidence can be placed in meta-analytic results, as they are based on a larger sample that minimizes the likelihood of chance findings, and because the weaknesses of individual studies are balanced out. To explain this further, the results of one study could be accidental or influenced by something that was not investigated, whereas the results of a meta-analysis that combine data from multiple studies are much more likely to be a true reflection of an intervention's real impact. A key issue in a meta-analysis is how to select studies for inclusion (e.g., RCT studies only), since the methodological quality of the studies chosen affects the confidence that can be placed in the findings.

However, several authors have questioned whether RCTs provide a sufficient and appropriate methodology for intervention evaluation (Cox, Karanika, Griffiths & Houdmont, 2007; Nielsen & Miraglia, 2017). Specifically, it is argued that RCTs are not always feasible in organizational settings where, for example, randomisation is not practical or ethical, or when an equivalent control group (consisting of similar participants to the experimental group) is not available. Randomization can also be considered a change in itself that may affect employee perceptions of the intervention and experiences of work (Nabe-Nielsen et al., 2015). Furthermore, RCTs tend to focus on changes in outcomes and do not evaluate how the quality of the implementation process or organizational context shapes the effects of an intervention. In response to these concerns, alternative intervention evaluation frameworks have been proposed. Cox et al. (2007) suggested a framework that covers both intervention outcomes and implementation processes. Examples of implementation process variables include managers' advocacy of the intervention, workers' engagement with the intervention, and the availability of resources to support implementation. Cox et al. argued that consideration of process variables enables identification of the mechanisms determining intervention outcomes. Indeed, failing to consider process variables could lead to the erroneous conclusion that an intervention is ineffective when in fact the implementation was flawed. Nielsen and Abildgaard (2013) built on these insights to propose a longitudinal evaluation framework in which each of the intervention 'stages' (e.g., preparation, screening etc., as outlined earlier) are assessed separately to identify how each stage may influence subsequent stages and ultimately the outcome of the intervention. They also suggested that a range of intervention outcomes (e.g., changes in attitudes, working practices and well-being) should be addressed at each stage on the basis that these changes may become evident at different times.

Given the importance of intervention processes to the success of an intervention, and the limits of RCTs in organizational settings, it has been argued that assessments of the effectiveness of SMI should draw on systematic quantitative and qualitative evaluations and to include rigorous evaluations of SMI that do not meet the 'gold standard' of RCTs. Such an approach is thought to be particularly important in the evaluation of organizational-level SMI because, in comparison with individual SMI that tend to use existing techniques proven in other domains (e.g., CBT), organizational SMI are diverse in design and may be

tailored to the organization, increasing the likelihood of outcomes being influenced by process and context variables. Indeed, in light of these issues, process evaluations are now more evident in SMI studies.

Evidence for Secondary Individual-Level Interventions

A number of meta-analyses and systematic reviews of the effects of secondary individual-level interventions on stress and well-being have been conducted (see Bhui, Dinos, Stansfeld & White, 2012, for a review of these reviews). Two of the more comprehensive meta-analyses are by van der Klink, Blonk, Schene and Van Dijk (2001) and Richardson and Rothstein (2008) (Table 2). Both cover CBT and relaxation interventions across all types of employees. The Richardson and Rothstein meta-analysis builds on the van der Klink et al. study by covering an extra ten years of research and including unpublished studies (accounting for publication bias towards significant findings) but has stricter inclusion criteria, as it only selects RCT-based studies. A wide range of individual interventions are also covered by Kuoppala, Lamminpää and Husman (2008) but their analysis focuses on 'psychological' (i.e., education, biofeedback) and health promotion interventions (e.g., exercise), while the meta-analysis by Conn et al. (2009) focuses exclusively on health promotion interventions, specifically exercise and physical activity. Other meta-analyses focus on SMI in particular groups of workers. Ruotsalainen, Verbeek, Mariné and Serra's study (2015) covers CBT and relaxation methods in health care employees, while that by Regehr, Glancy, Pitts and LeBlanc (2014) focuses on individual-level interventions in physicians.

A conclusion that can be drawn from these meta-analyses is that that there is good evidence that secondary individual-level interventions are effective in reducing stress and promoting well-being (Table 2). Meta-analytic studies report significant medium and large effect sizes for cognitive-behavioral therapies (d=0.52, van der Klink et al., 2001; d=1.00, Richardson & Rothstein, 2008), small and large effect sizes for relaxation techniques (d=0.31, van der Klink et al., 2001; d=0.83, Richardson & Rothstein, 2008) and small effect sizes for health promotion methods (RR=1.25, Kuoppola et al., 2008; d=0.19, Conn et al., 2009). These findings suggest that CBT has a comparatively larger effect on stress and well-being and van der Klink et al., (2001) found that effect sizes for CBT were significantly greater than those for relaxation methods. However, this finding must be treated with caution, as their analysis included effects across all outcomes, including those unrelated to employee well-being. Furthermore, as there are no comparisons between CBT, relaxation and other interventions, it is difficult to make claims about relative effectiveness of secondary individual-level interventions at this juncture. It can also be noted that existing meta-analyses of secondary individual-level SMI do not focus on mindfulness training as a separate category, although mindfulness studies are included in some meta-analysis (e.g., Regehr et al., 2014). This means that we lack a statistical summary of their effects and a comparison of mindfulness and other methods. Promisingly, most primary studies report positive effects of mindfulness training on psychological well-being (e.g., Cohen-Katz, Wiley, Capuano, Baker, & Shapiro, 2005; Hülsheger et al., 2013), whereas only a few studies have failed to yield supportive evidence (e.g., Malarkey, Jarjoura & Klatt, 2013; van Berkel, Boot, Proper, Bongers, & van der Beek, 2014).

Meta-analytic studies of multimodal secondary individual-level interventions report significant medium effect sizes (d=0.48, van der Klink et al., 2001; d=0.60 and 0.42, Richardson & Rothstein, 2008). These effect sizes are not substantially different to studies of single secondary individual-level SMI, meaning that multimodal secondary individual-level SMI do not provide a clear advantage over single secondary individual-level SMI. But it is worth noting that Richardson and Rothstein (2008) found that the effects of multimodal SMI increase over time and their effects are longer lasting. One interpretation of this finding is that employees take longer to learn stress management techniques in multimodal SMI but, once learnt, their effects are stronger and more sustainable. Again, such a conclusion, while plausible, must be treated with caution for present purposes, as the comparison by Richardson and Rothstein included well-being and well-being related outcomes such as absenteeism and physiological responses.

Another important feature of research on secondary individual-level SMI is the heterogeneity and direction of effect sizes. In particular, effect sizes vary significantly and, to the best of our knowledge, almost all effects are positive in direction, even if they are non-significant. For example, in Van der Klink et al.'s (2001) meta-analysis, effect sizes across CBT and relaxation interventions ranged from 0.0 to 2.2, and 22 of the 35 studies reported non-significant findings. A similar heterogeneity in effect sizes is reported in other meta-analyses of SMI and in the literature on mindfulness training. This implies that although secondary individual-level SMI are not harmful to employee well-being, their positive effects are not realised in all contexts. The heterogeneity in effect sizes therefore suggests that implementation processes, contextual factors or participant differences (e.g., motivation, initial levels of well-being) may impact on the efficacy of secondary individual-level SMI. However, a lack of research and contradictory evidence prevent firm conclusions being drawn about the effects of context and implementation process on secondary individual-level SMI effectiveness (Van der Klink et al., 2001; Richardson & Rothstein, 2008; Rongen et al., 2013).

Table 2. Meta-Analyses of Stress Management Intervention Effectiveness

Intervention type	Effect size (Cohen's d unless stated)		N	Authors	Date	Outcome reported
Individual-Level						
Cognitive-behavioral	0.52	Large	14	van der Klink et al.	2001	Well-being
	1.00	Large	5	Richardson & Rothstein	2008	Well-being
	-0.25	No effect	4	Ruotsalainen et al.	2015	Stress (up to 1 month follow up)
	-0.28	Small	6	Ruotsalainen et al.	2015	Stress (1-6 month follow up)
Relaxation	0.31	Small	14	van der Klink et al.	2001	Well-being
	0.83	Large	5	Richardson & Rothstein	2008	Well-being
	-0.48	Medium	4	Ruotsalainen et al.	2015	Stress (up to 1 month follow up)
	-0.49	Medium	13	Ruotsalainen et al.	2015	Stress (1-6 month follow up)
Health Promotion	1.25 (RR)	Small	3	Kuoppala et al.	2008	Well-being
	0.19	Small	12	Conn et al.	2009	Stress
Multimodal	0.48	Medium	8	van der Klink et al.	2001	Well-being
	0.60/0.42	Medium	5/12	Richardson & Rothstein	2008	Well-being(low stress/low anxiety)
Organizational-Level						
All Organizational-Level	0.08	No effect	5	van der Klink et al.	2001	Well-being
	-0.31/0.17	No effect	2/3	Richardson & Rothstein	2008	Well-Being/Mental Health

Note: RR = Risk Ratio; Cohen's d effect sizes, 0.2 = small, 0.5 = medium, 0.8 = large. Effect sizes are uncorrected for reliabilities.

Evidence for Primary Organizational-Level Interventions

On the basis of existing meta-analyses, it could be concluded that primary organizational-level SMI do not improve employee well-being or reduce stress. Drawing on small samples of primary and secondary organizational-level interventions largely based on RCT designs, meta-analytic studies report small non-significant effect sizes (d=0.08, Van der Klink et al., 2001; d= -0.31 for well-being and d=0.17 for mental health, Richardson & Rothstein, 2008).[3]

In contrast, qualitative reviews of organizational-level SMI, which draw on a wider range of studies, including quasi-experiments without randomization, offer a 'cautiously positive' interpretation of

the effectiveness of well-designed organizational interventions (Bhui et al., 2012; Daniels et al., 2017; Egan, Bambra, Thomas, Petticrew, Whitehead, & Thomson, 2007; LaMontagne et al., 2007; Semmer, 2006, p518). Moreover, since these reviews, other organizational interventions have been conducted that further point to the positive effects of job redesign and social support interventions on employee well-being (Ahola et al., 2012; Bourbonnais et al., 2006; LeBlanc, Hox, Schaufeli, Taris, & Peeters, 2007; Linzer et al., 2015; Peterson et al., 2008; Sørensen & Holman, 2014). In particular, job redesign studies by Bond, Flaxman and Bunce (2008) and Holman and Axtell (2016) show that job redesign interventions alter job characteristics (e.g., job discretion, feedback) which in turn lead to improvements in employee well-being. These studies therefore confirm theoretical proposals that changes in job characteristics are a mechanism through which job redesign interventions influence employee well-being. Other studies point to the long-term impact of job redesign interventions. Kawakami et al. (1997) and Bourbonnais, Brisson and Vézina (2011) reported that improvements in job characteristics and well-being in the intervention group were sustained, respectively, one and three years after the intervention.

For multimodal organizational-level SMI, qualitative reviews all conclude that there is some evidence for their efficacy (Anger et al., 2015; Daniels et al., 2017; Egan et al., 2007; Kompier, Aust, van den Berg & Siegrist, 2000). However, what is less clear is whether their different parts have combined or additive effects on well-being, and whether they are more effective than potentially less-complex organizational interventions that focus on changing one discrete practice (i.e., only job design).

Despite a growing evidence base for the positive effects of organizational-level interventions, the continuing heterogeneity of their effects must be recognised, as some studies report no effect on well-being (Ghazavi et al., 2010; Leiter et al., 2011; Logan & Ganster, 2005; Uchiyama et al., 2013) and a very small number report negative effects (Ryan et al., 2005; Dahl-Jørgensen & Saksvik, 2005). One explanation for this heterogeneity, as we have already noted, is that implementation processes and contextual factors impact on the effectiveness of organizational SMI. In recognition of this, an increasing number of studies of organizational SMI evaluate and report on the nature of the implementation process. For instance, a job redesign study conducted by Dahl-Jørgensen & Saksvik (2005) across two different sites found that, in one of the sites, emotional exhaustion increased in the experimental group six months after the end of the intervention. Their qualitative process evaluation found that in this site the quality of the implementation process was low (in part due to high work demands and low management support), that some employees saw the intervention as a burden, and that other concurrent changes may have impacted negatively on employee stress, such as increased workload.

More generally, the empirical literature on intervention implementation has helped to confirm models of implementation processes outlined earlier (Cox et al., 2007; Nielsen et al., 2010). This literature suggests that attending to and supporting process-related activities at key stages (e.g., preparation and gaining support, screening for psychosocial risks, action planning, and implementation) can enhance the quality of implementation processes by increasing implementation intensity (i.e., greater time spent on intervention activities), providing support for employees (e.g., training in change process, communication skills), securing the necessary resources and fostering the implementation of change (Daniels et al., 2017; Kompier, Cooper & Guerts, 2000; Murta, Sanderson, & Oldenburg, 2007; Nielsen et al., 2010; Semmer, 2006; Sørensen, 2016), and fostering employee participation throughout all intervention activities (LaMontagne et al., 2007; Nielsen, Randall & Albertsen, 2007).

In addition, evidence suggests that organizational and participant characteristics can shape SMI effectiveness. For example, downsizing, poor management-employee relations and problematic HR practices may reduce employees' motivation to participate, prevent changes being implemented or counteract the positive effects of an intervention, such that augmenting interventions with wider changes in HR practices may be one means of reducing the risk of the organizational context impeding an SMI (Daniels et al., 2017). However, a lack of research prevents firmer conclusions being drawn about the effects of organizational context on SMI. With regard to participant characteristics (e.g., demographics, traits and attitudes), although they might be expected to influence SMI outcomes, few studies have systematically examined this issue (Egan et al., 2007; Rongen et al., 2013). The best evidence suggests that work redesign interventions are more effective when participants have an openness and willingness to change (Bond et al., 2008; Cunningham et al., 2002; Nytrø et al., 2000), make more positive appraisals of the intervention itself (Nielsen et al., 2007), and have previous experience of participation in decision-making procedures (Mikkelsen, Saksvik & Landsbergis, 2000). Motivated employees with the ability to participate in change processes therefore appear important to the success of organizational-level SMI, possibly because they are more likely to implement or respond positively to the types of change underpinning these interventions.

Conclusion

Our review of stress management interventions shows that organizations and managers have at their disposal a range of techniques and practices that can be used to reduce stress and promote the well-being of employees. There is a relatively convincing evidence-base for the effectiveness of secondary individual-level SMI, especially CBT, relaxation techniques, and mindfulness training, and the strength of the evidence base is growing for primary organizational-level interventions, particularly job redesign. Another encouraging conclusion that can be drawn from existing research is that we are gaining a better understanding of why interventions succeed, particularly that the success of organizational-level interventions appears to depend on the quality of implementation processes and employee participation. However, it is important to temper these positive conclusions with the fact that they may be skewed by publication bias and that they are based on studies with a range of methodological limitations. Indeed, there is a need to improve the quality of the evidence base on SMI by conducting more studies of higher methodological rigour and not just RCT designs. Rather, studies are needed using broad evaluation frameworks to assess quantitatively and qualitatively SMI outcomes and the effects of intervention processes on SMI effectiveness. In addition, we also know relatively little about the contexts in which SMI are most effective, particularly with regard to individual-level SMI, for which workers SMI are most beneficial, and the relative effectiveness of interventions, particularly because studies do not use comparable measures of well-being. Knowledge of these issues could help to target SMI more effectively and provide practical support where needed. Finally, questions remain about the long-term impact of SMI, as few studies assess the sustained benefits of SMI. Clearly, this has important implications for the management of SMI. Do organizations conduct SMI infrequently and reap the long-term benefits, or is sustained and continuing effort needed to ensure that well-being remains high?

CULTURE

Predictors of Subjective Well-Being Across Cultures

By Eunkook M. Suh & Soyeon Choi, Yonsei University

Citation

Abstract

We provide an overview of well-documented factors that predict and explain national and cultural differences in happiness. A brief history of the culture and happiness research is offered, followed by a literature summary on how cultural variations in happiness is related with objective life conditions, lay cultural beliefs of happiness, emotion patterns, characteristics of the self, and excessive concerns of social evaluation in East Asian cultures. We also briefly comment on findings from the culture-person fit research, and introduce recent biological and ecological papers that may point to new research directions for the culture and happiness field.

Keywords: subjective well-being, culture, self, emotion

Culture, as famously remarked by Durkheim (1895), is in many ways like "air." It permeates our mind and has a profound influence on our beliefs, feelings, values, and concerns about tomorrow. Yet, like air, culture rarely enters into our consciousness. It shapes our mind so thoroughly and naturally that being aware of its omnipresent influence on our mind is usually difficult.

This "invisible" culture started to draw the attention of subjective well-being (SWB) researchers in the early 1990s, the period that roughly overlapped with the publication of landmark papers on culture and self (e.g., Markus & Kitayama, 1991; Triandis, 1989). Important empirical foundations were laid, raising excitement and justifications for the study of culture and happiness. For instance, significant mean differences in happiness found between nations could not be attributed to simple methodological artifacts (Diener, Suh, Smith, & Shao, 1995), and longstanding determinants of happiness found in Western samples, such as self-esteem, were surprisingly weak predictors in non-Western samples (Diener & Diener, 1995). An edited volume (Diener & Suh, 2000), an *Annual Review of Psychology* article (Diener, Oishi, & Lucas, 2003), and a special issue of the *Journal of Happiness Studies* (Suh & Oishi, 2004) were devoted exclusively to the topic of culture and SWB. These works, in a sense, sprayed color to the once invisible culture, carving an exciting new niche in happiness research.

Now, most researchers find it quite obvious that culture plays a critical role in shaping virtually every aspect of happiness—how happiness itself is conceptualized, which life experiences are prioritized, how they are combined into an overall happiness judgment, preferred type of happiness state (low versus high arousal), to name a few. In addition to the development of more sophisticated research questions, lately, an unprecedented amount of large international datasets released by research organizations (e.g., Gallup, World Values Survey) have become available for happiness researchers. Thanks to these changes, cultural and national difference has now become a vibrant research field in happiness.

Given the huge volume of accumulated studies, our review of this topic is inevitably selective. While trying to maintain a balance between classic and recent research, this chapter focuses more on well-replicated cultural predictors of SWB that have been particularly informative for happiness researchers. We also suggest possible future directions for the culture and SWB research to expand, including more systematic consideration of ecological and biological factors.

Objective Conditions

One ongoing debate on cultural/national differences in happiness is whether growth in national wealth leads to increase in happiness. The spark of this debate dates back to Easterlin (1974), who proposed that while wealthier nations are generally happier than poorer nations, national income does not directly translate into more happiness after a certain point (see Easterlin, McVey, Switek, Sawangfa, & Zweig, 2010, for a review). In contrast, some researchers have shown opposing evidence that economic growth and happiness do go together. For instance, Deaton (2008) found from the Gallup World Poll that highest levels of well-being are found in Western European countries (especially Scandinavia), North America, Australia, and New Zealand, countries characterized as having many desirable objective conditions, such as wealth, good education, and political stability (e.g., for national differences, see Diener, Kahneman, & Helliwell, 2010; Diener & Suh, 1999; Hagerty & Veenhoven, 2003; Helliwell, Layard, & Sachs, 2016).

In response to this debate, recent studies that analyzed the Gallup World Poll data have suggested that economic conditions are correlated discriminately with SWB measures. That is, some type of objective measures correlate with some types of SWB but not with others. Across 132 countries, economic conditions (such as national income and public resources) were positively associated with the cognitive evaluation of one's life, but only weakly associated with emotional well-being (Diener, Ng, Harter, & Arora, 2010). In other words, people living in wealthier nations "think" they are happy, but not necessarily "feel" more positive emotions than those in poorer nations. A follow-up study even found that for the same level of personal income, people living in richer countries felt angry and worried more frequently (Tay, Morrison, & Diener, 2014). Overall, emotional well-being was largely predicted by personal factors rather than societal conditions. Positive feelings were dependent on psychosocial factors, such as social support, respect, and autonomy. Negative feelings were explained by both societal and personal factors (Diener et al., 2010; Ng & Diener, 2014; Tay & Diener, 2011).

Some researchers argue that both the volume of national wealth and the psychological factors that accompany it matters (see Diener, Oishi, & Lucas, 2015; Diener, Tay, & Oishi, 2013; Oishi & Schimmack, 2010). For instance, Oishi & Kesebir (2015) found that economic growth prompts increase in happiness when income is evenly distributed, but not when income inequality is high. They speculate that heightened sense of unfairness and social comparison may be the reason behind this phenomenon (see also Eksi & Kaya, 2017; Schröder, 2017). It is also found that progressive taxation is positively associated with SWB of nations (Oishi, Schimmack, & Diener, 2012).

However, it should be also noted that economic indices might shadow the effects of various positive social qualities on happiness that correlate with national wealth. It has been found in some dataset that national affluence raises happiness only through its effect on freedom, individualism, or democracy (Dorn, Fischer, Kirchgässner, & Sousa-Poza, 2007; Fischer & Boer, 2011; Inglehart, Foa, Peterson, & Welzel, 2008), prompting the need to "unpackage" wealth and find what precise elements of economic affluence contribute to the SWB of nations.

Lay Beliefs of Happiness

What is happiness, and what are the ingredients of it? The popular answer held by the average person varies much by culture. For instance, the definitions of happiness from dictionaries of 30 countries showed that some cultures focused more on external conditions or fortune, whereas others put more emphasis on positive internal feelings (Oishi, Graham, Kesebir, & Galinha, 2013).

Lay beliefs about happiness are often contrasted between collectivistic and individualistic samples. For example, when asked to indicate important criteria of a good and worthy life, Chinese focused on external and practical components, such as wealth and social status, whereas European Canadians chose more internal and private concerns, such as the self's positive impact on the world (Bonn & Tafarodi, 2013). There are also variations in the sense of agency. A thematic analysis revealed that collectivistic South Africans described happiness more on a societal level, such as social harmony and family ties, while Germans defined happiness more on a personal level, such as personal freedom and pleasure (Pflug, 2009). Similarly, Japanese people associated happiness with social balance, whereas Americans associated it with personal accomplishments and hedonic pleasure (Uchida & Kitayama, 2009).

Although cultural difference in lay beliefs of happiness has been examined by a wide array of studies, one common methodological weakness is that most of the responses are obtained through a structured questionnaire format. The questionnaire items in many cases are pre-selected by the researcher in reference to existing theories or well-established empirical findings. Merely given the option of either agreeing or disagreeing with questionnaire items, participants have little room to express their spontaneous beliefs about happiness. Consequently, by design, such studies tend to obtain theory-confirming results about happiness beliefs rather than novel insights.

To overcome this limit, in one recent study (Shin, Suh, Eom, & Kim, 2017), Korean and American participants are asked to write three words that immediately come to their minds when they think of "happiness." Regardless of cultural background, individuals who mentioned more words related with social relationships or relational concepts (friendship, love) were happier than others. However, interesting cultural differences were also found at a more detailed level. For instance, the most commonly associated word with happiness in Korea was "family" (13% of all responses), whereas affective states or expressions, such as "smile," and "laugh" topped the list (11% of responses) in the US. The most central type of relationship linked with happiness also differed. Whereas ascribed, in-group relationships (family) were nominated prominently in Korea, American respondents more often linked self-chosen social connections (romantic partner, friend) with happiness. Although social experiences are believed to be commonly important in both cultures, the type of relationships through which this need is fulfilled seems to show cultural variation.

Besides different beliefs on the content of happiness, cultures also vary in how desirable they think happiness is. In the US, for instance, people generally hold a glowing view of a "happy" person. A happy person, compared to a less happy person, is viewed not only to be more desirable, but even more likely to go to heaven by Americans (King & Napa, 1998). However, not all cultures are as enthusiastic about happiness. In some cultures, people are ambivalent about being overly happy, because happiness is believed to be followed by unhappiness at the end (Ji, Nisbett, & Su, 2001).

Also, the common Western belief that happiness is an inalienable right and a product of an individual's action appears less strongly among those brought up in East Asian or Islamic cultures (Lu & Gilmour, 2006; Joshanloo, 2013). Reflective of this contrasting cultural attitude, it has been suggested that Western cultural members might implicitly feel a certain degree of "pressure to be happy" (Suh, 2000), whereas some degree of "aversion to happiness" may exist in non-Western cultures (Joshanloo & Weijers, 2014).

Cross-cultural stereotypes about a "happy" person align with this difference. Choi, Suh, & Shin (2017) asked respondents from 45 nations to imagine overhearing a person who claims to be extremely happy and satisfied with life. Then, they were asked to guess how well various positive (e.g., warm, moral) and negative (e.g., arrogant, selfish) personality traits might characterize this self-proclaimed happy person. As expected, culturally held stereotypes about a happy person's character differed considerably across cultures. Although this stereotype was highly positive in cultures that report high levels of happiness (e.g., US, South America), in certain regions, people were underwhelmed about the happy person. For instance, in Japan, a nation that reports low happiness in comparison to its economic level, people believed that the imaginary happy person is more likely to possess negative (e.g., selfish, shallow) than positive personality traits. Across countries, how positively people thought about a happy person (indexed by subtracting the estimated likelihood of possessing negative from positive traits) significantly predicted the actual happiness level of each nation. This correlation remained even after controlling for relevant factors, such as emotion norms, resentment towards expressing happiness, individualism, and gross domestic product (GDP).

Most recently, an interesting argument has been proposed as to why cultures vary in their desirability judgments about happiness. Koh and her colleagues (2017) claim that one factor that sets apart cultures that strongly value happiness from those that value it less is the level of pathogen threat historically present in the environment. The high social nature of a happy person, although it has various positive assets in low pathogen regions, may inadvertently increase the chance of bringing infectious diseases through active social interactions. In high pathogen regions, people might have been reinforced to de-value traits or emotions (happiness) associated with exploration and contact of strangers. This hypothesis was not only supported in laboratory experiments, but interestingly, even predicted the voting pattern of nations in the United Nations (UN) General Assembly meeting regarding an international happiness resolution (adopting happiness as a national guide for policy). As predicted, UN member states that sponsored this resolution had a significantly lower level of pathogen than non-sponsoring states.

Studying lay beliefs of happiness across cultures goes beyond gratifying academic curiosity. Certain beliefs held by the person about happiness, and how much she values it actually make a difference in how happy she is. For instance, people's belief on whether the total amount of happiness they will experience in life is predetermined and "fixed" or "infinite" leads to divergent habits and choices related with happiness. Importantly, the fixed-amount theorists were significantly less happy with their lives (Koo & Suh, 2006), controlling for personality factors. There is also the finding that in countries where positive emotions are highly valued, people report higher life satisfaction and experience more positive emotions (Bastian, Kuppens, De Roover, & Diener, 2014).

Emotion

A defining aspect of emotional well-being is the relative frequency of positive over negative affect (Diener, Suh, Lucas, & Smith, 1999), which has led to a heavy focus on the affective dimension of valence (positive or negative) in happiness research. Thanks to cross-cultural research, psychologists now recognize that there are other dimensions of positive affect that are relevant for understanding happiness (Tsai, 2007). For instance, Euro-Canadians highly value high activation positive affect (HAP), such as excitement and elation, whereas Chinese and Japanese value low activation positive affect (LAP), such as calmness and serenity (Ruby, Falk, Heine, Villa, & Silberstein, 2012).

This cultural variation in ideal positive affect causes a difference in the link between positive emotion and happiness. Researchers found that the discrepancies between ideal and actual HAP led to poor mental health for European Americans and Asian Americans, but not for Hong Kong Chinese (Tsai, Knutson, & Fung, 2006). By contrast, discrepancies between ideal and actual LAP led to poor mental health for Asian Americans and Hong Kong Chinese, but not European Americans.

In addition to valence and arousal, Kitayama and colleagues (e.g., Kitayama & Markus, 2000;

Kitayama & Park, 2007) suggest that the happiness of Japanese and Americans also relate differently with another pole of positive emotion—Japanese centered more on socially engaged (feelings of closeness to others, friendly feelings) emotions, whereas Americans rely more on socially disengaged (pride and feelings of superiority) emotions. Related to this difference, it is reasoned that the pursuit of happiness itself may lead to different outcomes between cultures. According to Ford et al. (2015), motivation to pursue happiness predicted lower well-being in the US, whereas it predicted higher well-being in Russia and East Asia. The authors attribute this difference to the possibility that collectivistic cultural members tend to pursue happiness in more socially engaging ways than individualistic cultural members.

Cultures also differ in their beliefs about the relation between positive and negative affect. In general, East Asians have a more dialectic view than Western cultural members; therefore, they are more likely to believe that events or experiences that seemingly contradict can co-occur (Peng & Nisbett, 1999). As a result, European Americans tend to have fewer mixed emotional experiences (feeling bad and good at the same time) than East Asians (e.g., Miyamoto, Uchida, & Ellsworth, 2010; Shiota, Campos, Gonzaga, Keltner, & Peng, 2010), a pattern mediated by dialectical beliefs (Spencer-Rodgers, Peng, & Wang, 2010). Some have employed this dialectic script to explain cultural differences in emotion regulation, such as the dampening or savoring of positive emotions (Miyamoto & Ma, 2011) or why people try to maximize positive emotion and minimize negative emotion more strongly in one culture than another (Sims et al., 2015).

Another widely replicated finding concerns cultural difference in the use of affect in overall judgments of happiness (Kuppens, Realo, & Diener, 2008; Schimmack, Radhakrishnan, Oishi, Dzokoto, & Ahadi, 2002; Suh, Diener, Oishi, & Triandis, 1998). The "affect-as-information" theory (Schwarz & Clore, 1983) has suggested that people use their momentary mood as a heuristic cue for making various evaluative judgements, including life satisfaction. Research has found that this phenomenon occurs more reliably among individuals who chronically view themselves as an independent being than those who construe themselves as an interdependent person.

This pattern is found between cultures as well as within a culture as function of one's self-view. For instance, when Americans are primed of the relational aspects of self, they tend to base their life satisfaction judgment quite heavily on others' evaluations of their lives (the typical collectivistic pattern); conversely, Koreans primed on their unique aspects of the self shifted their attention to inner emotions (individualistic pattern) during life satisfaction judgment (Suh, Diener, & Updegraff, 2008). Thus, the type of information used in constructing global self-judgments of happiness seem to systematically differ between cultures, depending on whether the autonomous, unique aspects of the self versus the fundamentally socially embedded nature of the self are stressed. This difference is also observed with implicit measures. In an association-judgment task, European Americans who were satisfied with their lives associated happiness with more positive emotion words, but this pattern was not found for Koreans and Asian Americans (Koo & Oishi, 2009).

Emotion norms that have implications for both the experience and expression of happiness also vary between cultures. In general, in non-Western cultures, positive emotions (happiness) are valued less, whereas negative emotions are believed to have important functional values, compared to highly individualistic cultures, (e.g., Eid & Diener, 2001; Joshanloo et al., 2014; Oishi et al., 2013). Although national differences in SWB are not completely explained by difference in emotion norms, researchers need to be aware of their influence. For instance, according to a recent finding by Sheldon et al. (2017), Russians (compared to Americans) reported a greater inhibition in the expression of happiness to strangers. Interestingly, the greater happiness inhibition to strangers was unrelated with the experienced happiness of Russians, but negatively predicted the happiness level of American samples (see also, Soto, Perez, Kim, Lee, & Minnick, 2011). In this study, the self-reported SWB level between the two cultural groups did not differ, suggesting that the size of the discrepancy between experience and overt expressions of happiness may differ across countries.

Importance of the Self: High Esteem, Consistency, and Clarity

Cultures also differ in how important the self is for SWB (for review, see Suh, 2000). Having a positive belief about one's overall self seems to matter more for the happiness of individualist than collectivist cultural members. Following Diener and Diener's (1995) groundbreaking paper on cultural difference in self-esteem and life satisfaction, studies have repeatedly found that self-esteem is a stronger predictor of happiness in Western than Asian cultures (Uchida, Kitayama, Mesquita, Reyes, & Morling, 2008; Yuki, Sato, Takemura, & Oishi, 2013). It appears that the positive aspects of the internal self strongly determine the person's overall happiness in the West, whereas the relational tone between the self and other significant selves (e.g., family) seem to be more salient for the well-being of collectivist cultural members. One of the first empirical demonstrations of this difference was by Kwan, Bond, and Singelis (1997), who

found that compared to the US, the relative importance of relationship harmony to self-esteem was greater in Hong Kong.

Having a clear, and consistent idea of oneself also seems to matter more in individualistic than collectivistic cultures. People who have an inconsistent self-concept across social situations have lower life satisfaction and affective well-being, but this relationship is weaker in collectivistic cultures, where being flexible to situational demands is highly appreciated by others (Bleidorn & Ködding, 2013; Church et al., 2014; English & Chen, 2011). For instance, Suh (2002) found that Koreans are less consistent in rating their personality across social roles, and this degree of inconsistency had a smaller association with SWB, compared to North Americans. In Korea, a more important predictor of SWB than consistency was how individuals believed their life was evaluated by significant others (perceived social appraisal). In a similar vein, Oishi, Diener, Scollon, and Biswas-Diener (2004) found that the within-person variability of affect across situations (e.g., the effect of being with a romantic partner versus stranger on positive affect) was greater among Japanese and Hispanic students than European Americans. Also, it is found that the relationship between clarity of one's feelings (being able to describe one's feelings accurately) and SWB was stronger in more individualistic countries (Lischetzke, Eid, & Diener, 2012).

Broadly speaking, happiness in collectivist cultures seem to depend less on private and personal aspects of the self, but more on relational and even distal societal factors. This might be because the inner self seems to be a more pivotal anchor of psychological experience in individualistic than collectivistic cultures (Suh, 2000). Conversely, how well one's family, group or country might be doing might matter more for collectivists. A study by Morrison, Tay, and Diener (2011) illustrates this point. Although personal factors are prime predictors of happiness in Western countries, they found that the overlap between satisfaction with one's country (national satisfaction) and personal satisfaction becomes larger in collectivist nations.

Concern for Social Approval and Conflict

If the inner state of the self is a crucial predictor of happiness in the West, how the self's exterior layer is evaluated and recognized by others is critical for the happiness of East Asians. This is because East Asians and other collectivist cultural members, chronically vigilant of their value as a social member, are far more likely to adopt a third-person perspective about themselves than European Americans (Cohen & Gunz, 2002). How I am "seen" by others are in many cases more important to a collectivist person than how the world subjectively appears to her. Such thinking extends to various realms of life, and creates several cultural variations in link to happiness.

For one, the "good life" is visualized somewhat differently. For instance, the individual's perceived social image predicts life satisfaction beyond the effects of emotions and personal achievement in India and Pakistan, but not among White British and European Americans (Rodriguez Mosquera & Imada, 2013). In comparison of how the good life is viewed by mainland Chinese and European Canadians, Bonn and Tafarodi (2013) conclude that one of the key difference is the "focus of concerns"—tending towards either inner/personal versus socially defined goods. The Chinese sample, for instance, was more likely to emphasize security, wealth, and social success (status) in their visions of a desirable life than the European Canadians. The latter group focused on less concrete and practical factors, such as meeting one's inner potential.

Since being acknowledged by others is easier when the person possesses something easily visible or quantifiable, collectivistic cultural members put much effort to embellish the external aspects of the self. This explains why money is strongly believed to be critical for happiness, even in highly affluent East Asian societies. In one study, Singaporeans, but not Americans, expected that a person with a higher income would be more likely to have a high-quality life than a person with lower income (Wirtz & Scollon, 2012). Compared to the US, extrinsic goods (e.g., money, physical appearance) are stressed more by Koreans, a pattern that partly explains the happiness difference between the two countries (Koo & Suh, 2015). In a similar line, objective social status (education) is more strongly associated with happiness among Japanese than Americans, whereas subjective social status is more strongly associated with happiness among Americans than Japan (Curhan et al., 2014). The authors' interpretation is that the Japanese trust objective markers that others can see more, while Americans trusted their own judgments.

Using a more common psychological term, the contingency of self-worth (Crocker & Wolfe, 2001) seems to differ between cultures. It is found that between Eastern and Western cultures, other's approval contingency of self-worth (CSW) is notably different, which mediates the happiness difference between Taiwan and US samples (Liu, Chiu, & Chang, 2017). It suggests the possibility that East Asian's self-judgments of happiness could be more prone to fluctuations, depending on the tone of social feedback. This appears to be the case. In one study, Korean and American college students were asked to describe a recent pleasant event and rate how happy they felt during the experience (Choi, 2013). Several weeks later, the

participants rated once again how happy they felt about the same event they wrote earlier, after receiving bogus feedback that other people either agreed (also thought the event was fun) or disagreed (thought the event was rather boring) with them. Interestingly, the Koreans' evaluations of the self-nominated happy event changed as a function of others' approval or disapproval, whereas Americans did not. It implies that even the hedonic evaluation of a highly personal experience is affected by other's evaluation in collectivistic Asian cultures.

A flipside of this heightened social sensitivity is that East Asians are much more concerned about potential damages to their social image than Western cultural members. As such, some active and promotive social gestures that benefit happiness are less pursued, in fear that they may instigate negative reactions. A good example is, contrary to what might be expected from cultural stereotypes, East Asians are in general *less* likely to seek social support from others than European Americans (Kim, Sherman, & Taylor, 2008). This is because Asians are more concerned about the negative relational consequences of help seeking, such as stressing the support provider or being viewed as an incompetent person. One recent cross-cultural paper finds a highly similar pattern occurring in the link between capitalization and happiness (Choi, Oishi, Shin, & Suh, in press). Koreans, compared to Americans, were more hesitant to celebrate positive events (capitalization attempts) with others because of possible relational costs (e.g., being seen as immature, inappropriate).

The East Asians' excessive concern of other's view might be a key psychological reason for why their happiness level is lower than expected by economic indices (Suh, 2007; Suh & Koo, 2008). It may be the common underlying cause of several interrelated phenomena that are known to be detrimental for happiness: a) being more focused on external, materialistic aspects of happiness, b) not being able to create and use idiosyncratic standards for self-judgment, which is an essential strategy for maintaining self-enhancing views (cf. Dunning & McElwee, 1995), c) being oriented more towards preventive than promotive decisions in everyday life.

Culture-Person Fit Issue

One popular conceptual framework employed in explaining happiness across cultures is the culture-fit, or the culture-person matching hypothesis. The key idea is that, other things equal, the person is happier when her personal characteristics (personality, value, emotion) resembles the dominant practices or values of the residing culture.

Because cultures differ in emotion norms, the degree to which an individual's emotion experience pattern fits with the social norm could matter (cf. Gruber, Mauss, & Tamir, 2011). Using an implicit measure of cultural fit of emotions, De Leersnyder, Mesquita, Kim, Eom, and Choi (2014) recently found across US, Belgium, and Korea that individual's level of emotion fit with the culture's average emotion profile across social contexts (e.g., with family, friends) predicted relational well-being.

Fulmer et al. (2010) found that the relationship between an individual's personality and SWB is also strengthened when the individual's personality matches the common personality type in the culture. In a society where extraverts were prevalent, culture boosted the positive effect of extraversion on happiness. Furthermore, researchers showed that while civic virtue is usually positively associated with happiness, virtuous individuals were not happier than selfish individuals in cultures where transgressions are common and easily justified (Stavrova, Schlösser, & Fetchenhauer, 2013). A similar pattern has been examined in the domain of personal and national religiosity (Diener, Tay, & Myers, 2011).

Despite the popularity of the culture-person fit idea, strong versions of this argument may lead to cultural relativism, possibly undermining the pan-cultural, universal elements of human happiness. Few would recommend a person who lives in a highly totalitarian society, for the sake of culture-person fit, to give up personal autonomy as a strategy for increasing happiness. In fact, there are findings that challenge the fit notion. According to the fit theory, the happier Koreans should be the ones whose personal values align with strong collectivistic ideals. This was not the case (Kim, 2012). Even in Korea, individuals who valued autonomy and enjoyed typical individualistic experiences (e.g., feeling unique) were happier than the more culturally fitting counterparts, especially among the affluent group.

Newcomers: Ecological and Biological Factors

Thus far, this chapter has reviewed cultural differences in predictors of happiness mainly using the framework of individualism and collectivism. However, this dichotomous cultural contrast offers little insight to why the different regions of the world came to adopt certain cultural values in the first place. Before concluding, it is worth a brief overview of some emergent findings relevant with happiness that explore the role of ecological and biological factors. This approach might offer some fundamental insight about the origins of cultural variation, and how SWB is related to such non-psychological factors.

As for ecological factors, a group of scientists claim that the historic prevalence of pathogens in the

local environment leads to the emergence of individualism and collectivism (Fincher, Thornhill, Murray, & Schaller, 2008; Murray & Schaller, 2010). The claim is that central features of collectivism, such as strong in-group favoritism or conformity, developed as a group-level psychological response to inhibit the transmission of pathogens. This parasite-stress is claimed to increase in-group assortative sociality, which is culturally expressed in the form of strong family ties (Fincher & Thornhill, 2012). As mentioned, in line with this argument, Koh et al. (2017) found through a series of studies that happy individuals are viewed less positively in high pathogen regions, presumably because the behavioral features associated with happiness (e.g., risk-taking, novelty seeking) increase the spread of disease.

Another ecological factor that may influence perceptions of happiness is resource scarcity. Being somewhat complacent and optimistic about one's surrounding is more acceptable when the environment is safe and resource is abundant. However, this free-spirited attitude may become problematic when an immediate change or improvement of the situation is required, as when food or other crucial survival resources need to be replenished. Probably for this reason, a recent study finds that resource scarcity leads to a more negative perception of a happy person (Shin & Suh, 2017).

Climate has also been associated with well-being (Rehdanz & Maddison, 2005). Harsh climates (hot summers and cold winters) negatively predict SWB. In an analysis of 58 countries, Fischer and Van de Vliert (2011) showed that demanding climates predict ill-being in poor nations but not in wealthy nations, because resources buffer the negative effects of climate. Coming from a more evolutionary angle, Li & Kanazawa (2016) found that population density is negatively correlated with life satisfaction. The authors explain that when group size and population density becomes higher than what was common in our ancestral environment, people are likely to be stressed out more easily.

One of the latest newcomers to the study of culture and happiness are recent work on genes. In one study, researchers reported that people in collectivistic cultures are more likely to carry short allele of the 5-HTTLPR than individualist cultural members (Chiao & Blizinsky, 2010). Interestingly, a culture-gene coevolution was found. That is, the frequency of short allele carriers lowered the prevalence of affective disorders, and increased collectivism mediated this relationship. Another recent study reports that national percentages of people with high positive affect were correlated with the national prevalence of the rs324420 A allele in the FAAH gene (Minkov & Bond, 2017). Although most of the current findings on genetic and ecological factors are highly tentative, they shed light on a host of new factors that were once completely outside the attention span of happiness researchers.

Conclusion

Although cultural variations clearly exist, we would like to simultaneously stress that there are undeniably universal aspects of well-being. So far, research has not yet found any single country in which happiness correlates in a reverse direction with well-known predictors of happiness—income, extraversion, positive affect, etc. Even in collectivist cultures where inner emotions seem to play a less defining role in happiness, for instance, the correlational direction is similar to other countries. Hence, appreciating the cultural variance in happiness is important, but not to the extent of obscuring the universal aspects of human well-being.

One of the most pressing research needs is gaining a more in-depth understanding of how and why the culture-specific beliefs and practices of happiness arise. This would require researchers to go beyond cataloguing surface differences between regions, and make creative, theory-driven speculations on what underlying adaptive functions the different cultural contours of happiness might serve. Culture is created by humans, who are not exceptions to the basic evolutionary principles (Hill & Buss, 2008). Basic evolutionary needs, such as safety or social belongingness, are pursued in a widely different manner by two individuals who differ in personality, values, and habits. Likewise, the different cultural shades of happiness, influenced by ecological constraints and historical factors, might merely be different scenes seen from multiple paths. They are all likely headed toward a common destination—securing essential needs for survival and reproduction (social respect, belongingness, resource).

Subjective Well-Being in Nations

By Ruut Veenhoven, Erasmus University Rotterdam, Netherlands, Erasmus Happiness Economics Research Organization and North-West University, South Africa, Optentia Research Program

Abstract

Subjective well-being is a main goal in modern society, thus it is worth knowing 1) how subjective well-being differs across nations, 2) how it develops over time, 3) what the determinants of subjective well-being in nations are and 4) what the consequences of more or less well-being are. In this chapter, I focus on one particular aspect of subjective well-being, that is, *life-satisfaction*. I take stock of the research on this matter, drawing on the World Database of Happiness. This reveals the following patterns: a) life-satisfaction differs much across nations, b) average life-satisfaction has risen over the past decade in most nations, while inequality in life-satisfaction in nations decreased, c) several societal determinants of life-satisfaction have been identified, many of which are part of modernity, and, d) high life-satisfaction in a nation has several positive effects and pursuit of greater happiness fits as such with wider policy aims.

Keywords: happiness, life-satisfaction, subjective well-being, comparative, cross-national, policy implication

Why This Topic?[1]

All humans want a satisfying life for themselves and their children and this appears in high rankings of happiness in the value hierarchy of students all over the world (Diener, Suh, Smith, & Shao, 1995). Individually, people seek ways to a more satisfying life and, in Western societies, this quest manifests in soaring sales of 'how-to-be-happy books', such as 'The art of happiness' by the Dalai Lama (1998). It also reflects in the development of life-coaching businesses. Citizens in western societies call on governments for improvement of what they consider to be required social conditions, 85% of the British agree with the statement that 'a governments prime aim should be achieving the greatest happiness of the people, not the greatest wealth' (BBC 2006, question 14).

Consequently, interest in subjective well-being is rising among policy makers; it is a new topic on the political agenda, along with sustainability. The international conference on Happiness and Well-being held at the UN headquarters in New York in April 2012 (Thinley, 2012) is a recent manifestation of this trend. The subsequent decision of the General Assembly in June 2014, to celebrate an 'International Day of Happiness' on March 20 every year, illustrates its importance.

Information Needs

This call for greater well-being creates a demand for information. Policymakers seek answers to the following questions.

Is greater well-being in the country possible? Policymakers will hear some experts say that pursuit of greater happiness for a greater number is pointless. A common argument is that subjective well-being depends on comparison with compatriots, and that relative differences do not change when absolute conditions improve for everybody in the country (e.g. Brickman & Campbell, 1971). Next, there is the theory that subjective well-being depends very much on 'national character', which is rooted in historical conditions, such as the many revolutions in France, which have created a cynical view on life among the French, as Inglehart (1990, p. 30) suggests. The first thing a government needs to know is whether subjective well-being in nations is immutable.

How does the country do well-being wise? Once it is clear that average subjective well-being in a nation can change, the next step is to estimate the chances for creating greater well-being in one's own country. This requires a view on how well people currently feel in your country, which calls for survey studies. The next step is comparison, both comparisons of present day sense of well-being with subjective well-being in earlier times in one's country and with subjective well-being in other countries. Governments can then see how their country is doing well-being-wise on a range between the highest and lowest levels ever observed in other nations.

Since most governments are also concerned about equality among their citizens, they are also interested in dispersion of subjective well-being in their country, and how this compares to inequality in the sense of well-being in other nations.

Can governments do much about how well citizens feel? If the level of well-being in a country lags behind the possible level, the next question is whether a government can change that situation for the better. In this context, a first question is to what extent the differences in subjective well-being are in things that are beyond the control of governments, such as a prevalence of depressive genes in the population, poor climatic conditions or historical legacies.

If subjective well-being in a country appears to depend on things that can be changed, the next question is whether a government can bring about that change. This is the question of limits to social engineering. In this context, it is worth knowing how other governments have fared in their attempts to improve subjective well-being in their countries: Have they made any difference or have attempts to create a better society mostly resulted in the opposite as critics of utopian engineering suggest (e.g., Avery, 2000)?

What can governments do to foster subjective well-being? If a government decides to pursue greater subjective well-being in their country, the next question is where to start. In this context, a government typically wants to know whether there are pockets of misery in their countries, or actually, whether there is any truth in the claims about subjective ill-being in particular categories of citizens advanced by organized advocacy.

Taking a broader view, governments would like to know what the drivers of differences in subjective well-being among citizens are: in particular, to what extent these correspond with things over which a government has some control, such as income, schooling, health care and safety. Again, this typically involves the sifting of competing claims of special interests, presented by lobbyists. Interior struggles also call for information about winners and losers of particular policies, for example, whether the emancipation of women will come at the expense of the well-being of men and children.

In an even wider perspective, which some governments take, questions about societal conditions for happiness arise. What are the secrets of the happiest countries, such as Denmark? Are they in institutional things such as a strong welfare state? Are they found in the political regime, such as interest groups having much voice? Or is the high level of happiness due to particular policies, such as promotion of equal rights for men and women? What is the role of the well-being professions, such as psychologists and life-coaches?

How compatible with other policy aims? Subjective well-being is only one of the aims states pursue and typically not a very prominent one. This begs the question of how well the pursuit of greater subjective well-being fits major policy aims, such as economic competitiveness, political democracy and social peace. In this context, one question is to what extent the things required for greater subjective well-being will also add to these causes, such as schooling adding to both subjective well-being and economic growth. Or, how the question is put most of the time, to what extent do the things government does anyway for other causes also add to subjective well-being.

A related question is what will be the consequences of greater subjective well-being: will it foster decadence and decay, as some prophets of doom predict, like Huxley (1932), who depicted happy citizens as shortsighted consumption slaves. Or will a happy populace be more productive, democratic and peace minded, as is now commonly assumed in positive psychology? These contradictory speculations call for empirical assessment.

Plan of This Chapter

In this chapter I explore the knowledge required to answer these questions. I start with a conceptual analysis and focus on subjective well-being in the sense of life-satisfaction in section 2. I describe how that concept is measured in section 3. Next, I provide an overview of the research findings on differences in life-satisfaction across nations in section 4. I review the determinants of these differences in section 5. I consider the consequences of more or less happiness in nations in section 6 and present an agenda for further research in section 7.

What ‘Well-Being’?

When used in a broad sense, the term ‘well-being’ is synonymous with 'quality of life' or with 'happiness’ when used in philosophy. In this meaning, well-being denotes that a life is good, but does not specify what is good about that life. The word ‘well-being’ is also used in more specific ways, and these meanings can be clarified with the help of the classification of qualities of life presented in Scheme 1.

Four Kinds of Well-Being

Vertically in Scheme 1, there is a difference between *chances* for a good life and actual *outcomes* of life. Horizontally, there is a distinction between *external* and *internal* qualities. Together, these two dichotomies mark four qualities of life, all of which have been denoted by the term 'well-being'.

Livability of the environment. The left top quadrant denotes good living conditions. Economists sometimes use the term 'welfare' to indicate this meaning. 'Livability' is a better word, because it refers explicitly to a characteristic of the environment. Politicians and social reformers typically stress this quality of life.

Life-ability of the person. The right top quadrant denotes inner life-chances. That is, how well we are equipped to cope with the problems of life. This aspect of the good life is also known by different names. In biology, the phenomenon is referred to as 'adaptive potential'. Elsewhere, it is denoted by the medical term 'health'. Sen (1992) calls this quality of life variant 'capability'. I prefer the simple term 'life-ability', which contrasts elegantly with 'livability'. This quality of life is central in the thinking of therapists and educators.

Usefulness of life. The left bottom quadrant represents the notion that a good life must be good for something more than itself. This presumes some higher value, such as ecological preservation or cultural development. In fact, there is a myriad of values on which the usefulness of a life can be judged. Moral advisors, such as your pastor, emphasize this quality of life.

Satisfaction with life. Finally, the bottom right quadrant represents the inner outcomes of life. That is the quality of a life in the eye of the beholder. As we deal with conscious humans, this quality boils down to subjective appreciation of life. This is commonly referred to using terms such as 'subjective well-being', 'life-satisfaction' and 'happiness' in a limited sense of the word. This is the kind of well-being I deal with in this chapter.

Scheme 1
Four kinds of well-being

	Outer qualities	*Inner qualities*

Four Kinds Satisfaction

This brings us to the question of what 'satisfaction' is precisely. This is also a word with multiple meanings and again we can elucidate these meaning using a simple scheme. Scheme 2 is based on two distinctions; vertically between satisfaction with *parts* of life versus satisfaction with life *as-a-whole*, and horizontally between *passing* satisfaction and *enduring* satisfaction. These two bi-partitions yield again a four-fold taxonomy.

Pleasures. Passing satisfaction with a part of life is called 'pleasure'. Pleasures can be sensory, such as a glass of good wine, or cerebral, such as the reading of this text. The idea that we should maximize such satisfactions is called 'hedonism'.

Part-satisfactions. Enduring satisfaction with a part of life can concern a *domain* of life, such as 'working-life', and an *aspect* of life, such as its 'variety'. Sometimes the word happiness is used for such part-satisfactions, in particular for satisfaction with one's career.

Peak-experience. Passing satisfaction can be about life-as-a-whole, in particular when the experience is intense and 'oceanic'. This kind of satisfaction is usually referred to as 'peak-experience'. When poets write about happiness, they usually describe an experience of this kind. Likewise, religious

writings use the word happiness often in the sense of a mystical ecstasy. Another word for this type of satisfaction is 'enlightenment'.

Life-satisfaction. Enduring satisfaction with one's own life-as-a-whole is called 'life-satisfaction' and commonly referred to as 'happiness'. Elsewhere I have delineated this concept in more detail and defined happiness as 'the overall appreciation of one's life-as-a-whole' (Veenhoven, 1984).

Conceptual Focus of This Chapter

This paper is about subjective well-being in the sense of life-satisfaction that is, enduring enjoyment of one's life as a whole.

Measurements of Life-Satisfaction

Life-satisfaction is something we have in mind. Consequently, life-satisfaction can be measured using questions, that is, by asking people how much they enjoy their life-as-a-whole. Questions on happiness can be posed in various contexts; clinical interviews, life-review questionnaires and survey interviews. The questions can also be posed in different ways; directly or indirectly, and by means of single or multiple questions.

All questions on subjective well-being that have ever used were checked for fit with the above definition of happiness[2]. About half failed that test for face-validity. Accepted questions are listed in the collection 'Measures of Happiness' of the World Database of Happiness (Veenhoven, 2017c).

A common question[3] reads as follows:

All things considered, how satisfied are you with your life as a whole these days?

0 1 2 3 4 5 6 7 8 9 10

Dissatisfied Satisfied

Many misgivings have been advanced about such self-report of life-satisfaction; it has been doubted that responses validly reflect how people feel about their life, that responses are erratic and incomparable across persons and cultures. Though plausible at first sight, these qualms have not been supported by empirical research, see for example Diener & Oishi (2004), VanPraag & Ferrer-i-Carbonell (2004) and Veenhoven (1984, 2008a). Other indications for the validity of happiness self-reports are: their stability over time, fit with rating by others and correlation with various aspects of a good life, such as reported in this paper. Particularly telling is that self-reported happiness predicts longevity (Veenhoven, 2008b).

Life-Satisfaction in Nations

Questions on life-satisfaction are commonly used in large-scale survey studies, such as the General Social Survey in the USA and the Eurobarometer in the EU. This has taught us much about the differences in life-satisfaction *within* and *across* nations.

Findings on Life-Satisfaction in Nations

Research findings on life-satisfaction in nations are gathered in the World Database of Happiness (Veenhoven, 2017a-f). This 'findings archive' involves two kinds of research results: *distributional findings* on how satisfied citizens are in particular times and places and *correlational findings* on things that go together with more or less life-satisfaction in countries. To date (January 2018) the archive lists 8543[4] distributional findings on life-satisfaction in the general public in 173 nations in different years (Veenhoven, 2017d), and some 1000 correlational findings about societal characteristics that correspond with more or less life-satisfaction in a nation (Veenhoven, 2017e).

In this chapter, I use the World Database of Happiness as an online appendix. This allows me to sketch the main trends, without going into detail, since the reader can check in the database. The findings archive is continuously updated and this will allow the reader a view on research findings that have become available after this chapter was published. An overview of the most relevant entries in the World Database of Happiness to date (January 2018) is presented in scheme 3.

Scheme 3
Findings on life-satisfaction in nations in the World Database of Happiness

Distributional findings: *frequencies, mean, SD*	
• By nation	8543 nation/year observations
• By measure type	sorted in 52 measure types
• Rank reports	Rankings of 142 nations for which comparable data is available
• Trend reports	Trends in 25 nations for which at least 10 comparable data-points over 20 years is available
Correlational findings*: various measures of association*	
• Attitudinal climate in nation	13 findings
• National character	82 findings
• Societal conditions	959 findings
• Position of the nation	15 findings

Differences Within Nations

Happiness differs considerably within nations. The surveys show extremely satisfied and dissatisfied people in all countries, as is illustrated in figures 1 and 2. In Denmark, responses cluster at the positive end of the scale, which results in a mean of 8,4 and a standard deviation of 1,6[5]. In Ukraine, most responses are at the middle of the scale and the dispersion is greater, which results in a mean of 4.4 and a standard deviation of 2.4[6]

Figure 1
Life-satisfaction in Denmark

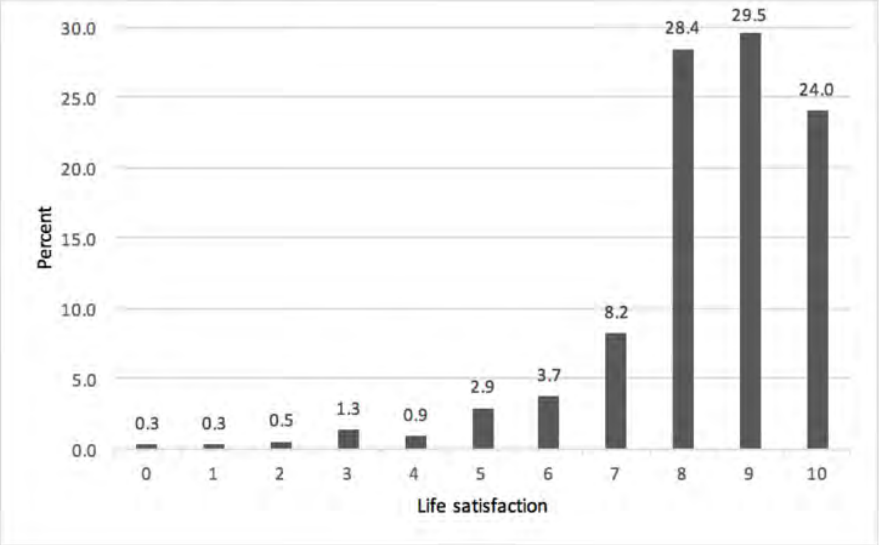

Figure 2
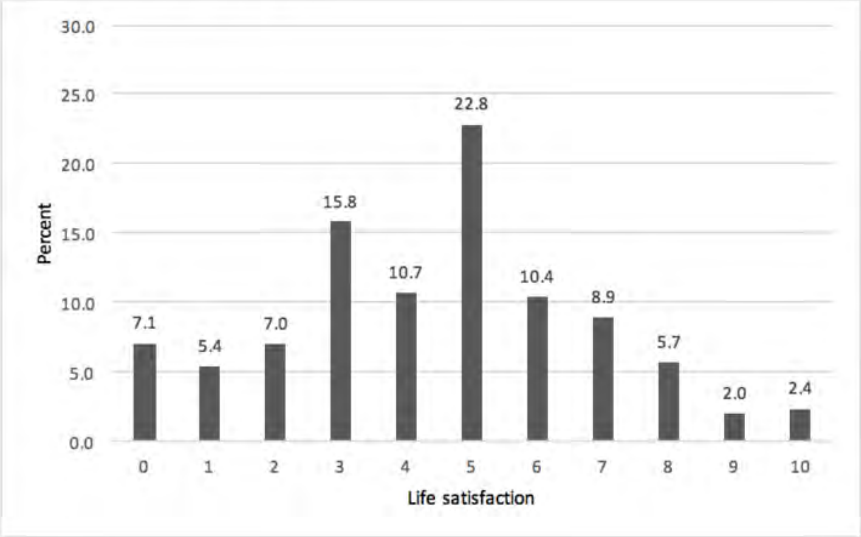
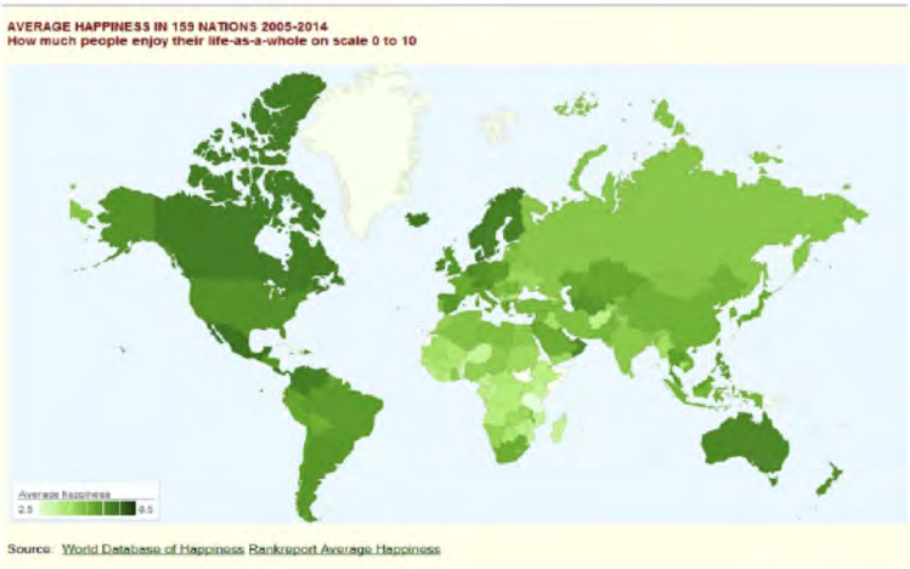
Life-satisfaction in Ukraine



Differences Across Nations

Happiness has now been assessed in most countries of the world, a notable exception being North Korea. A world map of happiness is presented in Figure 3. Differences in average happiness are indicated by the shade of the green; the darker the green, the happier the people in the nation. One can now see that the high average happiness in Denmark is typical for developed nations. One can also see that the low level of happiness in Zimbabwe is no exception, since happiness is equally low in most African nations. Latin America surprises us in this picture, with higher scores than one would expect based on the news reports emanating from that region.

Figure 3
Average happiness in 159 nations 2005-2014



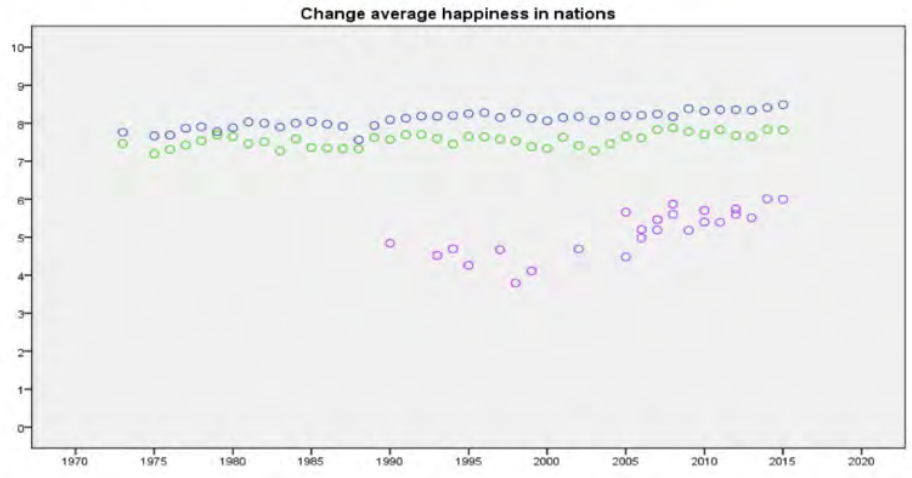
Source: Happiness in Nations (Veenhoven 2017d)

Trend of Life-Satisfaction in Nations

Survey research on life-satisfaction started in the late 1940s and took off in the early 1970s. Until recently, it was difficult to discern a pattern in the data; changes over time tend to be small and our view of a trend is often blurred by minor variations in sampling and questioning. Now that we have more and better data, we can see that life-satisfaction has risen in most nations, though not in all (Veenhoven, 2014). Some illustrative cases are presented on Figure 4. This rising level of life-satisfaction is accompanied by a decline of inequality in life-satisfaction among citizens as measured by the standard deviation (Veenhoven, 2017g).

Figure 4

Trend average happiness in Denmark, The Netherlands and Russia



Source: Happiness in Nations (Veenhoven 2017d)

Determinants of Life-Satisfaction in Nations

As we have seen in section 4.2, there are large differences in average life-satisfaction across nations and this has instigated much research on the causes of these differences. The findings can be ordered using the different kinds of well-being presented in scheme 1; part of the findings concern variation in external living conditions in nations and fits the *livability* quadrant upper-left in scheme 1. Another part of the findings is about variation in inner characteristics and fits the upper-right *life-ability* quadrant of scheme 1. Findings on the relation between average happiness in nations and livability factors are presented in table 1 and findings on the relation between average happiness and modal life-ability of inhabitants are presented in table 2.

The many dark shaded cells in these tables indicate that the subject is well -researched. In the column 'partial', the dark shaded cells denote that many attempts have been made to clean the zero-order correlation from spurious effects, typically using regression analyses involving many controls. Since national characteristics are typically much inter-twined, this involves a risk of underestimation. The blank cells indicate that no data is available yet.

Livability of Society

The main findings about the relation between external living conditions and average life-satisfaction in nations are summarized in table 1.

Wealth. People live typically happier in rich countries than in poor ones. This difference is at least partly due to an effect of material affluence as such, since much of the correlation remains when other nation characteristics, such as climate, are controlled. Analysis of change over time reveals that economic growth goes together with rising happiness (Veenhoven & Vergunst, 2014). This contradicts the well-known 'Easterlin Paradox', which holds that rising wealth in nations does not add to the happiness of citizens (Easterlin, 1974). Economic growth adds more to happiness in poor nations than it does in rich ones.

Freedom. People also live happier in nations that provide the most opportunities to choose. Economic freedom adds more to happiness in developing nations than in developed ones, but political freedom correlates stronger with happiness in developed nations. Data on private freedom are limited to developed nations. A related finding is that people live happier in individualistic cultures than in collectivistic ones (Veenhoven, 1999). Correlations between freedom and happiness are much reduced when economic development is controlled. The rise of liberal values in Western nations (Inglehart & Wetzel, 2005) goes together with a rise in average happiness (cf. section 4.3).

Equality. Gender-equality stands out as a strong correlate of happiness, but income-equality does

not. The positive correlation with gender-equality is largely due to a greater opportunity to choose. The non-correlation with income equality is probably the result of both positive and negative effects that balance out (Berg & Veenhoven, 2010).

Security. Surprisingly, there is no correlation between murder rate and average happiness in nations, probably because of the small number of people affected. Below we will see a much stronger correlation with corruption, which affects a greater share of the population. At first sight, social security is positively correlated to average happiness in nations (Pacek & Radcliff, 2008), but analysis of change over time does not show a decline in happiness in western nations following cuts in welfare expenditure (Veenhoven, 2011).

Institutional quality. People live happier in well-organized societies, where they can count on rule of law and where government organizations function properly. This pattern also appears in a negative correlation with corruption. In the case of government effectiveness, the 'technical' quality of the bureaucracy counts more than its 'democratic' responsiveness. The effect of quality of government on the happiness of citizens is stronger in developed nations than in developing ones, among other things because central coordination is more required for the functioning of complex modern societies (Ott, 2010).

Much of the correlation with institutional quality remains when wealth of the nation is controlled, which is again a rather severe test, since institutional quality is an important determinant of economic success. In this line, it is argued that institutional quality also facilitates success in individual lives, since it provides us with a predictable environment in which we are not too dependent on kin and can safely invest in our future. At this point, there is an important connection between institutional quality and freedom.

Irrespective of these effects on personal goal achievement, a solid institutional environment is rewarding in itself, like playing a soccer match is more pleasurable when the rules of the game are respected. Frey, Benz, and Stutzer (2004) refer to this effect as 'procedural utility'.

Modernity. Most of the above-mentioned societal correlates are part of the 'modernity' syndrome and more direct measures of modernity also show a strong correlation with average life-satisfaction, such as urbanization and globalization. The more modern a country, the happier its citizens are. This finding will be a surprise to prophets of doom, who associate modernity with anomie and alienation. Though modernization may involve problems, its benefits are clearly greater (Veenhoven & Berg, 2013).

The macro-social conditions listed in Table 1 together explain about 75% of the differences in average happiness in nations depicted on the world map on Figure 3. Since measurement error in all variables is likely to have attenuated the coefficients, this is close to perfect correlation. Explained variance is lower in individual level analysis when country characteristics are entered after personal characteristics.

Life-Ability of Inhabitants

Less research has been done on the relation of average happiness in nations with psychological characteristics of the population**.** The following findings are listed in table 2.

Self-direction. Life-satisfaction is typically higher in nations where inhabitants take control over their lives. This appears in positive correlations with measures of modal individualism, internal locus of control, intrinsic motivation and self-confidence. Several of the national character traits mentioned below are also indicative for the ability to take control over one's life.

Mental health. Life-satisfaction is typically lower in nations where a greater share of the population is in poor mental health, as appears in high rates of anxiety, neuroticism and psychoticism.

Personality. Life-satisfaction tends to be higher in nations where the following personality traits are the most common: extraversion, and openness for experience. Life-satisfaction is lower in nations where people are the most competitive. Average life-satisfaction in nations appears to be unrelated to modal agreeableness and conscientiousness.

Trust. A lot of studies show that life-satisfaction is typically higher nations where people trust their fellow citizens and public institutions, and where tolerance is high.

Values. Life-satisfaction appears to be higher in nations where people value enjoyment positively, which contradicts with claims that that the pursuit of happiness is self-defeating (e.g. Schooler, Ariely, & Loewenstein, 2003; Mauss, Anderson, & Tamir, 2012). Life-satisfaction is also higher in nations where honesty is most valued and where secular values prevail. These latter findings fit earlier observations that people tend to be less happy in the most religious countries (Berg & Veenhoven, 2009)

Key Variable: Choice

Most of the above findings support the view that happiness in nations depends to a great extent on freedom of choice. This involves an external *opportunity to choose* and the internal *capability to choose*.

External opportunity to choose requires that there is *something to choose*, and modern affluent societies typically offer more options than traditional and poor societies do, among other things in occupations and marriage arrangements. A further requirement is that *choice is not limited*, by law or informal pressures, e.g. that gay people can live a life that fits their sexual orientation. Though all societies will set some restraints to free choice, the restraints are less in nations that score high on freedom and tolerance.

Internal ability to choose requires *awareness of alternatives*, which will be higher in nations where openness for experience prevails. It also requires an *inclination to choose*, which is reflected in the findings on self-direction and a positive stance to pleasure. A further requirement is the *mental strength* to choose, which will be higher in populaces in good mental health and with a rational outlook.

Together, these conditions allow people to choose a way of life that fits them best and to escape from situations in which they feel unhappy (Abdur Rahman & Veenhoven, 2017; Brule & Veenhoven, 2014). Though choice involves costs, the benefits clearly prevail. That fact fits the view that human nature tends to a preference for independence (Veenhoven, 1999).

Consequences of Life-Satisfaction in Nations

Above, we have discussed the observed correlates of average life-satisfaction in nations as causal factors. Yet reversed causality is also possible, a happy populace can stimulate the economy in various ways and can foster freedom and equality in a country. A happy population may also adopt socialization practices that foster the development self-direction, mental health and trust. Research at the micro-level of individuals has revealed effects of life-satisfaction that could work out this way (e.g. Lyubomirsky, King, & Diener, 2005). At the macro-level of nations, considered in this chapter, we are not yet able to disentangle causes and effects of subjective well-being.

Directions for Future Research

So much, for what we do know now. What do we need to know more about subjective well-being in nations?

Follow-up. As noted above we cannot yet distinguish causes and effects of life-satisfaction. Though this will always remain difficult at the macro-level of nations, we will be able to shed more light on this issue when more trend-data become available for a greater number of countries. The many white cells in the 'longitudinal' columns in tables 1 and 2 illustrate that there is still a long way to go.

Causal paths. Assessing the direction of causality is one thing. The next step is to assess how causality works. Several mechanisms have been suggested in section 4.1, but yet it is difficult to

demonstrate such effects empirically and to assess their relative importance.

Specifications. Most cross-national studies have looked for effects of social conditions on the happiness in the general public. Yet some effects are likely to be contingent on persons and situations, for example, a high degree of freedom in a country may be more beneficial for higher educated citizens than for their low educated compatriots and may add more to happiness in stable countries than in situations of social turmoil. Research on such differences will allow governments to make more informed policy choices. The many white cells on the right in the tables 1 and 2 illustrate that there is still a world to win.

Fit with wider policy goals. The available findings on determinants of average life-satisfaction in nations suggest that the pursuit of greater happiness fits well with several current policy goals, such as economic growth, freedom and good governance. The findings on consequences of happiness also suggest synergy with several common goals, such as furthering civil participation. Yet we are not yet able to see synergy and conflict in much detail. We need a better view on causes and consequences of life-satisfaction in nations to include this aim in standard policy analysis.

Footnotes

Culture and Subjective Well-Being: Conceptual and Measurement Issues

By Shigehiro Oishi, Department of Psychology, University of Virginia

Citation
Oishi, S. (2018). Culture and subjective well-being: Conceptual and measurement issues. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

The present chapter reviews conceptual and measurement issues related to culture and subjective well-being (SWB). Historically, the concepts of happiness gradually shifted from good luck and fortune to the satisfaction of desires and goals. There are still large cultural variations in the concepts of happiness (e.g., fragility). The majority of the popular scales (e.g., the Satisfaction with Life Scale, the Subjective Happiness Scale) have been successfully translated into various languages. However, most scales have not been subjected to sophisticated psychometric analyses (e.g., Item Response Theory). Cross-cultural mean comparisons require some caution due to cultural differences in response style, self-presentational concerns, and memory and judgmental biases. In addition to the use of advanced statistical techniques, the use of qualitative and non-invasive measures is recommended.

Key Words: Culture, Subjective Well-Being, Measurement, Concepts of Happiness

Happiness is used to describe at least two distinct psychological states. The first common use is to describe an individual's momentary affective state (e.g., feeling happy at this very moment, which is typically accompanied by a smile on the face). The second common use is to depict an individual's relatively permanent state of being well (e.g., feeling happy about one's life in general or how one's life is going). Subjective well-being (SWB) researchers are typically interested in the latter happiness, as it reflects one's entire life more closely than the momentary affective state of happiness. Among researchers, the term SWB has been used since Diener (1984) to refer to an individual's relatively longstanding state of being well. Since some researchers think that a relatively permanent state of well-being should include other dimensions of human excellence, other terms such as psychological well-being (PWB) and eudaimonic well-being have been used (Ryan & Deci, 2001; Ryff, 1989). Yet, other researchers have advocated that meaning in life is another aspect of being well (Heintzelman & King, 2014; Steger, Frazier, Oishi, & Kaler, 2006).

Among psychologists, the main debate concerning the concepts of well-being has centered on hedonic versus eudaimonic well-being (Kashdan, Biswas-Diener, & King, 2008; Ryan & Deci, 2001; Ryff, 1989). Among philosophers, the main debate has centered on the meaning of eudaimonia, the term ancient Greeks used to describe a good life or living well. For some, eudaimonia means living a virtuous life, while for others it is living a complete life with a sense that nothing is missing (Nussbaum, 1986/2001). Yet, other philosophers attach non-moral excellence to the notion of eudaimonia. For instance, Haybron (2016) argues that eudaimonia could be best described as nature-fulfillment in terms of capacity-fulfillment and goal-fulfillment. Thus, there is not yet a consensus on the notion of eudaimonia among philosophers (see 41 definitions of eudaimonia in Vittersø, 2016). However, it is clear that most philosophers view eudaimonia to capture living well in terms of virtues, excellence, and fulfillment of human potentials that go beyond a much narrower notion of meaning or purpose in life.

In the current chapter, we will focus on cultural and historical variations in the concepts and measurements of happiness and life satisfaction, as empirical research on SWB has focused on happiness and life satisfaction (Diener, Oishi, & Lucas, 2015; see Oishi & Gilbert, 2016; Uchida & Oishi, 2016 for a general review on culture and SWB). Then, we will discuss substantial measurement-related issues on cross-cultural comparisons of SWB.

Historical and Cultural Variations in Concepts of Happiness

The historian Darrin McMahon (2006) provides a comprehensive review on historical changes in the concept of happiness. The ancient Greek term eudaimon consists of *eu* (good) and *daimon* (god, spirit, demon). Thus, the concept of eudaimonia "contains within it a notion of fortune-for to have a good daimon on your side, a guiding spirit, is to be lucky" (McMahon, 2006, p .3-4). He went on to state that "happiness is what happens to us, and over that we have no control" (p. 19). Similarly, the philosopher Martha Nussbaum (1986/2001) argues that "events beyond our control may affect, for good or ill, not only our

happiness or success or satisfaction but also central ethical elements of our lives; whether we manage to act justly in public life, whether we are able to love and care for another person, whether we get a chance to act courageously" (p. xiv). Whereas ancient Greek philosophers such as Socrates and Plato (but not Aristotle) denied the role of luck in ethical understanding, Nussbaum observes that ancient Greek poets recognized the central role of luck in human happiness. Nussbaum goes on to argue that "by ascribing value to *philia* in a concept of the good life, we make ourselves more vulnerable to loss" (p. 361, philia = love). Overall, the ancient Greek concepts of happiness centered on fortune and good luck, which are external and fragile.

According to McMahon (2006), the concept of happiness became less fragile and more controllable in the 13th century. Specifically, McMahon describes that St. Thomas Aquinas proposed a new view on happiness, namely that happiness was attainable via achieving theological virtues of charity, hope, and faith. The result was a divine gift of being blessed. In the 16th century, with the rise of Lutheranism and Calvinism, the concept of happiness became even more agentic in that not just the achievement of theological virtues but also calling to engage in some economic activities would bring happiness. Over time, the ancient concept of happiness that centers on being "beyond one's control" has gradually transformed to the agentic concept of happiness that is within one's reach.

Although there is a historical change in the concept of happiness described by McMahon (2006), it is also true that the luck and fortune notion of happiness has not completely disappeared. For instance, dictionary definitions of happiness in 30 nations (Oishi, Graham, Kesebir, & Galinha, 2013) revealed that 24 of the 30 nations studied (Australia, Brazil, China, Estonia, France, Germany, Guatemala, Indonesia, Iran, Israel, Italy, Japan, Kenya, Korea, Malaysia, Mozambique, Norway, Pakistan, Portugal, Romania, Russia, Senegal, Singapore, and Turkey) had good luck and fortune as definitions of happiness.

Related to the cultural differences in the dictionary definitions of happiness, the linguist Anna Wierzbicka (2004) observed that the English terms 'happy' and 'happiness' are broad and could describe a minor positive event, whereas the French, Polish, German, and Russian terms are more specific and describe only a rare positive event. Wierzbicka states, "Happy-unlike *heureux, scastlivyj, and glucklich*-is not restricted to exceptional states (like *bliss*), but rather is seen as referring to states within everyone's reach. There is nothing exceptional about being *happy*" (p. 38). It is possible that the good luck and fortune definition of happiness connotes a relatively rare state of bliss, whereas other definitions (e.g., satisfaction of desires) imply that happiness is common.

Interestingly, earlier definitions of happiness in Webster's Unabridged English Dictionary (e.g., 1850, 1853, 1861, 1888, 1895, 1910) had good luck and fortune as the primary definition (Oishi et al., 2013). However, in the 1961 edition, the definition of "good luck and good fortune" was denoted as "archaic." Oishi et al. (2013, Study 2) then analyzed the use of the terms happy and happiness in the State of the Union addresses from 1790 to 2010 and found that the good luck and fortune use disappeared around 1920. In addition, the Google Ngram Viewer search of "happy nation" and "happy person" showed that "happy nation" appeared more frequently than "happy person" in published books in the U.S. from 1800 until around 1920. However, since then, "happy person" has appeared more frequently in American books (Oishi et al., 2013, Study 3). These analyses show that until around 1920, the terms "happy" and "happiness" in American English might have been referring to lucky external conditions.

Several programs of empirical research have also revealed cultural variations in the connotation of happiness. For instance, Lu and Gilmour (2004) found that Americans tend to associate excitement and success with happiness, whereas the Chinese tend to associate peace and calm with happiness. Similarly, Jeanne Tsai and her colleagues found that Taiwanese and Hong Kong Chinese value low-arousal positive affect such as calmness, whereas Americans typically value high-arousal positive affect such as excitement (Tsai, Knutson, & Fung, 2006). Interestingly, Taiwanese children's books depicted a mild smile more often than a wide smile, whereas American children's books depicted a wide smile more often than a mild smile (Tsai, Louie, Chen, & Uchida, 2007). Similarly, Christian texts often use high arousal positive emotions, whereas Buddhist texts often use low arousal positive emotions (Tsai, Miao, & Seppala, 2007). Given that American concepts of happiness center on achieving of one's goals, it makes sense that the resulting emotions are excitement and pride. In contrast, given that Chinese conceptions of happiness center on luck, the resulting emotional state might not be excitement but rather akin to gratitude and satisfaction.

Uchida and Kitayama (2009) also explored Japanese concepts of happiness using free associations. They found that Japanese spontaneously mentioned that happiness could disrupt interpersonal relationships via evoking envy and jealousy in others. In contrast, Americans' descriptions were concerned mostly with personal achievement and positive hedonic experiences (e.g., joy, smiling). Whereas happiness is construed among Americans as a bond between people (e.g., smile is a gateway to a new friendship), happiness in Japan is a potentially dangerous emotion that could disrupt important social relationships.

Interestingly, several studies showed that Chinese expect a bad thing after a series of good things,

whereas Americans tend to expect a good thing after a series of good things (Ji, Nisbett, & Su, 2001). This particular Chinese thinking style, dialecticism, has an important implication for the concepts of happiness. Namely, those who believe in dialecticism should be worried about their current happiness, as happiness is likely to be followed by unhappiness. Indeed, when Joshanloo and colleagues (2014) explored the potential pitfalls of happiness using the fear of happiness scale (sample items include "I believe the more cheerful and happy I am, the more I should expect bad things to occur in my life," "disasters often follow good fortune" and "excessive joy has some bad consequences"), Hong Kong Chinese endorsed the fear of happiness items far more than Brazilians and New Zealanders. Similarly, Koreans tend to hold the belief that there is a fixed amount of happiness one can experience akin to a fixed amount of luck (Koo & Suh, 2007). Thus, if a Korean person feels happy (lucky) today, she is likely to say she might not be happy (lucky) tomorrow because she is using up all her happiness (luck) today. Just like ancient Greek poets (Nussbaum, 1986/2001), many East Asians today hold the fragile view of happiness (see also Miyamoto & Ma, 2011).

Related to the fragility of happiness, the Hindu notion of happiness is dramatically different from the American notion of happiness today. Srivastava and Misra (2003) argue that Hindu Indians view happiness and sorrow as the results of past lives and not just the present ones. To the extent that one has no control over past lives, Hindu concepts of happiness appear to be consistent with the ancient Greek view. Furthermore, Srivastava and Misra observe that Hindu Indians tend to feel happiness when they sacrifice their material possessions and/or respond to others' needs. Like Buddhist traditions, Hindus see attachment to objects as a cause of suffering. Thus, Hindu happiness is concerned with the attainment of *ananda*, or "a transcendental journey from a lesser self fraught with hedonistic concerns to a greater self that involves realization of connectedness or oneness" (Nagar, in press).

Islamic conceptions of happiness are also quite different from the American notion of happiness. Joshanloo (2013) argues that Islamic conceptions of happiness are fundamentally anti-hedonic. He cites Shiite writer Musawi Lari: "One who seeks happiness through the pursuit of pleasures will find nothing except anxiety and bafflement…The more that we succeed in subduing our lusts and desires, the closer shall we move to happiness" (p. 1862). In addition to stoicism, the Islamic view of happiness is squarely centered on the fear of, total submission to, and worship of God. It also includes the concept of perishable body and an everlasting soul.

Finally, in some cultures, the concepts of happiness are more physical in nature. For instance, the Fante speakers of Ghana describe happiness/excitement literally as "eye-get" ("anigye") and joy/contentment as "eye-agree/reach" ("anika"), in contrast with shame as "eye-die" ("aniwu") and guilty as "eye-put" ("anyito" in Dzokoto & Okazaki, 2006). These descriptions suggest that among the Fante speakers of Ghana, happiness and associated positive emotions are eye-catching and easy on the eyes, whereas shame and guilt are hard on the eyes. Interestingly, Dzokoto and Okazaki (2006) found that the Dagbani speakers of Ghana describe happiness as "white heart," peace as "heart at rest," anger as "agitated heart," and sadness as "destruction of the heart." These descriptions suggest that for the Dagbani speakers of Ghana, positive emotions are physically low arousal states, whereas negative emotions are physically aroused, agitated states. These physical descriptions of happiness suggest that for the Fante and the Dagbani speakers of Ghana, the concepts of happiness are tied to objective bodily reactions to external events and less concerned with the satisfaction or fulfilment of one's desires and goals, which tend to be more subjective, internal, and mentally constructed.

In sum, good luck and fortune has been a dominant definition of happiness around the world since antiquity (McMahon, 2006; Oishi et al., 2013). However, the meaning of happiness has expanded and changed over time in different parts of the world (due in part to different religious beliefs and economic, social, political, and physical conditions). The diversity in the concepts of happiness across cultures and time poses a major challenge to empirical research on happiness (see below how scientists have approached this issue). However, it is also important to note that the inquiry into diverse concepts of happiness using diverse methods has enriched our understanding of what it means to be in a relatively permanent state of being well.

Measurement of Happiness Across Cultures

One of the first happiness scales was developed by George Hartmann (1934). He asked respondents to rate on the following single item: "If you compare yourself with others of the same sex and age, how would you rate your own general happiness? Use this definition as a guide: 'A relatively permanent state of well-being characterized by dominantly agreeable emotions ranging in values from mere contentment to positive felicity.' Give due weight to both inner and outer factors or manifestations: most unhappy of all, a great majority of persons are happier than you are, a slight majority of other people are happier than you are, about average, somewhat happier than the general run of mankind, far happier than the great majority

of human beings, the happiest of all" (p. 206). One-month test-retest reliability was .70, and the correlation with informant reports was .34. In 1946, a 3-point happiness item ("Take altogether, how would you say things are these days-would you say you are very happy, pretty happy, or not too happy") was included in a national survey (Easterlin, 1974). In 1965, Hadley Cantril used a single-item ladder scale (0 = the worst possible life; 10 = the best possible life). Unlike Hartmann, Cantril's scale was used to measure the subjective evaluation of life accomplishments (more similar to life satisfaction than the feeling of happiness). These single-item measures of happiness and life satisfaction have been used widely in large international surveys such as the World Values Survey and the Gallup World Polls.

Multiple-item scales. Bradburn (1969) was the harbinger of positive psychology that emerged in the late 1990s. He was already concerned that researchers in the 1950s and the 1960s were preoccupied with mental illness and not paying enough attention to mental health. He used the conceptual model of well-being similar to "older pleasure-pain or utility models that view an individual's happiness or well-being in terms of the degree to which pleasure predominates over pain in his life experiences" (p. 9). To measure the degree to which pleasure predominates pain in life, Bradburn developed a 10-item scale called the affect balance scale (ABS). The five positive items were as follows: (1) "Pleased about having accomplished something?" (2) "That things were going your way?" (3) "Proud because someone complimented you on something you had done?" (4) "Particularly excited or interested in something?" (5) "On top of the world?" (answered in the Yes/No format). Bradburn overturned the prevailing assumption about positive and negative affect being the opposite ends of one dimension and showed that positive affect and negative affect are relatively independent; that is, there are people who are high in both positive and negative affect, as well as those who are low in positive and negative affect. It is also noteworthy that decades later the Gallup World Polls adopted the affect items similar to Bradburn's ABS, using the yes-no format.

Devins et al. (1997) explored cross-cultural equivalence of the affect balance scale with Chinese, Vietnamese, and Laotian refugees to Canada (those who arrived in 1979-1981). The researchers could not translate the item "Have you been feeling on top of the world?" into South Asian languages. Thus, they used only 9 items that were translatable. Confirmatory factor analyses showed that the remaining 9 items formed two factors (positive and negative affect), just like in an English-speaking Canadian sample. It should be noted, however, that these items capture mostly high arousal positive emotions that are deemed more ideal for North Americans than East Asians. Furthermore, MacIntosh (1998) analyzed the World Values Survey data from 38 nations, and found that the full 10-item, 2-factor solution did not fit data in most nations. (Curiously, the 2-factor model fit best in Nigeria, where CFI was .90 and RMSEA was .056, and South Africa, where CFI was .94, and RMSEA was .061; in other nations, fit was worse.)

Watson (1988) criticized the affect balance scale for having relatively low internal reliability (alpha = .54 for positive, .52 for negative affect) and poor convergent validity with other affect measures. Instead, Watson, Clark, and Tellegen (1988) developed the 20-item Positive and Negative Affect Schedule (PANAS). Like the ABS, the PANAS items focused on high arousal positive affect such as excited, enthusiastic, and inspired. When Japanese psychologists, Tokihiro Ogawa and colleagues (Ogawa, Monchi, Kikuya, & Suzuki, 2000), developed an emotion scale, they included items such as ゆっくりした (slow/relaxed), のどかな (rustic/peaceful), 静かな (quiet/tranquil), and the low arousal positive affect formed a distinct factor from general positive and negative affect. The general emotion scale created by these Japanese psychologists did not include pride. Similarly, Hamid and Cheng (1996) asked Hong Kong Chinese to nominate 10 emotion words and created the Chinese Affect Scale. This scale included low arousal states such as comfortable, relaxed, and peaceful, as well as agreeable (more interpersonal affective state). The Chinese Affect Scale also does not include pride. Therefore, it is not surprising that pride is not a part of the positive affect factor among Asian samples (Scollon, Diener, Oishi, & Biswas-Diener, 2005), nor does it correlate highly with general positive emotion (Kitayama, Markus, & Kurokawa, 2000). It is also noteworthy that when Thompson (2007) created the international PANAS by testing out the original PANAS items with culturally diverse samples, the resulting positive affect items were *determined*, *attentive*, *alert*, *inspired*, and *active* (i.e., *enthusiastic*, *strong*, *interested*, *excited*, and *proud* dropped out).

Whereas the ABS, the PANAS, and other emotion scales were focused on happiness and other positive emotional experiences as an indicator of emotional well-being, other researchers assessed an evaluative dimension of a relatively permanent state of well-being, that is how an individual sees her/his life to be. Lyubomirsky and Lepper (1999) developed the 4-item subjective happiness scale (SHS), which is very similar to Hartmann's (1934) scale. The SHS items are the following: (1) "In general, I consider myself…1 = not a very happy person to 7 = a very happy person" (2) "Compared to most of my peers, I consider myself…1 = less happy and 7 = more happy" (3) "Some people are generally very happy. They enjoy life regardless of what is going on, getting the most of out of everything. To what extent does this characterization describe you?" and (4) "Some people are generally not very happy. Although they are not

depressed, they never seem as happy as they might be. To what extend does this characterization describe you?" (reversed item). As the SHS focuses on a trait-like happy person, test-retest reliability was quite high (one-month test-retest reliability, r = .85 to .90; one-year test retest reliability, r = .55). The SHS has been successfully translated into Japanese (Shimai, Otake, Utsuki, Ikemi, & Lyubomirsky, 2004), Malay (Swami, 2008), German and Tagalog (Swami et al., 2009).

Among many scales to measure a relatively permanent state of being well, the Satisfaction with Life Scale (SWLS: Diener, Emmons, Larsen, & Griffin, 1985) is the most popular in psychology. The 5-item scale of life satisfaction captures several aspects of being well: favorable objective external conditions (Item 2: "The conditions of my life are excellent"), a small gap between reality and ideal (Item 1: "In most ways my life is close to my ideal"), goal-fulfillment (Item 4: "So far I have gotten the important things I want in life"), and positive evaluation of life (Item 3: "I am satisfied with my life," Item 5: "If I could live my life over, I would change almost nothing").

Oishi (2006) evaluated the cross-cultural equivalence of the SWLS between Chinese and American university student samples. First, when the one-factor model with free factor loadings was examined using the multi-group structural equation model (SEM), the fit was acceptable (GFI = .981; RMSEA = .06). The standardized factor loadings were all above .67 among the U.S sample, whereas they were high for the first three items (.62, .66, .72) among the Chinese sample. The goal fulfillment item was .49, and the last item, "If I could live my life over, I would change almost nothing," was the weakest with .38 (see similar results for Orang Asli, aboriginal people in Malaysia in Howell, Howell, & Schwabe, 2006). When factor loadings were constrained to be the same between the two samples, Item 5: "If I could live my life over, I would change almost nothing," was the only item that showed an item bias (constraining this item to be equivalence decreased the fit significantly worse). When Oishi (2006) used the differential item function (DIF) analysis of the Item Response Theory (IRT), which models not only factor loadings but also item difficulty, 4 of the 5 items showed a significant item bias. In particular, Item 4: "So far I have gotten the important things I want in life" and Item 5: "If I could live my life over, I would change almost nothing" showed large DIFs. It is interesting to note that the most equivalent item was explicitly concerned with favorable external conditions: "The conditions of my life are excellent." In contrast, two items regarding the past accomplishments showed a large discrepancy. Namely, among Chinese students, those who endorsed favorable external conditions were not necessarily those who endorsed goal fulfillment items. Among American students, those who endorsed favorable external conditions were those who endorsed past accomplishment items. Overall, the results of the IRT analyses were consistent with the conceptual analyses discussed above (Lu & Gilmour, 2004; Tsai et al., 2006). Furthermore, given that the good luck and fortune definitions are prominent in many cultures (Oishi et al., 2013), the first three items of the SWLS might be the most appropriate, least biased life satisfaction items across many cultures (see Tay, Huang, & Vermunt, 2016; Tay, Meade, & Cao, 2015 for the application of IRT in cross-cultural research).

It is also noteworthy that some researchers modified the SWLS to fit a local culture and education levels of respondents. For instance, Biswas-Diener and Diener (2001) used the 7 faces (1 = frown to 7 = extreme smile) instead of 1 = strongly disagree to 7 = strongly agree when they administered the SWLS to slum dwellers and sex workers in Calcutta, India.

Alternative measures. Global, retrospective measures of SWB have been criticized on various grounds (e.g., Kahneman, 1999; Schwarz & Strack, 1999). One issue is concerned with memory bias, in that global measures might not capture everyday affective experiences. To address this issue, experience sampling method (ESM), in which respondents were prompted to report their momentary mood at random moments, has been used in cross-cultural research on SWB (e.g., Oishi, 2002; Oishi, Diener, Scollon, & Biswas-Diener, 2004; Scollon et al., 2005). Some researchers used the time-contingent recording (e.g., noon, 3pm, 6pm, and 9pm in Mesquita & Karasawa, 2002). In addition, daily diary method has been utilized to gather daily life satisfaction and positive emotional experiences (Kitayama, Mesquita, & Karasawa, 2006; Oishi et al., 2007). Due to these methods often being taxing to participants, some researchers relied on Day Reconstruction Method (DRM: Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004), in which respondents were asked to recall various episodes in the morning, in the afternoon, and in the evening of the previous day (Oishi, Kurtz, Miao, Park, & Whitchurch, 2011; see Diener & Tay, 2014 for a review on DRM).

In addition to "online" measures, others have used informant reports to address some of the judgmental bias issues. Saeki et al. (2014), for instance, used informant reports and found that Japanese informants (the target's friends) tended to view the target's life satisfaction to be higher than the target him/herself, d = .51. Although in terms of domain satisfaction, the differences were much smaller (e.g., satisfaction with weather, d = .10; satisfaction with love life, d = .02).

With the rise of implicit measures (e.g., Implicit Association Test: IAT), several researchers have

attempted to develop an implicit, reaction-based measure of SWB. For example, Constantini et al. (in press) developed the IAT-based positive orientation scale and found a small but positive correlation with the SWLS, $r = .24$, $p < .001$ (however, it is equally strongly correlated with global self-esteem, $r = .23$, $p < .001$, as well). Yamaguchi et al. (2007) found that Japanese reported lower levels of global self-esteem explicitly than Americans, but their IAT-based self-esteem was as high as Americans. Thus, IAT-based measures of SWB could be promising in future cross-cultural research (see however Falk & Heine, 2015; Schimmack & Diener, 2003 for some cautionary notes).

More recently, researchers have started to use social media data such as Facebook and Twitter to gather information regarding users' state of the mind and feelings. Golder and Macy (2011) conducted the linguistic analysis of 509 million tweets from about 2.4 million individuals across the world, though limited to English speakers. They found that Indians were happier relative to North Americans in the morning, whereas Africans were relatively happier than Indians in early evening hours. Within the U.S., Eichstaedt and colleagues (2015) found that anger-related words used in Twitter predicted county-level heart disease mortality. This means that in the counties where heart disease mortality is high, residents were more likely to use anger in their Tweets than those living in counties where heart disease mortality is low. Similarly, Facebook Data Team (2011) applied automated sentiment analysis to the status updates and created an index of positivity and negativity. Techniques like this are extremely promising, as they capture a large number of individuals' everyday moods naturally (that is, without making them think about the purpose of research). However, when Wang, Kosinski, Stillwell, and Rust (2014) compared daily, weekly, and monthly Facebook's Gross National Happiness Index with daily, weekly, and monthly aggregate scores of self-reported life satisfaction (SWLS) among myPersonality Facebook application users, the Facebook positivity score was negatively associated with the SWLS in all three time frames. It should be noted that the linguistic analysis of Twitter updates also showed some discrepancies from self-reported SWB. For instance, conservatives typically report higher levels of happiness than liberals. However, Tweets were more positive and happier among the followers of the Democratic party than those of the Republican party (Wojcik, Hovasapian, Graham, Motyl, & Ditto, 2015). In short, social media present unprecedented large, ecological data. Although it is clearly promising in the context of cross-cultural research on SWB, it is also important to further validate specific indices in the future (see Kern et al., 2016 a review on how to use social media in psychological research).

Another way to measure SWB is to code the sign of positive and negative affective state from non-verbal behaviors. For example, Harker and Keltner (2001) coded yearbook photos for genuine smile and found that yearbook smiles predicted self-reported well-being over 30 years later (see Seder & Oishi, 2012 for smile intensity in the Facebook profile photos). Oettingen and Seligman (1990) observed bar patrons' non-verbal behaviors unobtrusively and found that East Berlin workers (then living in the communist country) smiled and laughed less and showed more slumped posture than did West Berlin workers.

As many surveillance cameras are placed in public space (e.g., 33 permanent cameras in Washington DC), it might be possible to use scenes captured on these surveillance cameras for SWB across cultures (Tay, Jebb, & Woo, 2017). For instance, MIT Media Lab researchers Javier Hernandez, Mohammed Hoque, and Rosalind Picard (2012) set up a camera on 4 different locations on a university campus and assessed the degree to which people who passed by were smiling for 10 weeks. The researchers report that over the study period, thousands of people passed by the camera and showed the pattern expected from academic schedules such as exam periods, holidays, and graduation day. The "mood meter" like this could provide a naturalistic behavioral index of happiness that could be scaled up for cross-cultural comparison (e.g., Hernandez et al. (2012) calculated the average intensity of smile among people present in an image, thus the mood meter ranges from 0% to 100%).

Finally, numerous researchers have attempted to identify biological markers of SWB. Richard Davidson and his colleagues used electroencephalography (EEG) asymmetry during the resting period as an indicator of SWB (Urry et al., 2004). Using EEG, Lun, Oishi, Coan, Akimoto, and Miao (2010) found that East Asians showed greater left prefrontal cortex activation (than European Americans) when they felt understood by others.

Some researchers have examined cortisol outputs and found, for instance, that anger and tension are associated with higher levels of cortisol in the evening (Adam, Hawkley, Kudielka, & Cacioppo, 2006). Yet other researchers have explored heightened expression of genes associated with NF-κB and under-expression of genes associated with anti-inflammatory glucocorticoid response elements as indicators of ill-being (e.g., Cole et al., 2007). More recently, Fredrickson and colleagues (2013) used 53 genes to indicate the "conserved transcriptional response to adversity" (CTRA) and showed their associations with hedonic and eudaimonic well-being (see Nickerson, 2017 for a critique). Kitayama, Akutsu, Uchida, and Cole (2016) measured the same 53 genes' expression status and found the similar patterns of correlations with self-reported hedonic and eudaimonic well-being. The central claim of Fredrickson et al. that

eudaimonic well-being is more strongly associated with CTRA than hedonic well-being has been questioned due to the high correlation between two types of well-being (r = .79 in Fredrickson et al., 2013; r = .70 in Kitayama et al.). However, the gene expression of the CTRA appears to be reliably associated with self-reported well-being. Thus, CTRA and related RNA measures appear to be a promising biological index of well-being that might be of use to cross-cultural comparison in the future.

Indigenous scales. Although the majority of cross-cultural research on SWB has taken the etic approach (translate an original scale), several researchers have used the emic approach. For instance, Hitokoto and Uchida (2015) developed the interpersonal happiness scale to capture the Japanese view on happiness, which is characterized by interpersonal harmony, relational worth, stability, and being above the minimum acceptable standard. Sample items include the following: "I believe that I and those around me are happy," "I feel that I am being positively evaluated by others around me," "Although it is quite average, I live a stable life," and "I believe I have achieved the same standard of living as those around me."

Similarly, Lee et al. (2013) developed the peace of mind scale to capture the Chinese way of being well. Sample items include these statements: "My mind is free and at ease," "I feel content and comfortable with myself in daily life," "My life style gives me feelings of peace and stability" and "I have peace and harmony in my mind." As expected, it is moderately correlated with the SWLS, r (135) = .54, $p < .001$. Furthermore, Lee et al. found that Taiwanese college students scored higher on the peace of mind scale than European American college students, $t = 3.61$, $p < .001$, $d = .55$.

Singh, Raina, and Sahni (2017) created the Sukha-Dukha scale to capture uniquely Indian concepts of happiness. Sukha refers to favorable experiences, and Dukha refers to unfavorable experiences. The ultimate level of happiness is thought to be achieved when "dualities of sukha and dukha cease to exist" (p. 118). The 23-item sukha scale resulted in 4 factors: happiness due to contentment ("khush" "saubhagya"), happiness due to physical and mental well-being ("svastha" "sakaratmak"), happiness due to social well-being ("Santosh" "hita"), and happiness due to spiritual well-being ("utsah," "rasa").

Finally, Wang, Wong, and Yeh (2016) created the dialectical coping scale to capture a uniquely Chinese way of coping: Sample items include these sentiments: "When I experience difficulties, I remind myself that misfortune coexists with blessings," "I believe that the problems in my life don't last forever," and "In understanding the obstacles in my life, I can see the interconnections between negative and positive events." Overall, indigenous scales might be able to capture aspects of SWB that cannot be adequately assessed by existing mostly Western measures.

Qualitative approach. Because the concepts of happiness are diverse, some researchers have used a qualitative approach (see also Biswas-Diener, this volume; Thin, this volume for the utility of the qualitative approach). Kral et al. (2011), for instance, interviewed the Inuit people and asked them about meanings of happiness, as well as health, sadness, healing, and social change. The Inuit's happiness was deeply intertwined with family. When asked about happiness, one respondent (male, age 47) said, "Summer life. Family. Having a good family relationship with my wife and with my daughters" (p. 430). Although family is often mentioned in the context of happiness across the globe, the second most frequently mentioned category among the Inuit was being on the land. This indicates the Inuits' deep attachment to their land, which is very different from the residents of many developed countries.

When Galinha et al. (2016) interviewed extremely poor people in Maputo, Mozambique, by far the most frequently mentioned happy events were concerned with family and weddings: "When I got married it was a happy time with a great party with his family and mine. As my grandfather had oxen, he offered an ox to me" (p.79). Whereas many focus exclusively on happiness or related concepts, others explore respondents' life stories overall. For instance, Cox, Casablanca, and McAdams (2013) used the life story interview, asking interviewees to talk about their life overall, key events, challenges, beliefs, and future prospects. The life story interview shows some common themes of unhappiness among sex workers in Managua, Nicaragua: early family problems, early departure from home, difficult romantic relationships, and financial difficulties. The interview contents could be coded in terms of positivity and negativity.

Substantive Measurement Issues

With the introduction of internet, cross-cultural research has become much easier than decades ago. Yet, there still remain many challenges to cross-cultural research on SWB. In this chapter, we will focus on the three main issues: response style, self-presentation concerns, and judgmental biases.

Response style. There appear to be cultural variations in the tendency to use a certain number in responding to the survey questions. Some cultures are more acquiescent than others. For instance, when asked "how introverted are you?" and "how extraverted are you?", Koreans were more likely to agree with both introversion and extraversion items than Americans were (Choi & Choi, 2002). The researchers speculated that East Asians can think of the situations in which they felt introverted as well as extraverted

and thus tend to endorse both items. This tendency could easily have an impact on emotional items. Namely, if East Asians are more likely than Americans to endorse both positive and negative emotion items, then the positive-negative emotion correlation should be positive among East Asians, whereas it should be negative among Americans. Indeed, Schimmack, Oishi, and Diener (2002) found that the frequency of positive-negative emotional experiences correlation was positive among Hong Kong (r = .09) and Japanese participants (r = -.07), whereas it was negative among Americans (r = -.36) and Australians (r = -.37). It is important to dissect the degree to which acquiescence affects SWB responses. For instance, researchers can use two conceptually identical items worded oppositely: "It should be forbidden completely to smoke in malls" and "It should 'not' be forbidden to smoke in malls" (Baron-Epel, Kaplan, Weinstein, & Green, 2010).

Related to acquiescence, Chen, Lee, and Stevenson (1995) found that Americans use the extreme response more and the middle response less than Taiwanese and Japanese. Similarly, several large-scale cross-cultural surveys found systematic cultural variations in response styles (e.g., Smith et al., 2016). These findings present a major concern for the observed mean differences in SWB across cultures. For instance, when Americans report higher levels of life satisfaction than Japanese, would the difference be driven by extreme responding (or extreme response avoiding)? As an initial test of the role of extreme responding, Oishi (2010) re-coded the original 7-point scale of the SWLS to the 3-point scale (1 to 3 = 1; 4 = 2, 5 to 7 = 3). In this recoding, 5, 6, 7 responses were coded as the same. In the original 7-point scale, the U.S-Japan difference was substantial, d = .81. When the 3-point scale was used, the difference was almost identical, d = .79. To make sure this is not just specific to the U.S-Japan comparison, Oishi also tested the Chile-Japan difference. The magnitude of the mean difference remained virtually unchanged: d = 1.24 in the original 7-point scale, d = 1.25 in the 3-point scale.

In addition, when the IRT scoring method was utilized, the U.S-China difference in the SWLS remained substantial, d = .71 (only 1 of the 5 items was equivalent, thus the IRT scoring weighed this one item more heavily than other "biased" items), whereas the U.S.-China difference in the original scale (sum score) was d = 1.18 (Oishi, 2006). These findings suggest that although extreme responding might affect the mean score, the magnitude of the mean difference seems to be relatively unaffected (it should be noted, however, that when a large number of respondents respond randomly or use extreme categories, the conversion could result in a dramatically different result, see Vittersø, Biswas-Diener, & Diener, 2005 for an example; see also Batz, Parrigon, & Tay, 2016 for the number conversion issue in cross-cultural comparisons).

Related to the number use, self-presentation concerns could blur true mean differences. For instance, Americans typically say "Good" or "Great!" to answer "How are you?" In contrast, many East Asians typically say "OK" or "So-so." It is not uncommon for Japanese to say "not so good" or "dying." In the U.S., there is a pressure to be positive, whereas elsewhere there is a pressure not to be too positive. Then, the self-presentational concern (e.g., to appear modest) could be a serious issue. Kim, Schimmack, and Oishi (2012) utilized informant reports and found that European Canadians were more positive overall (positive toward themselves and positive toward others) than were East Asians. Once this general positivity bias was statistically removed, the mean difference in self-reported SWB disappeared.

Although happiness is highly valued across cultures, there are cultural variations in the desirability of happiness (Diener, 2000). Americans, Australians, and Argentine value happiness far more than Chinese and Indian. It is noteworthy that when Americans are led to think that happiness is a particularly desirable quality, they tend to exaggerate their current levels of happiness (Wojcik & Ditto, 2014). Kim and Lee (2011) also found that American college students who are concerned about self-presentation (those who post only happy photos on Facebook) also reported being a happier person (the SHS). These findings present a possibility that observed mean differences in self-reports of SWB could be due to self-presentational differences rather than "real" differences.

To address the self-presentation issue, Oishi (2010) examined the U.S.-Japan differences in the SWLS using informant reports as well as self-reports: In self-reports measured in two time points, American students reported higher levels of life satisfaction than Japanese students (M_{us} = 23.08 vs. M_{japan} = 21.27, t [174] = 2.13, p = .035, d = .32 at Time 1, M_{us} = 23.78 vs. M_{japan} = 20.77, t [174] = 3.74, p < .001, d = .57 at Time 2. American students' life satisfaction rated by their informants was also higher than Japanese students' life satisfaction rated by their informants, M_{us} = 23.15 vs. M_{japan} = 21.77, t [174] = 2.06, p = .041, d = .31. Japanese informant reports were also similar to self-reports in terms of the means cores. Thus, these results suggest that self-presentation concerns might not play a huge role in cross-cultural comparisons of the SWLS scores. However, Saeki et al. (2014) found that Japanese informant reports were substantially higher than self-reports of the SWLS. It is unclear, however, whether the target's

friend exaggerated the target's life satisfaction, or the target downplayed their life satisfaction. In order to ascertain the rater effect and the target effect, it is critical to have a Round Robin type measure (group member providing self-reports as well as ratings of all other members; see Kwan, John, Kenny, Bond, & Robins, 2004; Su & Oishi, 2011 for the use of Round Robin measure on culture and self-enhancement).

Memory and judgmental bias. A potential memory bias emerges when two individuals or two groups of individuals do not differ in terms of daily experiences of happiness, yet they report different levels of overall happiness. Oishi (2002, Study 1) found that the mean of daily satisfaction over 7 days did not differ between European Americans and Asian Americans, yet European Americans evaluated the whole week to be more satisfying than did Asian Americans. A regression analysis suggested that Asian Americans took into account the best day and the worst day during the 7-day period when evaluating the whole week, whereas European Americans took into account only the best day. Oishi (2002) replicated this finding with an experience sampling method (Study 2) and the evaluation of life events. Furthermore, Oishi and Diener (2003) used a performance task such as an anagram and a free throw task and measured online emotional experiences, recalled emotional experiences, and replicated Oishi (2002).

However, the third study of this kind, Scollon, Diener, Oishi, and Biswas-Diener (2004), in which online emotional experiences were assessed using an experience sampling method, did not replicate the findings from Oishi (2002). Instead, Scollon et al found that Japanese reported lower levels of happiness than Americans both online and retrospectively. Since Japanese reported less happiness online already, Scollon et al. did not find cultural differences in memory bias. It should be noted, however, that Oishi et al.'s (2007) 21-day daily diary study in the U.S., Japan, and Korea showed again that European Americans reported higher levels of life satisfaction (the SWLS) than Japanese and Koreans. However, the average daily satisfaction of European Americans was not different from Japanese. Oishi et al.'s (2011) DRM study in the U.S. and Korea further replicated these findings (i.e., no cultural difference in the average positive emotion felt across various episodes on the previous day, but difference in the SWLS). Kitayama et al.'s (2006) 14-daily diary study on engaging and disengaging emotions also showed that Japanese and Americans did not differ in the daily experience of socially engaging positive emotions (e.g., shitashimi [friendly feelings], although Americans reported more socially disengaging emotions such as pride than Japanese). Likewise, Oishi (2010) reports that the intensity with which Japanese and American respondents reported positive moods at the time of completing a questionnaire was virtually identical (M_{us} = 6.12 vs. M_{japan} = 5.97, t [530] = .87, p = .38, d = .08), yet Americans reported being happier about their lives in general than Japanese (M_{us} = 6.10 vs. M_{japan} = 5.69, t [530] = 2.35, d = .20).

Overall, although some studies (e.g., Scollon et al., 2004) found cultural differences in online positive emotional experiences, the degree of cultural differences in online positive emotional experiences tends to be smaller than in global reports. Online reports are based on specific situations and events that just happened. Thus, a general belief about the typical level of happiness (e.g., "I am a happy person") or cultural norm ("I should be happy") play a relatively small role. In contrast, global reports are based on events that are remembered (Tov, 2012), as well as a general belief about the typical level of happiness (Robinson & Clore, 2002) and cultural norms. Therefore, global reports appear to magnify cultural differences in everyday emotional experiences, especially when cross-cultural comparisons involve two groups that differ in desirability of happiness (see Oishi, 2010 for more details).

A related issue is concerned with a positivity bias, or the degree to which global domains are more positively evaluated than their corresponding, specific domains. For instance, overall satisfaction with education should be comparable to the average satisfaction with professors, lectures, and textbooks. Diener, Scollon, Oishi, Dzokoto, and Suh (2000) found that the positivity bias score (global domain ratings – average specific domain ratings) was higher among the countries with higher mean levels of life satisfaction measured by the SWLS, r = .57, p < .001. These findings suggest that countries where people report higher levels of life satisfaction might be evaluating the overall life more positively. However, at this point it is unclear whether it is fair to say this is a "bias" or a characteristic of a happy person/culture.

One way to address the issue of positivity bias is to use vignettes and see how people from different cultures evaluate others' lives. Angelini, Cavapozzi, Corazzini, and Paccagnella (2014) used such a method and found that there are indeed large cultural differences. For instance, John was described to be 63-years old, a widow, relatively poor, and with heart problems. However, his children and grandchildren visit him regularly. Over 20% of Germans and Dane thought John was satisfied or very satisfied with his life. In contrast, less than 10% of Italian respondents thought John was satisfied or very satisfied. Once researchers controlled for the vignettes' ratings, cross-national differences in self-reported life satisfaction between Italy and Denmark disappeared. Like Diener et al. (2000), however, it is inconclusive whether vignette ratings are capturing judgmental biases or naturally positive inclinations. In addition, cultural differences in

ratings of John's life satisfaction might be shedding light on one's values rather than positivity bias *per se*. For example, this example might tell us that Germans and Dane consider children and grandchildren's visits more important than financial conditions. It is also possible to interpret the results as indicating that in Denmark and Germany, one can live happily without much money thanks to better social welfare programs and public goods, whereas in Italy one must have money to live a good life. It is important to discern values from judgmental biases in the future by perhaps creating diverse vignettes (Angelini et al. used only two vignettes).

Conclusion

The concepts of happiness are diverse across times and cultures (McMahon, 2006; Oishi et al., 2013). They contain the notions of good luck and fortune, bliss, the satisfaction of desires, and a physical sensation of "eye-get" ("anigye" in Fante, Ghana). At this point, however, the notions of happiness in Africa, Middle East, and South Africa are still relatively unknown. It is critical to explore various concepts of happiness in even more diverse cultural samples in the future.

Over the last twenty years, researchers have developed many ways to assess different concepts of happiness using divergent terms ("on top of the world", "calm," etc.), assessing multiple concepts (e.g., the SWLS items) or multiple life domains, using indigenous scales (e.g., the Sukha-Dukha scale), using informant reports, assessing momentary moods, and analyzing non-invasive, social media (e.g., Twitter) or camera data (e.g., "mood meter").

Cross-cultural comparisons are challenging in many ways, ranging from conceptual and measurement equivalence to potential differences in number use, self-presentational concerns, and memory and judgmental biases. Researchers have access to ever more diverse and large cross-cultural datasets. The conceptual refinement goes hand-in-hand with the refinement of measures. Researchers should be fully aware of sophisticated statistical methods to test measurement equivalence (e.g., Eid & Diener, 2001; Kim et al., 2012; Tay et al., 2016; Tay, Woo, Klafehn, & Chiu, 2010) in cross-cultural research on SWB. At the same time, it should be recognized that qualitative approaches (e.g., life story interview, Cox et al., 2013; free associations, Dzokoto & Okazaki, 2006) shed a new light on the concepts of happiness. The advancement of culture and SWB research hinges largely on conceptual clarification and solid measurement. To this end, SWB researchers must be aware of diverse methods and measurement issues summarized above and strive to go beyond the extant "good enough" measures of SWB.

The Subjective Well-Being of Small Societies

By Robert Biswas-Diener, Portland State University and Noba

Abstract

So-called "small societies" such as Amish communities and traditional tribal groups offer a unique opportunity to chart the conceptual territory of subjective well-being (SWB). First, these groups offer an alternative to standard cross-national comparisons that are so common in happiness research. Because of their smaller size and relative isolation, each small society represents a relatively homogenous experience of happiness that can shed light on the ways that social ties, community norms and practices might influence SWB. This chapter explores both culture and methods as they relate to SWB. Three diverse "case studies" are discussed including the Amish, Tonga Islanders, and the Maasai. Finally, recommendations are given for improving SWB research.

Keywords: subjective well-being, happiness, small societies, traditional cultures, culture, Amish, Tonga, Maasai, Research Methods

In recent years the study of subjective well-being has grown exponentially. Academic articles and chapters on the topic have increased dramatically over the last two decades. This academic interest in happiness has coincided, to some degree, with the advent of the modern positive psychology movement (Seligman & Csikszentmihalyi, 2000). Subjective well-being has also experienced an uptick in academic attention as it is increasingly legitimized as a field of study in a broad range of disciplines including law (Posner & Sunstein, 2010), economics (Stevenson & Wolfers, 2008), philosophy (Haybron, 2008) and anthropology (Thin, 2009). These trends are reflected in an increasing number of academic journals devoted to well-being related topics including *Journal of Happiness Studies*, *International Journal of Wellbeing*, *Journal of Positive Psychology*, and *Psychology of Well-being*.

One interesting subset of studies in this area has focused on the ways that cultural factors influence subjective well-being. Frequently, national identity is used as a proxy for culture (e.g. Diener, Diener & Diener, 1995). The emphasis in these types of studies is almost exclusively cross-cultural (examining cultural similarities and differences) as opposed to cultural (seeking to understand concepts as they exist within one culture; Jahoda & Krewer, 1997). Cross-cultural research has the advantage of allowing comparisons between diverse groups. This has been helpful in business-related research (Hofstede & Hofstede, 2005) as well as in understanding societal differences in social, material and environmental well-being (Biswas-Diener, Diener, & Lyubchik, 2015). Unfortunately, an emphasis on contrasting cultures necessitates the use of standard measurement, which usually translates to quantitative methods and the use of surveys created in, by and for members of industrialized societies. Similarly, an emphasis on contrasting also encourages the use of convenience sampling; especially through employing college student samples.

There has been a conspicuous absence of research attention to small societies and traditional cultures. Traditional culture is a term used to describe the beliefs, norms, roles, and practices of people whose traditions are anchored in a shared cultural heritage (Biswas-Diener & Thin, 2017). Specifically, traditional culture is associated with historical practices that exist in the larger modern context. This concept is often understood to be culture that is pre-industrial and pre-colonial. The cultures of indigenous people in nations such as Canada and Australia are examples of traditional culture even though many of these people have assimilated with more mainstream society or use modern technologies. Members of some small societies, such as Amish farmers or hunter-gatherers, are especially likely to retain their traditional culture because of their limited contact with mainstream or colonial cultures.

Conducting research with small societies with traditional cultures is difficult. Often, members of these groups have experienced prejudice and discrimination and can be distrustful of researcher motives. In addition, there are methodological complications including translation difficulties and the obstacles presented by remote geographical locations in which these societies are located. Despite these hardships, I argue that it is both wise and important to include traditional cultures in the larger research program of subjective well-being research. Research with small or traditional societies adds a layer of specificity to a topic—culture—that is plagued by fuzzy boundaries. In many cross-cultural studies in psychology, for example, nationality is treated as being synonymous with culture (e.g. Suh, Diener, Oishi & Triandis, 1998). However, nations such as China, for example, are too diverse to realistically have some monolithic,

unifying culture. Demarcating cultural boundaries by collecting data from smaller and more traditional groups can help us understand cultural factors that are broad and regional versus those that are unique and local.

In addition, the bulk of the research attention to culture in psychology has focused on broad cultural concepts such as individualism and collectivism (Triandis, 1995). Individualistic cultures are those in which the primary unit of measurement is the individual. These cultures emphasize uniqueness and generally have greater social and geographic mobility. By contrast, collectivist societies are those in which the unit of measurement is the family. These cultures tend to emphasize social harmony and social obligation. Although individualism and collectivism are, arguably, the most researched dimensions of culture in psychology, other conceptualizations of culture have also been studied. These include cultures of honor (Nisbett & Cohen, 1996), indexical versus referential cultural (Landrine, 1992), cultures with positivity biases (Diener et al, 2000), and independent versus interdependent self (Markus & Kitiyama, 1991).

The Measurement of Well-Being in Cultural and Cross-Cultural Research

In this chapter, I generally use terms such as well-being, happiness, and subjective well-being interchangeably. I do so out of linguistic convention and to promote a better experience for the reader. That said, I also acknowledge that each of these concepts is distinct, and that—for research purposes—each can be operationalized in unique ways (Diener, 1984). For a thorough discussion of definitions related to happiness please see Haybron (2007) and Diener and Biswas-Diener (2008). Similarly, I treat the terms small society as if it is synonymous with traditional culture. There are also instances in which these concepts overlap with "non-western culture" and "non-mainstream culture." While arguments can be made for the distinctiveness of these concepts a careful parsing of these terms is beyond the scope of this chapter. For a fuller discussion of this issues please see Mathews and Izquierdo (2009).

It is impossible to disentangle the findings of studies on the SWB of small societies from the very methods used to conduct those societies. That is, small societies present unique opportunities to focus on methodological difficulties even as they offer interesting possibilities for gaining new insights into happiness. To explore this issue in detail I will discuss some of the common research practices in the cross-cultural study of SWB as well as outline their limits. Thereafter, I will argue for the importance of enhancing current research practices with more attention to culturally sensitive data collection procedures including interviewing and qualitative analyses.

Methods Common to Cross-Cultural Studies in SWB

Researchers have long been interested in the role that cultural factors such as norms and values play in SWB. Studies have usually been structured around samples: their demographic categories and size. Some studies have employed large international samples from many nations (egs. Diener & Diener, 1995; Veenhoven, 2012). Other studies have targeted comparisons of samples from only a handful of nations (e.g., Biswas-Diener, Vittersø & Diener, 2005; Wirtz & Napa-Scollon, 2012). A third class of SWB studies uses analyses of data from only a single nation but using standard metrics that allow for comparison (e.g. Biswas-Diener, Tay & Diener, 2012). Consumers of this research can be reassured by the fact that many of these studies use longitudinal sampling or large samples of adults. Other studies have employed student samples. Interestingly, this is an instance in which student sampling is defensible because it allows for more direct cross-cultural comparison. Students samples, of course, limit the ability to generalize results to there is an inherent trade-off in the costs and benefits of this method of sampling.

In cross-cultural research on SWB a standard—typically quantitative—measure is used. Perhaps the most common of these is the Satisfaction with Life Scale (Diener, Emmons, Larsen & Griffin, 1985); a five-item questionnaire using a 1-7 Likert scale that directs respondents to indicate their agreement with each item. Although such methods offer the benefit of a standard medium of comparison these methods have been criticized as insensitive to cultural norms and contexts, and therefore difficult to interpret accurately (Thin, 2009). More recently, large samples such as the Gallup World Poll have attempted to address this shortcoming by employing the Cantril Self-Anchoring Striving Scale (Cantril, 1965). This so-called "Cantril Ladder" offers greater cultural sensitivity by anchoring life appraisals in the respondent's own experience, even those these are not made explicit. The ladders instructs, "The top of the ladder represents the best possible life for you while the bottom of the ladder represents the worst possible life for you." This allows for differences in context: a rating of 6 offered by two separate respondents is assumed to be comparable even though the best possible life might include menial employment for one and living in a mansion for the other.

There are those, myself included, who also argue for a greater use qualitative measures in cross-

cultural research. Qualitative measures allow for greater contextualization of data (Colby, 2009). This is especially important when studying a highly subjective phenomenon like happiness. Qualitative methods, such as structured interviews and ethnographic analyses, are generally more sensitive than are quantitative measures to cultural differences in happiness. This is not to suggest, however, that such methods are inherently superior. They are time consuming, can limit generalizability, and may be vulnerable to researcher bias during analysis and interpretation. Even so, a combination of quantitative and qualitative measures could be advantageous in this research. An example of this can be seen in a hypothetical study in which the Cantril Ladder was used in conjunction with interview questions that probed respondents' specific representation of the best and worst possible life. The subsequent interview information would provide the basis for better understanding the numeric ratings. They might also help future researchers understand just how comparable Cantril Ladder ratings truly are.

Case Studies

The bulk of this chapter will consist of case studies in research on the SWB of small societies. There are, of course, too many such societies to allow comprehensive coverage in of the research in this chapter. Instead, I have elected to focus on three small scale societies. I have chosen these specific three examples because they meet the following criteria:

a. Existing high-quality research on SWB. Many small-scale societies have been the subject of scientific scrutiny but this research attention has not focused explicitly on SWB or has been methodologically limited by small sample sizes or similar problems.
b. Diversity. I have chosen these examples because they represent two distinct types of diversity. First, they are societies with geographical diversity, located in the American Midwest, the South Pacific, and East Africa. This is important because small scale societies give us the opportunity to examine the ways that the natural environment influences daily psychological experiences. Second, these examples represent diversity in "types" of culture. Each society is unique in its means of food production, economy, language group, and spiritual beliefs.
c. Methodological lessons. Each of the example societies offers insights into the benefits and limitations of existing research practices. The research I will report has been carried out using both spanning qualitative and quantitative methods. I will argue that both types are necessary to ensure the quality of SWB research.

Intentional Culture: The Amish

The Amish of North America are famous for their intentional rejection of modern technologies such as electric light and motor vehicles. Because they live in close proximity to people who live an industrialized lifestyle, they have become a source of media fascination. They are depicted, alternately, with romanticism or vilification in movies and television shows. The Amish are a religious order and are part of the Anabaptist tradition that grew out of the Protestant Reformation (Hostetler, 1993). Anabaptists broke from the Catholic Church on the issue of baptism: the former group preferred baptism to occur in adulthood when people are, presumably, able to make a more informed choice regarding the acceptance of God. The Amish were persecuted in Europe and the earliest Amish immigrants to North America arrived from Switzerland. Their descendants speak "Pennsylvania Dutch" (a bastardization of the word "Deutsch") which is a dialect of German. Their largest population is concentrated in Pennsylvania and Ohio (USA), with smaller communities in Indiana, Illinois and other states. There are also communities living in Mexico, Belize and Canada.

Amish culture is centered on the Christian religion. They believe in the concept of "gelassenheit." Although in modern German *gelassenheit* means "carefree" it has a different meaning among the Amish. It indicates the unburdening that comes with submission to God (Kraybill, 1989). The Amish adopt a fairly literal interpretation of Christian scripture, pray daily, and engage in community worship. They emphasize community-based generosity and gratitude for their food, home, health and other material provisions (which they see as blessings from God). The Amish aspire to be intentional in their behaviors. For example, during the Vietnam War, a time when young males in the United States were drafted for military service, military-aged Amish males chose to be "contentious objector." As with many small societies, there is a relative lack of privacy in Amish communities and individual behavior is monitored by the group. In the most extreme cases, shunning (called "*meidung*" by the Amish) occurs as a social correction for wrong action. One Amish man describes it this way: "Shunning works a little bit like an electric fence around a pasture with a pretty good fence charger on it" (Kraybill, 1989, p.117).

Perhaps the most conspicuous aspect of their intentional approach to living is their rejection of modern technologies. The Amish avoid the "perils of worldliness" assumed to be in automobiles, tractors, electricity, the Internet and other technologies and conveniences. This separation from the world is based in

scriptural passages that admonish non-conformity to the world and to avoid being yoked to non-believers (Hostetler, 1993). As such, the Amish have gravitated toward a rural, agricultural lifestyle that allows for the greatest degree of self-sufficiency. Within Amish culture are there further sub-divisions, such as the distinction between Old Order and New Order Amish. The New Order Amish split from the Old Order in the 1960s. The New Order generally are more permissive toward technology (e.g., commercial airline travel, some electricity in the home) but share many conservative religious values with their Old Order spiritual counterparts.

The very intentionality of their lifestyle is suggestive of the prospect that Amish people might enjoy high levels of happiness. In past studies, researchers have found that people who engage in a voluntarily simple lifestyle enjoy high levels of subjective well-being (Brown & Kasser, 2005). Further, the researchers found that life satisfaction and affect balance were correlated with both the mindfulness and the intrinsic values that underscore an intentional lifestyle.

The majority of research conducted with the Amish has been either anthropological or medical in nature. The norm for inter-marriage among the Amish means that they have a relatively small gene pool compared with "the English" (as they refer to all mainstream Americans). The small gene pool makes them a useful group for the study of the genetic aspects of health and illness. One example of this type of research that is directly relevant to happiness is a study of Bipolar Disorder among the Amish (Egeland, 1988). In the early 2000s, my colleagues and I also collected data on subjective well-being from 52 Amish people (Old and New Order) living in 2 communities in Illinois (Biswas-Diener, Vittersø, & Diener, 2005).

The process of recruiting and sampling our Amish participants offers an important methodological lesson for the study of subjective well-being outside of college student samples. Because of their desire to separate from industrialized society the Amish must be approached with sensitivity and patience. I originally contacted the Amish through a small, local museum of Amish culture. It was both coincidental, and helpful, that my surname—Diener—is also a relatively common Amish surname. This curious point of contact allowed me to introduce myself and my project. I spent 3 months visiting Amish households before conducting my research. These social calls were often spent in silence or discussing genealogy, in order to gain the trust of community members. During this time I had the opportunity to spend the night in Amish homes, attend communal meals and festivities, and give public addresses in Amish primary schools. It turns out that these public talks were the "tipping point" in my recruitment of participants. Because the Amish have so little news of the non-Amish world they are curious about other cultures. My weekly talks on tribal society in East Africa grew in attendance and led to a number of introductions to people who eventually agreed to participate in our research.

We were able to recruit 52 Amish participants for our study of which 56 % were male and for which the average age was 44. Interestingly, the average levels of life satisfaction as measured by the SWLS (Diener et al., 1985) was 4.4; just above the neutral point. Above neutral scores are consistent with the idea that "most people are mildly happy" (Diener & Diener, 1996), and that mild happiness is evolutionarily advantageous (Fredrickson, 2001). Comparatively, the Amish satisfaction in our study can be interpreted as meaning that the Amish fall lower than members of many other groups. In a study of more than 13 thousand college students from 31 nations, for example, only students from Kenya (whose average life satisfaction was 4.0) scored lower than the Amish (Diener & Diener, 1995).

Anecdotally, the Amish society in which we conducted our study was fraught with contrasts. On the one hand, the Amish had a pronounced pro-social attitude. One man I interviewed, for example, had donated tens of thousands of US Dollars toward the medical treatment of his neighbor's son, with no thought of repayment. Similarly, the Amish often helped one another in quilting, construction, and food preparation. On the other hand, these neighborly behaviors were confined to in-group members. There was a conspicuous degree of prejudice toward out-group members, especially ethnic or religious minorities. One bishop, for example, asked me whether I thought the space shuttle Challenger exploded because there was a Jewish person (Judith Resnick) aboard.

Another set of contrasts could be found in the relationship between the Amish and the larger "English" society in which they live. While on the one hand there is a strong cultural push to remain separate from industrialized society. The Amish I spoke with were highly invested in publicly conforming to group norms related to abstaining from the use of industrial technologies and from remaining aloof from broader society. Privately, however, the Amish revealed themselves to be as curious and as human as people from any other society. One participant, for example, admitted that he used his workplace telephone —an allowable technology—to phone a newspaper number that hosts recordings of the world's news. Another informant revealed that she had secretly flown on an airplane. These examples reflect the on-going tension of a society that must—individually and collectively—continually re-negotiate its relation to the larger society in which it exists. Where subjective well-being is concerned, the tension between retaining

traditions and adapting to new circumstances is an interesting issue for research. Too often, we treat culture as if it is a static phenomenon. The acknowledgment that culture is a dynamic system is, itself, a call for more longitudinal data collection among small societies despite the hardship this may entail.

A closer examination of Amish satisfaction reveals some interesting cultural insights. In our study, we measure global life domains (e.g., "self" and "social life") as well as specific domains (e.g., "intelligence" and "family"). These satisfaction scores are shown in Table 1. Past research has revealed that discrepancies between global and specific domains reflect the role cultural norms play in the construction of satisfaction judgments (Diener, Napa-Scollon, Oishi, Dzokoto, & Suh, 2000; Oishi & Diener, 2001). Specifically, global and specific domain satisfaction should, theoretically, be in agreement. For example, if a person is satisfied with her romantic life, her friendships, and her family relationships—all specific domains—she should, logically, report about the same amount of satisfaction with her overall social life (the global domain). Diener and colleagues found that this correspondence occurred in some cultures, such as Japan. In other cultures, however, they discovered an inflationary effect. People in Colombia and the United States, for instance, are likely to inflate their global reports of satisfaction over that reported for specific satisfaction. Diener and his colleagues explained that the tendency toward or away from inflation is suggestive that—in the absence of clearly defined criteria for making a judgment—people default to a cultural norm for positivity.

Table 1. Amish Satisfaction

Amish Satisfaction			
Self-Satisfaction		*Social Satisfaction*	
Self	4.2	Social Life	5.7
Intelligence	4.7	Friends	6.1
Morality	5.3	Family	5.9
Physical Appearance	5.1	Romance	6.1

In the case of the Amish in our study, you can see that no such inflationary effect occurs. In fact, it appears, at least in this instance, which the Amish tend toward a deflationary effect. It does not make logical sense that Amish participants would report relatively high satisfaction with various aspects of the self, but report significantly lower satisfaction with the self globally. In this case, the whole is less than the sum of the parts. Although we cannot be certain, one possible explanation for this trend is to be found in cultural norms for self-abnegation. It may be, for the Amish that experiencing "too much satisfaction" with the self is akin to the perceived sin of pridefulness and too far from the virtue of humility.

In this respect, the Amish provide an interesting case study of small society happiness. They appear, upon a close examination of their life satisfaction, to evaluate their lives positively. They seem appreciative of their material circumstances and enjoy the benefits of living a values-congruent lifestyle. On the other hand, their unique religious views give rise to cultural norms that, perhaps, dampen some of this psychological positivity. It is here that the usefulness of more qualitative and ethnographic measures can be easily seen. Rather than assuming an operational definition of happiness it makes sense to ask "what is happiness for the Amish?" To some degree, it is not the upbeat emotional experience sought by many mainstream Americans. Instead, it is a state of being "blessed by God" as the result of right thought and behavior.

Social Roles in Small Society: Tonga Islanders

The South Pacific region and its Polynesian cultures are, perhaps, the least researched on the planet. Their geographic isolation adds financial and time costs to any study of well-being among these widespread island nations. One interesting exception to this is a study of the well-being of Tonga Islanders (Moore & Younge-Leslie, 2005). Like many of its neighbors, Tonga is an archipelago of more than 100 islands although it has a population of only about 100 thousand people. Of these, about 70% live in the "main island" of Tongatapu. Tongan society is a constitutional monarchy that has traditionally resisted colonial incursions in the region. Approximately 70% of Tongans living in remote areas rely on subsistence production, an activity that is largely governed by cultural prescriptions for male and female roles (food production for men and text-tile production for women). In more populous areas approximately 37% of people have full-time employment and are involved with fishing, agriculture, and tourist industries (Younge-Leslie & Moore, 2012).

Moore and Younge-Leslie (2005) were interested in understanding aspects of Tongan happiness, called *fiafia*, that were universal (similar to patterns found elsewhere) as well as those that were locally unique. They recruited 227 respondents who completed written surveys on a wide range of constructs related to well-being. They discovered trends that link their Tongan sample with the results of wider research. For example, they found that the Tongans in their study were generally happy, a conclusion reached by other researchers (eg. Diener & Diener, 1996; Biswas-Diener, Vittersø, & Diener, 2005). In fact, the average satisfaction reported was comparable to that of people studied in the Dominican Republic and Brazil. Specially, she found the average levels of general life satisfaction were 2.36 out of 5, indicating reports just above the neutral point. This might reflect the generally adaptable quality of mild happiness (Diener, Kanazawa, Suh & Oishi, 2014; Fredrickson, 2001). Moore and Younge-Leslie also discovered strong collectivistic leanings in their sample. Using statistical regression, they found that social concerns such as kinship duties were significant predictors of happiness while individualistic concerns were not.

As is the case in many small societies, Tongan culture places a heavy emphasis on social cohesion (Younge-Leslie & Moore, 2012). This includes fulfilling social roles, social and kinship duties. Tongan culture includes institutional practices to reinforce this point. The community gathers together in *fono* meetings, during which matters of community concern are discussed. Similarly, Tongan society is hierarchically organized and elders enjoy higher status than do younger people. Members of society are assumed to fulfill specific roles including those that are status based, such as offering deference and respect to elders, as well as material gifts. This can be seen reflected in the fact that elders, in general, reported higher life satisfaction than did younger people in the study. Younge-Leslie and Moore offer a preliminary psychological explanation for the higher well-being of older participants: their status affords them greater autonomy to make personal decisions. This line of reasoning is supported by research from self-determination theory (Ryan & Deci, 2000).

Tongan society offers a case study of the ways that social structure, and the cultural norms surrounding it, can affect well-being. The formal social bonds and relatively fixed structure of society can be seen reflected in many other studies of small societies. For example, Adelson (2009) reports that the well-being of members of Cree society of Eastern Canada is similarly related to kinship ties and obligations. Their concept of *miyupimaatisiiun* translates to "being alive well" and includes a heavy emphasis on responsibility to kin, fulfilling prescribed social roles, and the maintenance of social networks. These same emphases have been found by other researchers investigating the well-being of other cultures. Kral and Idlout (2012), for example, found the theme of family was the single most important to the happiness of more than 100 Inuit participating in their study. Although it is true that social relationships are generally highly correlated with happiness (Tay & Diener, 2011) the Inuit in this study placed a special emphasis on visiting with family—especially elders—and fulfilling prescribed social roles such as parenting. Similarly, Galinha and colleagues (2013) found that subjective well-being is better predicted by relationship satisfaction in a large sample of Mazambicans (relative to Americans). The emphasis on high quality social bonds is a call for more sophisticated research on culture and subjective well-being. Future researchers can parse the concept of relationships into constituent categories (e.g. fulfilling obligations, number of friends, social status, size of family, etc.) to better understand which types of relationships impact well-being.

Cultural understanding of Positivity and Negativity: The Maasai

The Maasai are an indigenous group living in East Africa. They are semi-nomadic pastoralists (herders) and their language (Maa) is Bantu. Historically, the Maasai have resisted English and German colonial rule in the region and have retained many of their traditional practices such as medicine men (*laibon*), the ritual circumcisions of adolescent males and females, polygamy, and a period of warrior hood for young males (*morani*). The Maasai are largely pre-literate and live in houses made of stick frames supporting dried mud and cow dung for the walls and roof. The traditional Maasai diet consisted of cow milk mixed with cow blood but in recent times they have supplemented this with *ugali* (corn meal), tea, and chicken eggs. Roles such as gathering firewood and herding cattle are culturally prescribed by sex. Social status is important to the Maasai. Traditionally, men enjoy the highest status. Among men, status is conferred by wealth (having many cattle, wives, and/or a large family), leadership (being recognized as wise and honest among one's age peers; the Maasai have clear generational age groups), and bravery. Women have lower status and children have no status.

Biswas-Diener, Vittersø, and Diener (2005) interviewed 127 Maasai living largely outside of the tourist industry and world economy. Fifty-two per cent of our sample was female and the average age of our sample was 32. The respondents were from 10 villages in the Megwerra (also, Megwara) region of Kenya. Although the respondents in this study had no formal education they live near the border of the Maasai Mara National Park. Tourists can be seen traveling to and from the park and approximately 20% of the park fees are paid back to the Maasai to fund medical clinics and similar extra-cultural services.

Increasingly, Maasai children attend Christian missionary schools and some Maasai are beginning to live in homes with tin roofs.

Our study began with translating and back translating our measures into Maa using separate native translators. During this process, we also conducted preliminary interviews aimed at better understanding the local conceptualization of happiness. We were informed, in art, by earlier research suggesting that cultural concepts are bound to specific language (Wierzbicka, 2004). For example, we identified a number of distinct linguistic concepts related to happiness such as: 1) *enchipai* (general happiness; the state of being in a joyful mood), 2) *ashipai* (literally to have a "bright heart," this concept is deep contentedness), and 3) *ebiotishu* (the state of being healthy and fit). Understanding local concepts of happiness is more than simply a translation issue; it also an opportunity to place these happiness-related concepts in the context in which they occur: event antecedents, cultural norms and values, individual appraisals and behavior (Mesquita, 2001). Simply put, one limitation of current cross-cultural research on subjective well-being is that reported mean levels of affect do not provide needed information about how these emotions are interpreted, tolerated, or used.

The Maasai also enjoy a cultural pride that is common in many tribal societies. For example, they believe that *Ngai* (God) endowed the Maasai with dominion over all the cattle on Earth. As pastoralists the Maasai do not engage in hunting and generally harbor prejudices toward members of nearby tribal groups who do. The Maasai collectively refer to these groups as *Dorobo*, which is a derogatory term. One Maasai informant in our study said, "During Creation the Maasai were given all the cows. The Dorobo were given other animals because there were no cows left. They [the Dorobo] are looked down on and are poor. Sometimes we beat them up."

The Maasai in our sample reported relatively high levels of happiness. For example, they reported an average score of 5.4 out of 7 (where 4 is the neutral point) on life satisfaction (Biswas-Diener, Vittersø, & Diener, 2005). Similarly, they reported frequent experiences of positive emotion including joy and pride. They did report moderate amounts of worry and anger. Further, we were able to obtain two informant reports of emotion for each of our respondents. There was a high degree of agreement across our peer raters and all of the peer reports of affect balance (positive emotion divided by negative emotion) were significantly greater than zero.

A better understanding of how the Maasai understand emotion can be found in our previously unpublished qualitative data. We asked each of our respondents to list positive and negative memories from the previous day (with the order of these two tasks counter-balanced across participants) and to repeat this task for positive and negative memories for the prior year. We were able to collect this data from 111 individuals. In Table 2, we display the total number of events listed for each time period and for both positive and negative valences. All but one of our respondents could list one or more positive events from the previous day. This single exception—a 24-year-old woman—had had six goats killed by hyenas the previous evening. Of our 111 respondents, 59 of them could not list a single negative memory from the previous day. Of the remainder who did report a negative memory these included mentions of severely sick or hungry children (N = 4), goats being killed by leopards and hyenas (N = 3), and sick or dying livestock (N = 7). Interestingly, the health concerns of friends (e.g., miscarriage, illness) were mentioned with the same frequency as personal health concerns.

Table 2. Maasai Memory Reports

	Maasai Memory Reports (N = 111)	
	Yesterday	*Last Year*
Positive Events Reported	211	206
Negative Events Reported	59	162
Memory Balance Score	3.58	1.27

What could account for the highly positive memories of the Maasai in our study? It is interesting to consider a number of culturally relevant factors. Culture could impact the way that the Maasai cognitively process and use the information necessary for making life evaluations. Past research has shown that culture can affect the ways that visual information is processed and retrieved (Nisbett, 2003) and the way that norms are integrated into satisfaction judgments (Suh, 2000). Although it is speculative, these data are suggestive of a number of interesting possibilities. First, the Maasai may have a culturally unique appraisal

system for negative events wherein only events meeting some critical threshold are encoded as negative. For example, a minor illness may not be viewed as "complaint worthy" whereas losing livestock to a predator is. In addition, the Maasai seem to have a relatively high threshold for what constitutes a negative event. There were no events that were comparable to common daily complaints in industrialized society (e.g., "I was stuck in a traffic jam," "I was late for a meeting," "I had a frustrating interaction with customer service"). Instead, the Maasai complaints were more comparable to our more serious complaints such as car accidents or major financial setbacks.

Both of these trends can be seen in the memory reports for negative events occurring during the prior year. All but a small handful of respondents with whom we collected memory reports reported negative events for the previous year. Of these, the overwhelming majority were specifically about the drought that had plagued the region. Most of these reports mentioned livestock dying and many mentioned outbreaks of illness. Only a handful of participants specifically mentioned a personal hardship such as falling ill themselves. Of these personal hardships, four were complaints about money (all four were tangentially involved with either tourism or the selling of cornmeal.

As with the memory reports for recent events the yearly memory reports offer an intriguing look into Maasai psychology. First, it is noteworthy that so many of them reported the same negative event (the drought). That is, the drought—for the Maasai—was on the scale that the 2006 Indian Ocean Tsunami or Hurricane Katrina were for the regions those disasters impacted. It should be noted that there have been 12 such droughts since 1975, making them a far more frequent occurrence than their counterpart natural disasters in other parts of the world. The wide agreement about the negative impact of the drought is evidence that the Maasai experience their lives as linked to the natural environment and linked to one another. This can especially be seen in the fact that very few mentioned a personal hardship ("I had to walk 15 kilometers to fetch water") whereas many mentioned illness in other people or the death of livestock.

The way the Maasai conduct mental appraisals of past events is not well understood and is in need of further study. These preliminary findings point, however, to new research questions. For instance, researchers have found that memory of events is related to but not identical to the actual experience of events (e.g., Wirtz, Kruger, Scollon & Diener, 2003). Further, research reveals that more global judgments, such as yearly as opposed to daily judgments, are more likely to draw upon cultural norms (Diener et al, 2000; Suh, Diener, Oishi & Triandis, 1998). The Maasai offer a unique opportunity to test cultural differences in appraisal thresholds for both types and frequency of events as well as into the shared nature of appraisal.

Conclusion

Small societies offer well-being researchers a unique laboratory in which to improve our methodology and gain new empirical insights. Regarding the first point, the lion's share of international study in the field of well-being is ensconced in cross-cultural approaches. While this approach offers a standard by which to compare individuals and groups it is also limiting. Well-being researchers are advised to expand their methodological approaches by increasing their focus on cultural, rather than cross-cultural, understanding of key concepts. This typically means the collection and analysis of more qualitative data. This is especially important in establishing a sensitive and comprehensive understanding of local definitions of well-being (see Sell & Nagpul, 1992). This is a difficult challenge because, from a practical standpoint, it means increased time in the field, longer duration of study, fewer participants, higher expenses, more travel, and more complexities regarding linguistic translation. Despite these challenges it is a worthwhile undertaking. In part, because small societies are, by their very definition, small and isolated. This means that it is easier to get representative samples of the population and that the society itself can act as a laboratory in which certain conditions are naturalistically controlled.

The methodological complexities of investigating the well-being of small societies also raises the prospect of increased Interdisciplinary collaboration. Well-being researchers, and especially psychologists and economists who gravitate toward cross-cultural approaches, might benefit from the expertise of those who are oriented toward cultural approaches. Historically, disciplinary approaches to definition and measurement have served as an obstacle to effective cross-disciplinary research. Even so, there are examples in the well-being literature of interdisciplinary theory (Ahuvia et al, 2015) as well as empirical study (Inglehart, Foa, Peterson & Welzel, 2008). Greater dialogue between academics could help researchers improve methods, enrich their understanding, and bridge levels of analyses.

Small societies also offer unique opportunities to better understand well-being. It may be that, historically, small societies have been treated as nothing more than curious case studies that are so small and so culturally relativistic that results from their study are not generalizable. To the extent that this claim is true it is likely more so in psychology than in anthropology. Rather than thinking of small societies as interesting oddities, well-being researchers would do well to consider them as unique laboratories. In many

cases, the geographical isolation, possible in-group biases, and small populations mirror—to some extent — the controlled conditions of the research laboratory. The linguistic and cultural challenges they present also encourage researchers to reflect on their methodological assumptions and continue to innovate data collection and analysis.

All cultures change, including those of small societies. In fact, as technology increases globalization, it is small societies that face the most dramatic impacts and the most rapid potential change. As some traditional practices and languages face extinction, research offers us an opportunity to investigate how pace of change and type of change affect well-being. Embedded within our interviews, surveys, and other small society data are invaluable insights into kinship, vulnerability, resilience, and the pursuit of happiness.

Materialism and Living Well

By Tim Kasser, Ph.D., Knox College

Citation
Kasser, T. (2018). Materialism and living well. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

Materialism is a psychological construct reflecting the extent to which an individual believes that it is important to attain money, possessions, image, and status, relative to other aims in life. This chapter reviews evidence showing that materialism is a fundamental aspect of the human value system that stands in relative conflict with intrinsic values concerning personal growth, close interpersonal relationships, and helping others. Meta-analytic results and longitudinal studies demonstrate that people report lower levels of well-being when they prioritize materialistic values and goals. Because materialism is also negatively associated with pro-social and pro-environmental attitudes and behaviors, a strong focus on such aims is likely to undermine the well-being of other people, other species, and future generations. Recent studies show that materialism can diminish when people receive interventions that encourage intrinsic values, that involve deep inward reflections, or that lead them to disengage from and question the messages of consumer culture.

Keywords: Materialism, Values, Goals, Well-being, Social Behavior, Ecological Behavior

This chapter has four main goals. First, it will show that the construct of materialism can be understood as an aspect of the human value system. Second, it will review the substantial empirical evidence which has documented that people experience lower levels of personal well-being to the extent they place a relatively high priority on materialistic values and goals. Third, it will show that when people prioritize materialistic values and goals, they are also likely to hold attitudes and engage in behaviors that interfere with the ability of others to live well. Finally, the chapter will describe some interventions that hold promise for decreasing materialism and increasing well-being.

Materialism as a Part of the Human Value System

Psychologists and consumer researchers who study materialism have conceived of the construct in varying ways. Belk (1985) first introduced the construct empirically as a personality trait with facets of possessiveness, non-generosity, and envy. Others have considered materialism to be a feature of people's identities (Dittmar, 2008; Shrum et al., 2013). Still others have thought of the construct as composed of a set of attitudes about money and wealth (Forman, 1987; Tang, 1992). Most empirical work, however, has followed Richins and Dawson (1992) and Kasser and Ryan (1993, 1996) by conceiving of materialism as a set of values, goals, and/or strivings. That is, to say that a person is materialistic is to suggest that s/he believes it is important to have money and possessions that convey status and a desirable image, and that these aims in life are relatively high priorities compared to all the other aims for which a person might strive.[1]

Support for a value-based conceptualization of materialism comes from research showing that such aims consistently emerge as a fundamental set of values across cultures. For instance, Schwartz's (1992) cross-cultural work has identified a cluster of *self-enhancing* values that includes "wealth," "preserving my public image," and "social power," as well as being "ambitious," and "influential." Further, Burroughs and Rindfleisch (2002) demonstrated that the Richins and Dawson (1992) measure of materialistic values is highly positively correlated with these self-enhancing values (as well as with hedonistic values). Using a measure of personal "aspirations" or goals, Kasser and Ryan (1996) similarly showed the emergence of an *extrinsic* factor composed of aspirations for financial success (e.g., "I will be financially successful"), image (e.g., "My image will be one others find appealing"), and popularity (e.g., "I will be admired by many people"). Grouzet et al. (2005) demonstrated that these three extrinsic aims consistently cluster together in the goals of college students from 15 nations.

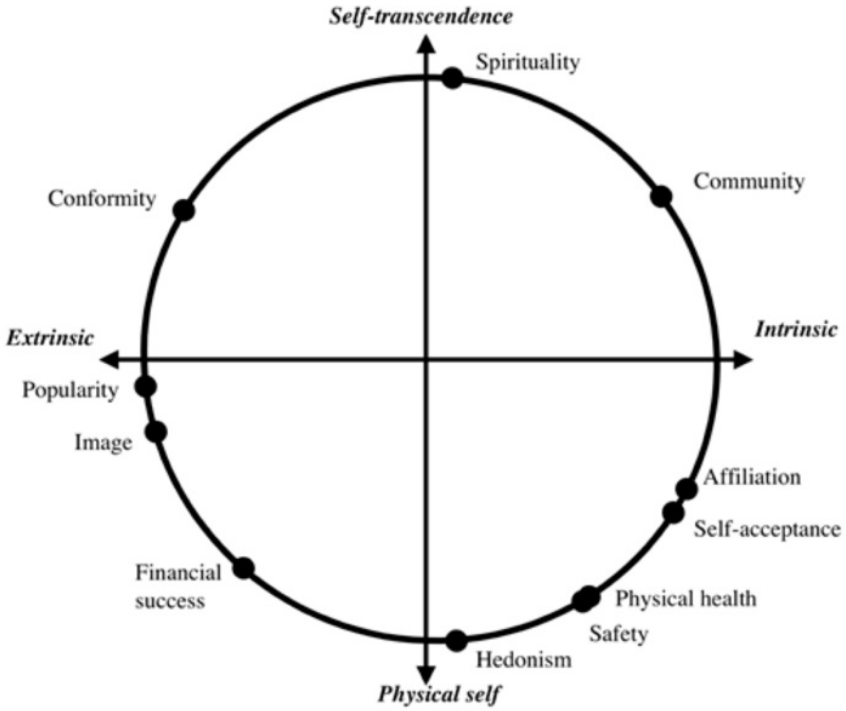
This body of research suggests that people experience aims for money, possessions, power, status, and image as being relatively compatible with each other. For example, one can relatively easily pursue both financial success and image aspirations, given that image is usually expressed through possessions (e.g., cars, handbags) that require some level of financial success to purchase. Similarly, wealth typically brings access to power, and power typically provides opportunities to attain wealth.

The finding that certain values are compatible with each other carries with it a corollary: Certain

values are also in conflict with each other. In the late 1980s and early 1990s, Schwartz (1992) made the important discovery that across cultures the human value system is organized in a remarkably consistent fashion, such that to the extent a person prioritizes a particular value, s/he is also likely to prioritize certain other compatible values and to de-prioritize certain other conflicting values. Schwartz represented the statistical extent of compatibility and conflict between values via a "circumplex" model in which the aims that people experience as relatively consistent with each other are next to each other in the circle, the aims that are in relative conflict are on opposite sides of the circle, and the aims that are neither in conflict nor compatible are approximately 90 degrees apart on the circle.

Figure 1 shows a circumplex model derived from the cross-cultural work my colleagues and I conducted on the importance people place on personal goals (Grouzet et al., 2005). In the west and south-west portion of the circle, the reader can see that goals for financial success, popularity, and image cluster together; their nearness to each other represents their relative compatibility, i.e., that they are relatively easy to pursue together. It can also be noted that financial success goals are relatively compatible with hedonism (as Burroughs and Rindfleisch (2002) also found) and that image and popularity goals are relatively compatible with conformity goals. These findings are intuitively sensible, as money is often used to purchase sensually pleasurable products and services, and one usually has to conform somewhat to others' opinions in order to obtain their praises.

Figure 1. Circumplex model representing the relative compatibility of extrinsic, materialistic goals (for financial success, image, and popularity) and their relative compatibility and conflict with other goals (from Grouzet et al., 2005, Journal of Personality & Social Psychology). Reprinted by permission of the American Psychological Association.



Note as well the aspirations on the opposite side of the circumplex from these extrinsic values. Here the reader will find the *intrinsic* values for self-acceptance (e.g., "I will choose what I do, instead of being pushed along by life"), affiliation (e.g., "I will feel that there are people who really love me"), and community feeling (e.g., "I will help the world become a better place"). The arrangement depicted in Figure 1 reflects that people tend to experience the intrinsic aims as in relative conflict with materialistic, extrinsic aims. That is, these values stand in dynamic tension with each other, such that it is relatively difficult to simultaneously pursue them. For example, the strong opposition between financial success and community feeling goals reflects the rather obvious fact that it is difficult to be simultaneously greedy and generous. Similarly, the opposition between image/popularity and self-acceptance aspirations reflects that in order to be popular and praised for one's image, one must be concerned with what others will approve

of, an approach to life that is typically inimical to one's own personal growth (Rogers, 1961). Notably, goals for financial success and spirituality are also at opposite ends of the circumplex, reflecting the conflict between these aims mentioned in most religious traditions (see e.g., Belk, 1983).

Parallel results occur with Schwartz's (1992) values measure, in which the self-enhancing values of money, power, and achievement stand in relative conflict with *self-transcendence* values of universalism (e.g., "unity with nature," "social justice") and benevolence (e.g., being "honest" and "helpful"). Burroughs and Rindfleisch (2002) similarly found that Richins and Dawson's (1992) measure of materialism was in relative conflict with these universalism and benevolence values, as well as with values for community and religiosity.

In sum, this body of evidence strongly supports the validity of conceiving of materialism as a set of values and goals that people have for money, possessions, power, status, and image. It further suggests that prioritizing materialistic values comes at the cost of de-prioritizing certain other values. As will be described below, this fact has important ramifications for well-being.

Materialism and Personal Well-being

One of the primary questions that researchers have asked about materialism is whether prioritizing such values promotes or hinders people's personal well-being. Since the earliest studies on this topic (Belk, 1985; Cohen & Cohen, 1996; Kasser & Ryan, 1993, 1996; Richins & Dawson, 1992), dozens more have been conducted. Dittmar, Bond, Hurst, and Kasser (2014) recently undertook a thorough search for and subsequent meta-analysis of published and unpublished studies on the relationship between materialism and well-being. The search yielded 175 studies using 258 distinct samples across which researchers reported 749 associations between a measure of materialism and a measure of personal well-being. Across the 749 effects, Dittmar et al. (2014) found the mean size of the correlation between materialism and well-being to be -.15; when only a single effect was selected from each of the 258 distinct samples (to control for non-independence), the effect was also -.15 (95% CI = -.18 to -.13). Thus, the negative association between materialism and well-being appears to be quite robust, even if it is not large.

Dittmar et al. (2014) also examined whether the size of the effect depended on the type of materialism measure that researchers had used; to test this, they categorized 143 distinct materialism measures into eight basic types. Substantial variation in effect sizes was notable. Stronger associations between materialism and well-being (rs between -.19 and -.16) occurred when researchers used multi-faceted scales that assessed materialistic values and beliefs (e.g., Richins & Dawson, 1992) or scales that assessed the importance of goals for money, image, and popularity relative to other non-materialistic goals (e.g., Kasser & Ryan, 1993, 1996). Weaker effects (rs between -.07 and -.11) were typically obtained when researchers used measures of materialism that were quite brief, that assessed general beliefs about money and wealth, or that assessed the value participants placed on money in absolute (rather than relative) terms.

The size of the association between materialism and well-being also depended on how researchers measured well-being. Dittmar et al. (2014) placed 497 well-being measures into 12 distinct categories to examine this issue. Significant effects were obtained for all 12 categories of well-being, but the size of the effects varied substantially. In decreasing order of effect size, materialism was associated with more compulsive consumption (r = .44), engaging more frequently in risky health-related behaviors (like smoking cigarettes and drinking alcohol, r = .29), a more negative self-image (r = .28), less positive affect (r = -.23), more depression (r = .19), lower overall subjective well-being (r = -.19), a less positive self-image (r = -.17), more anxiety (r = .17), more symptoms of a variety of DSM Axis I disorders (r = .16), worse physical health (r = -.15), more negative affect (r = .15), and lower life satisfaction (r = -.13). It thus appears that there are manifold types of well-being negatively related to materialism.

Dittmar et al. (2014) also tested 25 potential moderators of the association between materialism and well-being; these included study, sample and cultural characteristics. 18 of these potential moderators were non-significant, and seven were significant. Specifically, the negative relationship between materialism and well-being was stronger: a) when well-being was assessed with questionnaires (rather than interviews); b) when participants were under (rather than over) age 18 years; c) in samples that included large percentages of women (rather than men); d) in samples that included relatively few (vs. many) business, economics, and law students and practitioners; e) in samples from nations with less (rather than more) economic inequality; f) in samples from nations with slower (rather than faster) economic growth; and g) in samples from nations that place relatively high (vs. low) importance on pleasure and an exciting life. Importantly, none of these significant moderators revealed any conditions under which the relationship between materialism and well-being was positive; instead, the effects were more weakly negative.

In sum, the Dittmar et al. (2014) meta-analysis demonstrates that the relationship between

materialism and well-being is small but consistently negative. Certain measures of materialism tend to produce stronger results than do others, and certain types of well-being are more strongly related to materialism than are others. Further, although some sample and cultural characteristics decrease the size of the negative relationship, the association between materialism and well-being is consistently negative across different sorts of people and cultural circumstances.

Longitudinal and experimental studies. A clear weakness of Dittmar et al.'s (2014) meta-analysis is that it included only studies that were correlational and cross-sectional. A handful of studies have used more sophisticated methodologies to test how materialism and well-being relate to each other.

One approach researchers have taken is to test how changes in materialism over time correlate with changes in personal well-being over time. Studies of Canadian college students (Hope, Milyavskaya, Holding, & Koestner, 2014) and of Chinese business and engineering students (Jiang, Song, Ke, Wang, & Liu, 2016) demonstrate that well-being declines as materialistic values increase over the course of one year. Kasser et al. (2014) also examined longitudinal associations in samples of at-risk U.S. young adults, recent U.S. college graduates, and Icelandic adults over time frames ranging from 6 months to 12 years; in all three samples, individuals who increased in materialism over the relevant time period reported decreases in well-being. These person-level results are complemented by nation-level time-series analyses in Norway (Hellevik, 2003) and the U.S. (Twenge et al., 2010) revealing that as materialism levels increase in cohorts of citizens, their overall well-being declines.

A few experimental studies have tested whether focusing on materialistic values might cause decreases in well-being. Notably, however, ethical and practical difficulties mean that these studies typically involve briefly exposing study participants to relatively subtle materialistic primes (vs. control materials) before state well-being is assessed; it seems doubtful that such designs can shed much light on the types of well-being deficits that occur in people who dispositionally prioritize materialistic values and goals. Nonetheless, it is worth noting that increases in negative affect and decreases in positive affect have been observed after participants view luxury consumer goods (vs. neutral images; Bauer, Wilkie, Kim, & Bodenhausen, 2012) and think about their time as money (vs. control activities; Devoe & House, 2012). On the other hand, Solberg, Diener, and Robinson (2004) found no effects of other sorts of activations of materialism on well-being.

Explaining the negative association. A variety of explanations have been proposed for the consistent negative correlation between materialism and well-being. I will not attempt to review them all here, but will instead focus on the four explanations that have received the most attention in the research literature.

One possibility is that materialistic individuals experience decrements in well-being because they are not fully successful at attaining their goals of making money and obtaining possessions; this can be called the *goal-attainment* perspective. For example, Nickerson, Schwarz, Diener, and Kahneman (2003) found that the correlation between materialism and general life satisfaction was relatively weak (or non-existent) for wealthy individuals. That said, however, Nickerson et al. found that personal wealth did not moderate the negative correlation between materialism and satisfaction with relationships. Other research has found that progress at and attainment of extrinsic goals for money, image, and popularity do not improve well-being (Niemiec, Ryan, & Deci, 2009; Sheldon & Kasser, 1998); such results seem inconsistent with a goal-attainment perspective. Further, Dittmar et al.'s (2014) meta-analysis found no evidence that the association between materialism and well-being is consistently moderated by personal or household income. Meta-analytic results also showed that materialism's negative relationship with well-being is stronger in more (vs. less) economically-developed nations (i.e., those characterized by more income equality and slower economic growth); the goal-attainment perspective would seemingly predict a weaker relationship in more (vs. less) economically-developed nations, given the relative ease with which material possessions and wealth can be obtained in wealthier locales. In sum, while it seems premature to discard the goal-attainment hypothesis, this explanation of why materialism is negatively related to well-being has weak and relatively contradictory evidence.

A second explanation (Sirgy, 1998) suggests that people with strong materialistic values and goals experience substantial financial dissatisfaction, given that someone else is almost always wealthier and has nicer possessions, and given that marketplaces continually introduce new consumer goods that are advertised as being better than what one already owns. This dissatisfaction is thought to *spill over* into a more generalized dissatisfaction with one's life. Dittmar et al. (2014) tested this intriguing hypothesis using multi-variate meta-analysis for mediation on studies that reported relevant data; no support for the spill-over hypothesis was forthcoming, however.

A third, *environmental congruence*, hypothesis (Sagiv & Schwartz, 2000), suggests that materialism results in lowered well-being when people find themselves in environments that are at odds with their

values, as this leads to interpersonal conflicts, feelings of alienation, and fewer affordances for one's goals. Sagiv and Schwartz supported this hypothesis by showing that self-enhancing values (for power, status, money, etc.) were negatively correlated with well-being in psychology students but uncorrelated with well-being in business students. Other studies, however, have found that the negative correlation between materialism and well-being persists in business-oriented samples (e.g., Jiang et al., 2016; Kasser & Ahuvia, 2002), and that married couples who are both high in materialism have lower quality marriages than couples who are both low in materialism or couples with mismatched values (Carroll, Dean, Call, & Busby, 2011). Dittmar et al.'s (2014) meta-analysis found mixed support for the environmental congruence hypothesis. On the one hand, meta-analytic results showed that the negative association between materialism and well-being is somewhat weaker in samples composed of a large (vs. small) percentage of business, law, and economic students and practitioners. On the other hand, the association between materialism and well-being was still negative in samples with many business, law, and economic students and practitioners. Further, the negative association between materialism and well-being was stronger in samples from cultures more (vs. less) focused on pleasure and excitement; such a finding is a problem for the environmental congruence hypothesis because hedonistic goals are generally consistent with materialistic strivings (see Burroughs & Rindfleisch, 2002; Grouzet et al., 2005).

A fourth explanation (Kasser, 2002) has been derived from the research literature on the organization of value-systems (reviewed above), intrinsic and extrinsic motivation (Ryan & Deci, 2017), and humanistic/existential theories (e.g., Fromm, 1976; Maslow, 1954; Rogers, 1961). This *need-based* hypothesis suggests that people have inherent psychological needs to choose their own behavior (autonomy), to feel connected and close to other people (relatedness), and to be efficacious at their valued behaviors (competence). When these needs are well-met, well-being is high, but when these needs are frustrated, lower well-being occurs (see Ryan & Deci, 2017). The need-based approach proposes two main reasons why the strong prioritization of materialistic values and goals is associated with lower well-being. First, as people pursue their materialistic values and goals, they are likely to have many experiences that directly interfere with need satisfaction; for example, their strong pursuit of money likely leads them to spend more time working long hours at relatively uninteresting tasks they feel forced to complete, thereby interfering with the satisfaction of the need for autonomy. Second, because extrinsic values tend to be in relative conflict with intrinsic values (see Figure 1), people who prioritize materialistic values are less likely to spend time in the intrinsically-oriented pursuits that generally provide experiences of need satisfaction; for example, a person might spend so much time working or shopping in pursuit of her materialistic aims that she has less time for activities relevant to family or helping others, thereby interfering with the satisfaction of the need for relatedness. Kasser (2002) reviewed a variety of types of studies demonstrating support for this hypothesis, and Dittmar et al.'s (2014) meta-analysis showed that (dis)satisfaction of needs for autonomy, competence, and relatedness each partially mediated the negative association between materialism and well-being. In addition, Kasser et al. (2014, Study 2) found that the negative association between changes in materialism and changes in subjective well-being over two years was fully mediated by changes in need satisfaction, such that individuals who became more materialistic over time reported decreasing levels of need satisfaction, which, in turn, explained their decreases in well-being; see Wang, Liu, Jiang, and Song (2017) for similar results.

In sum, while there appears to be substantial empirical agreement that materialism is negatively associated with well-being, a consensus has not been reached as to why that is the case. At present, the need-based approach appears to have the most consistent empirical support of the four explanations reviewed here, but more research is needed on other sensible explanations that have been put forth (e.g., that materialism is an expression of traits such as neuroticism or agreeableness (Otero-Lopez & Villardefrancos, 2013; Roberts & Robins, 2000; Watson, 2014). In addition, a growing body of research shows that materialism is negatively associated with financial well-being and academic performance (see Kasser, 2016a); further research is also needed to examine materialism's negative relationships with these outcomes.

Materialism and "Living Well Together"

While living a happy, satisfying life free from depression, anxiety, compulsive consumption, and substance abuse is clearly part of what it means to "live well," from my perspective, it is only part. Individuals exist in families, communities, and ecospheres in which their actions affect the lives, and thus the well-being, of other people, other species, and future generations. Thus, it is theoretically possible that some individuals could experience relatively high levels of personal well-being while also behaving in ways that hinder the well-being of others. Such individuals would certainly not be "living well together" (Deneulin & McGregor, 2010).

As will be shown next, materialistic values are associated with a variety of attitudes and behaviors that are likely to undermine others' well-being. This is probably due to the fact, reviewed in the first

section of this chapter, that materialistic aims stand in relative opposition to values such as helping others, being honest, having close and loving relationships, and caring about social justice, equality, and unity with nature (see Figure 1). That is, as people place increasing priority on materialistic values, they tend to place less priority on the very values that would orient them towards nurturing their interpersonal relationships, contributing to the wider community, and behaving in ecologically sustainable ways.

In terms of their close interpersonal relationships, people who prioritize materialistic values and goals have lower-quality romantic and friend relationships (Carroll et al., 2011; Kasser & Ryan, 2001; Solberg et al., 2004). Perhaps this is because materialistic/extrinsic values are also associated with treating others in less empathic ways (Sheldon & Kasser, 1995), acting competitively rather than cooperatively (Sheldon, Sheldon, & Osbaldiston, 2000), and being more Machiavellian (McHoskey, 1999) and narcissistic (Kasser & Ryan, 1996). None of these are characteristics likely to support high quality interpersonal relationships.

Regarding potential effects on the well-being of the members of one's community, materialism is negatively associated with engaging in pro-social activities (Briggs, Landry, & Wood, 2007; Sheldon & Kasser, 1995) and positively associated with engaging in anti-social behaviors (Cohen & Cohen, 1996; Foulkes, Seara-Cardoso, Neumann, Rogers, & Viding, 2014, Kasser & Ryan, 1993). Individuals who prioritize materialistic values also engage in more interpersonally deviant workplace behaviors (Deckop, Giacalone, & Jurkiewicz, 2015) and care less about corporate social responsibility (Kolodinsky, Maden, Zisk, & Henkel, 2010), compared to their less materialistic counterparts. The broader community can also be negatively influenced by the anti-egalitarian, prejudicial, and socially dominant attitudes common in people who prioritize materialistic values (Duriez, Vansteenkiste, Soenens, & DeWitte, 2007; Flanagan, Gallay, Gill, Gallay, & Naana, 2005).

Ecological sustainability is another aspect of "living well together" with which materialism appears to interfere. To test this idea, Hurst, Dittmar, Bond, and Kasser (2013) meta-analyzed published and unpublished data from 13 independent samples that reported 26 different effects; results showed that materialism was negatively associated with pro-environmental attitudes ($r = -.22$, 95% C.I. from -.33 to -.11) and behaviors ($r = -.24$, 95% C.I. from -.30 to -.17). Apparently the desire for more and more money and stuff is one factor that leads people to treat the planet in ways that leave less for other people, other species, and future generations to meet their needs.

The conclusions that can be drawn from the correlational studies reviewed thus far are strengthened by experiments in which researchers momentarily activate materialistic values in study participants. After being primed with money-relevant (vs. control) stimuli, adults and children distance themselves more from others and behave in less pro-social ways (Gasiorowska, Zaleskiewicz, & Wygrab, 2012; Goldberg & Gorn, 1978; Roberts & Roberts, 2012; Vohs, Mead, & Goode, 2006; Wierzbicki & Zawadzka, 2016). Priming with money (vs. control) stimuli also leads to increases in social dominance orientation (Caruso, Vohs, Baxter, & Waytz, 2013) and more selfish behaviors in community and environmentally-relevant resource dilemmas (Bauer et al., 2012; Frey & Oberholzer-Gee, 1997).

Cross-national findings yield similar conclusions. Kasser (2011) obtained data on the extent to which citizens of 20 economically-developed nations prioritized hierarchy and mastery cultural values (i.e., values for money, status, power, achievement, etc.; Schwartz, 1999) relative to egalitarian and harmony values (i.e., self-transcendence and intrinsic values). After controlling for variations in national wealth, results showed that, compared to nations less focused on wealth, status, etc., more materialistic nations had children with lower levels of well-being, aimed more advertising per hour at children, had national maternal leave policies that were less generous, and emitted more CO_2 per capita (thus contributing to more climate disruption).

In sum, the existing evidence consistently documents that the more that people (and cultures) prioritize materialistic values and goals, the less kindly they treat other people and the planet. Such behaviors almost certainly will undermine the well-being of other people, other species, and future generations. Compared to work on materialism and personal well-being, the body of literature on materialism and others' well-being is still relatively new and under-researched. More work is needed in an array of diverse cultures with people of varying ages to explore the generalizability of these results. Future research is also required to test why materialistic values are negatively associated with pro-social and pro-environmental attitudes and behaviors; while the conflicting values perspective outlined at the start of this section seems a sensible hypothesis, it has not received sufficient direct empirical scrutiny.

Interventions to Decrease Materialism

Given the array of problems associated with highly prioritizing materialistic values and goals, it seems worthwhile to develop ways to diminish their prevalence in people, organizations, and society. One

approach, of course, is to implement policies aimed at this end; I have written elsewhere about such policies (see Kasser, 2016a, 2016b; Kasser & Linn, 2016) so will not discuss those types of recommendations in the current chapter. Instead I will review three types of person-level interventions that preliminary research suggests hold particular promise for decreasing materialism.

The first set of interventions is derived from research reviewed above on the human value system. Recall that this body of work shows that materialistic values stand in relative conflict with intrinsic, self-transcendece, and spiritual values (see Figure 1). As such, if people are encouraged to more highly prioritize these latter types of aims, then their focus on materialistic values should diminish. Indeed, several short-term experiments (Dechesne et al., 2003; Fritsche, Jonas, Kayser, & Koranyi, 2010; Stillman, Fincham, Vohs, Lambert, & Phillips, 2012; Weinstein, Przybylski, & Ryan, 2009) have found just that: Priming people with spiritual, pro-environmental, and pro-social values results in short-term decreases in materialistic values and behavior. Similar results were also obtained in a more extensive, multi-week intervention conducted by Lekes, Hope, Gouveia, Koestner, and Philippe (2012). In this study, college students were randomly assigned to write about either their two most important intrinsic values or their typical daily tasks (e.g., cooking). Participants in the intervention group received emails over the course of the next month reminding them of their intrinsic values, inviting them to reflect on those values, and providing them with inspirational quotes relevant to those values; participants in the control group received parallel emails. Results showed that at the end of the study, the control group's values were unchanged, but those participants in the intrinsic-activation group who reported getting immersed in the study's activities shifted away from extrinsic, materialistic values and toward intrinsic values. Further, this shift in values was associated with increases in personal well-being. Unfortunately, Lekes et al. did not follow the participants for very long after the intervention ended, so we do not yet know whether this promising type of intervention can have more sustained effects on people's values and well-being; future research could certainly investigate whether this is the case.

A second type of intervention shown to decrease materialism involves inward reflection. Sheldon, Arndt, and Houser-Marko (2003) found that when people are merely asked to pause and reconsider the way in which they have previously rated their values, they typically, on second thought, place less importance on extrinsic and more importance on intrinsic values. Another type of inward reflection associated with low levels of materialism is mindfulness, or a non-judgmental awareness of one's experience (Brown & Kasser, 2005); in fact, training in mindfulness can make people more satisfied with their current financial situation, which, in turn, can increase their well-being (Brown, Kasser, Ryan, Linley, & Orzech, 2009). Gratitude reflections also cause people to de-prioritize materialistic values (Lambert, Fincham, Stillman, & Dean, 2009), as do deep reflections on one's own death. That is, while brief reminders of one's death typically increase materialism (e.g., Kasser & Sheldon, 2000), a few studies have documented that engaging in deep, sustained reflections about one's death decreases materialistic values and behaviors (Cozzolino, Staples, Meyers, & Samboceti, 2004; Lykins, Segerstrom, Averill, Evans, & Kemeny, 2007); these effects are particularly strong for people high in the personality trait of Openness to Experience (Prentice, Kasser, & Sheldon, 2017). Together, this literature suggests that interventions involving inward reflection might decrease materialism, but the processes involved in this effect are not well-understood. Does inward reflection address and alleviate the feelings of insecurity known to orient people towards materialistic values (see Kasser, 2016a)? Does reflection help people get in touch with their psychological needs, and thus orient them towards intrinsic values? Is mindfulness really the catalyst? These are questions future research could address.

The third type of intervention addresses the well-established body of literature showing that, compared to less materialistic children, materialistic children ingest more advertising through their frequent exposure to commercial media (see Kasser, 2016a). These interventions therefore attempt to decrease children's exposure to, and acceptance of, social models proclaiming the worth of materialistic aspirations. Some work shows that when parents actively teach their children about the purposes of advertising and criticize ads' intentions, children's materialistic tendencies decline (Buijzen, 2007; Buijzen & Valkenburg, 2005). Kasser et al. (2014) integrated this work with ideas derived from the other types of interventions described above by testing an in-depth intervention to decrease adolescents' materialism. After completing baseline measures of well-being and materialism, adolescents and one of their parents were randomly assigned to a no-treatment control group or to an intervention adapted from an established financial literacy curriculum. Over the course of three, 3-hour group sessions, adolescents and their parents engaged in a variety of activities designed to help the adolescents question the messages they receive from consumer society that encourage them to spend money and acquire stuff; adolescents were also encouraged to save and share more of their money and to develop a values-based spending plan. Materialism and well-being were then assessed again ~2 and ~10 months after the intervention concluded. Two important sets of findings occurred. First, while adolescents in the control group increased in materialism over the course of

the study, adolescents in the intervention group decreased in materialism; thus, the intervention was successful and had lasting effects. Second, while adolescents who began the study high in materialism and did not receive the intervention decreased in self-esteem across the course of the study, adolescents who began the study high in materialism and received the intervention increased in self-esteem; thus, the intervention helped "at-risk" adolescents improve their self-image, and these effects were long-lasting.

In sum, preliminary evidence suggests that materialism can be decreased through each of the three types of interventions described above. More studies are needed, however, that include samples from a wider range of backgrounds, that involve sustained interactions with study participants (as opposed to one-shot, brief interventions), and that assess study participants' materialism levels for some months (or years) after the study has ended (as opposed to immediately afterwards). More tightly controlled intervention studies with stronger, placebo-treatment control groups are also necessary to determine whether demand characteristics might explain the apparent success of some interventions. Some evidence suggests that the decreases in materialism that occur after successful interventions are associated with increases in well-being, but more studies are needed to replicate such findings. Finally, no studies, to my knowledge, have explored whether interventions that decrease materialism also decrease materialistic individuals' tendency to treat other people and the Earth in ways that undermine others' well-being; research is needed to explore these types of outcomes.

Conclusion

In conclusion, I hope this review has helped readers to see that empirical evidence supports the conclusions that: a) materialism can be fruitfully understood as a fundamental aspect of the human value system; b) the more that people prioritize materialistic values and goals, the lower their personal well-being; c) the more that people prioritize materialistic values and goals, the more likely they are to treat other people and the Earth in ways that undermine others' well-being; and d) it is possible to intervene in people's lives in ways that decrease their focus on materialism and increase their well-being. While substantial research supports each of these conclusions, I hope that readers also see that much empirical work remains to be done to flesh out and better explain each of these conclusions.

End Notes

[1]Given this definition and these operationalizations of materialism, the current chapter does not review the growing research literature on the associations between well-being and *how* people use their money, e.g., if they spend it on experiences (Van Boven & Gilovich, 2003) or prosocially (Dunn, Aknin, & Norton, 2008). It would be interesting, however to connect these two literatures more explicitly, especially given that experiential and prosocial spending might reflect a person's attempt to incorporate intrinsic values into their monetary behavior.

Abstract

This chapter summarizes what we know about value—SWB relations and identifies some of what we do not know but would like to know. We first discuss the nature of values and the structured system they form. We draw on the ten values in the Schwartz (1992) theory that form a circular motivational continuum. We note three theoretical perspectives on relations of values to SWB. The first perspective seeks to explain direct relations between values and SWB. A second generation of direct relations research explains variation in relations across samples by pointing to societal-level moderators. The second perspective examines the congruence (or similarity) between people's values and the values prevailing in their environment as a determinant of SWB. The third perspective sees the attainment of valued goals as the source of SWB. We present these perspectives and the literature based on them, and note ideas for future research throughout.

Keywords: Values, Subjective Well-being, Cross-Cultural Variations, Value Congruence

Research on relations of personal values to subjective well-being has begun to flourish only recently. This is surprising because our values represent what we consider important and worth pursuing in life, and our subjective well-being (henceforth SWB) represents how happy and satisfied we are with the life we are leading. This chapter summarizes what we know about value—SWB relations and identifies some of what we do not know but would like to know. We first discuss the nature of values and the structured system they form. We then note three theoretical perspectives on relations of values to SWB (Sagiv & Schwartz, 2000; Sagiv, Roccas & Hazan, 2004). The first perspective seeks to explain direct relations between values and SWB. The second examines the congruence (or similarity) between people's values and the values prevailing in their environment as a determinant of SWB. The third sees the attainment of valued goals as the source of SWB. We present these perspectives and the literature based on them. Throughout, we note ideas for future research.

What Values Are and How They Are Structured

Both psychologists and lay people view values as broad motivational constructs that express what is important to people (e.g., Rohan, 2000; Rokeach, 1973; Schwartz, 1992). Based on their values, individuals perceive acts, objects, people, and events to be more or less desirable (Feather, 1995; Schwartz, 1992). People's values are central to their identities and concepts of self (Hitlin, 2003; Rokeach, 1973). Are they also related to our sense of well-being?

Most theorists agree in defining basic values as desirable, trans-situational goals, varying in importance, that serve as guiding principles in people's lives (Schwartz, 1992; cf. Kluckhohn, 1951; Rokeach, 1973). Each person holds numerous values (e.g., achievement, security, benevolence) with varying degrees of importance. Schwartz (1992, 2006, 2015) summarized six defining features of basic values found in the literature. (1) Values are beliefs, inextricably linked to affect. (2) Values refer to desirable goals. (3) Values transcend specific actions and situations. (4) Values serve as standards to guide selection and evaluation of people, events, actions, and policies. (5) Values are ordered in a hierarchy by their relative importance. (6) It is the *relative* importance of the values relevant to any attitude or behavior that motivates and guides that attitude or behavior.

The above features characterize *all* values. What distinguishes one value from another is the type of goal or motivation that the value expresses. Recognizing that every language includes thousands of value terms, researchers have proposed more inclusive basic values for studying value origins and consequences (e.g., Rokeach, 1973). The most popular current classification is from the theory of basic values by Schwartz (1992, 2015). This theory defines ten broad values according to the motivation that underlies each one. We draw on this theory to frame our examination of direct relations between values and SWB.

Presumably, the ten values are universal. This is because the values are based on one or more of three universal requirements of human existence: needs of individuals as biological organisms, requisites of coordinated social interaction, and survival and welfare needs of groups. People cannot cope

successfully with these requirements of human existence alone. To cope with them, people must articulate appropriate goals, communicate with others about these goals, and gain cooperation in pursuing them. Values are the socially desirable concepts used to represent and communicate these goals.

Figure 1 presents the ten motivationally distinct values in the form of a circular continuum. There is a wedge for each value. Values in opposing wedges in the circle conflict with one another motivationally (e.g., stimulation vs. security). Values in adjacent wedges are compatible (e.g., conformity and tradition). Two bi-polar, higher order dimensions summarize the relations among the ten values (Figure 1). *Self-transcendence versus self-enhancement* describes a conflict between values that express concern for the welfare and interests of others versus values that express concern for one's own interests above those of others. *Openness to change versus conservation* describes a conflict between values that emphasize independence of action, thought, and sensations and readiness for change versus security, predictability, and resistance to change. The theory proposes that this circular structure describes the pattern of conflict and compatibility among values across cultures. Research in over 80 countries largely confirms the circular motivational continuum of values (Schwartz, 2017). This suggests a universal organization of human motivations.

Figure 1. The circular structure of ten basic values, four higher order values, and two underlying motivational sources (adapted from Schwartz, 2015).

The outer two circles in Figure 1 specify two other principles that organize relations among the values. We discuss these principles later in this chapter. There, we cite literature that uses them to explain the associations of values to SWB.

Table 1 lists the ten values in their order around the circle. Each is defined in terms of its motivational goal.[1] Conceiving values as organized in a circular motivational continuum has an important implication: Any variable that is especially congruent with one basic value (e.g., supporting immigration with universalism) should also be relatively congruent with the adjacent values (benevolence and self-

direction) but should conflict with the opposing values (power, security and achievement). As we shall see, this pattern generally holds for associations of values with SWB.

Table 1. Ten basic values and their motivational goals.

Value	Motivational goals
Achievement	Personal success, demonstrating competence according to social standards
Power	Social status and prestige, control or dominance over people and resources
Security	Safety, harmony and stability of society, of relationships, and of self
Conformity	Restraint of actions likely to upset others and violate social expectations or norms
Tradition	Respect, commitment and acceptance of the customs and ideas that traditional culture or religion provide the self
Benevolence	Preservation and enhancement of the welfare of people with whom one is in frequent personal contact
Universalism	Understanding, and protection for the welfare of all and the environment
Self-Direction	Independent thought and action-choosing, creating, exploring
Stimulation	Excitement, novelty and challenge in life
Hedonism	Pleasure and sensuous gratification for oneself

Adapted from Schwartz (1992).

There are three main theoretical approaches to understanding relations between values and SWB. One approach holds that the specific motivational content of a value determines its influence on SWB. This approach postulates that inherent properties of particular values either promote or undermine SWB. That is, some values are 'healthy' and others 'unhealthy' (Sagiv & Schwartz, 2000; Strupp, 1980). A second approach emphasizes the congruence or similarity between a person's values and the values prevailing in the environment. A third approach emphasizes the extent to which the environment constrains or facilitates people's attainment of their valued goals. A third approach emphasizes the effects of successfully attaining valued goals on SWB. We discuss each approach in turn.

Direct Associations of Values With SWB: Healthy and Unhealthy Values

Theorizing by psychotherapists about value-SWB associations identified values that emphasize autonomy, responsibility, and fairness as healthy and those based on security, conformity, or status needs as unhealthy (Bergin, 1991; Strupp, 1980). Bilsky and Schwartz (1994) were the first social psychologists to identify healthy vs. unhealthy values. Building on Maslow (1943) and Rokeach (1973), they argued that healthy values are cognitive transformations of growth needs and unhealthy values are cognitive transformations of deficiency needs. They classified stimulation, self-direction, universalism, benevolence, and achievement as transformations of growth needs. Success in attaining the goals of these self-actualizing values leads people to attribute more importance to them. They classified conformity, security, and power values as transformations of deficiency needs. Failure to attain the goals of these self-protective values and thereby overcome deprivation and threat leads people to attribute more importance to them.

Self-determination theory (Deci & Ryan, 1995; Ryan & Deci, 2001) also links human well-being to the satisfaction of innate psychological needs (see Heintzelman, this handbook). It specifies three needs whose satisfaction promotes well-being: autonomy, competence, and relatedness. These needs are

transformed into intrinsic, self-actualizing goals or values. Parallels between the three intrinsic goals and the Schwartz (1992) values are autonomy—self-direction, competence—achievement, and relatedness—both benevolence and universalism (Sagiv & Schwartz, 2000). Self-determination theory also identifies extrinsic goals that derive from the need to obtain other people's approval, admiration, and praise and to avoid social censure (e.g., financial success, popularity, social dominance). The Schwartz values parallel to extrinsic goals include security, conformity, power, and, perhaps, tradition.

Sagiv and Schwartz (2000) noted three mechanisms through which values and SWB may be associated. First, pursuing healthy values may lead to perceptions (e.g. people are kind), attitudes (e.g., tolerance), or behaviors (e.g., helping) that, in turn, increase well-being. Conversely, pursuing unhealthy values may lead to perceptions (people are threatening), attitudes (intolerance), or behaviors (shunning others) that, in turn, undermine well-being. Second, pursuing healthy values may lead directly to well-being because it satisfies intrinsic, self-actualizing needs. In contrast, pursuing unhealthy values does not satisfy intrinsic needs and may require stressful ego-protective activity.

These first two mechanisms posit that pursuing particular values causally influences SWB. A third mechanism posits the reverse causal direction, the level of SWB influences value priorities. People who feel safe and satisfied with life have the emotional and cognitive resources to pursue autonomy (self-direction) and excitement (stimulation) and to care for the welfare of close others (benevolence) or society and nature (universalism). People who feel unsafe and threatened, in contrast, are preoccupied with their own problems and lack the resources to pursue these values. They emphasize values whose realization promises greater safety, certainty, and relief from anxiety (security, conformity, tradition, and power).

First Generation Studies

Sagiv and Schwartz (2000) published the first empirical study of associations between the ten values and SWB. They drew upon the above ideas to hypothesize that self-direction, benevolence, universalism, stimulation and achievement values promote SWB and that power, conformity, security, and tradition values to undermine SWB. As the value theory implies, the five values they expected to promote SWB are adjacent in the value circle as are the four values they expected to undermine SWB. They had no expectation for hedonism values, which lie on the boundary between these two sets. Subsequent researchers proposed similar or no hypotheses, simply examining the observed correlations.

We found eight studies of direct value-SWB associations in non-representative student or adult samples from seven countries (see Table 2). The SWB index was life satisfaction in most studies and positive affect in a few. Table 2 reveals a consistent, though not perfect, tendency across studies for power values to relate negatively and for benevolence, stimulation, and self-direction values to relate positively to SWB, as hypothesized.[2] Hedonism also related positively. Considering only significant findings, there was also a tendency for universalism values to relate positively and conformity values to relate negatively to SWB. Findings for achievement, tradition, and security were inconsistent. These studies offer only partial support for the initial theorizing. Although small sample sizes and cultural differences might account for some inconsistencies, improved theorizing and more rigorous research were clearly needed.

Schwartz (2012) and Sortheix and Schwartz (2017) suggested a new theoretical model of direct value-SWB associations. They proposed that relations of values to SWB depend upon the interplay between two motivational underpinnings of values. Every value has a social or a person focus, but it also expresses a self-expansive growth orientation or a self-protective, anxiety-based orientation (Schwartz, 2006, 2015). The self-protection concept improves on the earlier deficiency concept. Self-transcendence and openness to change values express self-expansive, growth orientations. They oppose conservation and power values, which express self-protective, anxiety-control orientations (the top vs. bottom values in the outer circle of Figure 1). Achievement values can be both self-expansive (expressing competence) and self-protective (meeting social standards) as Figure 1 shows.

Note. *p <. 05, **p < .01. PO = power, AC = achievement, HE = hedonism, ST = stimulation, SD = self-direction, UN = universalism, BE = benevolence, TR = tradition, CO = conformity, SE = security, SWLS = Satisfaction with life scale, PA = Positive affect, LS = Life satisfaction, PANA = Positive and negative affect, SWB = Subjective well-being (LS and PANA).

These authors argued that the growth orientation and the person focus both promote SWB (see Table 3). The growth orientation does so because it motivates self-actualizing, free expression of own ideas, abilities, and feelings (openness to change) and self-expansion to include concern for the welfare of others (self-transcendence). It satisfies intrinsic needs for autonomy and relatedness. The person focus does so because it motivates expression of one's ideas, abilities, and feelings (openness to change) and the pursuit of personal success and gains (self-enhancement).

In contrast, the self-protective, anxiety-control orientation and the social focus both undermine SWB. The self-protective orientation reflects a need to avoid threat and anxiety. It undermines well-being because it motivates subordinating the self to socially imposed expectations (conservation) or asserting control and dominance to overcome anxiety (self-enhancement). It is directed toward extrinsic needs for approval and status. The social focus undermines well-being because it draws attention to needs and problems of others that may arouse concern and worry (self-transcendence) and to social expectations and obligations that limit autonomy (conservation).

Table 3. Theorized associations between values and SWB based on crossing two sets of motivations underlying values: growth versus self-protection and person versus social focus.

Motivational Bases of Values and their Effects on SWB	Growth—Positive (+)	Self-Protection—Negative (-)
Person Focus—Positive (+)	Hedonism, Stimulation, Self-Direction (+ +)	Power Achievement (+ -)

Social Focus—Negative (-)	Benevolence Universalism (+ -)	Security, Tradition Conformity (- -)

Note: (++) = positive associations; (--) = negative associations; (+-) and (-+) = complex associations (Sortheix & Schwartz, 2017).

Based on this theorizing, Sortheix and Schwartz (2017) hypothesized: (a) Openness to change values, which combine a growth orientation and person focus, relate positively to SWB. (b) Conservation values, which combine a self-protection orientation and social focus, relate negatively to SWB.

The combinations of orientation and focus that underlie self-enhancement values and self-transcendence values have opposing implications for SWB (see Table 3). For achievement values, Sortheix and Schwartz (2017) expected no direct association with SWB across countries. They anticipated a trade-off between the self-protective interest in the extrinsic goal of approval by others and the person focus on the intrinsic goal of developing one's competence. They assumed that the opposing implications of the self-protection orientation and the person focus for SWB would be approximately balanced.

For power values, they expected a negative association with SWB because the negative implications would outweigh the positive. The self-protection goal of overcoming threats to one's status implies a sense of anxiety and need to control that may undermine SWB. Moreover, the positive implications of the person focus—free self-expression—would be neutralized by negative implications of pursuing self-interested dominance and wealth. These are extrinsic goals (Ryan & Deci, 2001) whose pursuit increases anxiety (Kasser & Ryan, 1996) and often elicit negative reactions from others.

For universalism values, they expected no association with SWB. They assumed that the negative implications of concern for the often-intractable problems of vulnerable out-group members and the wider society (social focus) would neutralize the positive implications of the self-expansive transcendence of personal interests (growth).

For benevolence values, they expected a positive association with SWB. They assumed that the negative implications of concern for the welfare of close others (social focus) are offset by its positive outcomes. This concern often motivates actions that promote good relations with family and friends and satisfy relatedness needs (Deci & Ryan, 1995). The positive implications of the self-expansive transcendence of personal interests (growth) should outweigh any weak negative implications of concern for close others (social focus).

Sortheix and Schwartz (2017) analyzed representative data from three rounds of the European Social Survey. Multilevel analyses across 35 countries confirmed their expectations for the associations of all ten values with a life-satisfaction index of SWB (Table 2). This supported their theorizing that what determines a value's association with SWB is its combination of growth- versus protection-orientation and person- versus social-focus.

Second Generation Studies: Contextual Moderation

Three recent studies sought to explain variation across samples in the direct relations of values with SWB. These studies introduced contextual variables as moderators that might explain this variation. We present each study in turn.

Sortheix and Lönnqvist (2014) analyzed data from 25 representative national samples of the European Social Survey. They drew upon Schwartz' (1992) distinction between the social and person focus of values. Social-focused values (universalism, benevolence, tradition, conformity and security) primarily regulate how we relate socially to others and affect their interests (on the right in Figure 1). Person-focused values (self-direction, stimulation, hedonism, achievement, and power) primarily regulate how we express personal interests and characteristics (on the left in Figure 1). Sortheix and Lönnqvist (2014) assumed that values' association to SWB depend on how well values function to help individuals cope with their environment. Different environmental contexts provide different opportunities and impose different affordances or constraints on the successful pursuit of valued goals (Gibson, 1977). They proposed that the level of human development in a country (HDI: affluence, health, and education) moderates direct value—life satisfaction (LS) relations.

For social-focused values, Sortheix and Lönnqvist (2014) argued that high HDI contexts (e.g. Norway) provide more resources for and fewer constraints against attaining their goals (e.g., equality, harmony). Moreover, these values motivate prosocial behavior and contribute to social capital and trust (Helliwell & Putnam, 2004; Devos, Spini, & Schwartz, 2002). They further argued that low HDI contexts (e.g., Ukraine) provide few resources for attaining social harmony and constrain people to look out for and

protect their own interests and the interests of close others. Sortheix and Lönnqvist (2014) noted two exceptions. They argued that security values are primarily concerned with self-protection, despite their social focus. Moreover, benevolence values express concern for close others that motivates people to help family and friends and promote harmony under all conditions. They hypothesized: (a) In low HDI countries, social focused-values (except benevolence) relate negatively to SWB. (b) In high HDI countries, social-focused values (except security) relate positively to SWB.

For person-focused values, Sortheix and Lönnqvist (2014) distinguished between openness to change and self-enhancement values. They noted that openness to change values satisfy autonomy needs and consistently related to higher well-being. They argued that openness to change values motivate behaviors that are especially instrumental for adapting to the difficult and unpredictable living conditions of low HDI environments. They further argued that power and achievement values motivate competitive, self-assertive behavior that conflicts with the values in high HDI contexts but could be especially instrumental for coping with the limited resources in low HDI contexts. They, therefore, hypothesized: (a) Openness to change values relate positively to SWB across countries, but more so in low HDI countries. (b) Self-enhancement values relate negatively to SWB in high HDI countries but positively in low HDI countries.

Across all countries, without considering moderation by HDI, Sortheix and Lönnqvist (2014) found that benevolence, self-direction, stimulation, and hedonism related positively to life satisfaction whereas power, security, and conformity related negatively (Table 2). They tested their two moderation hypotheses using the cross-level interactions between HDI and values in predicting SWB. All interactions were significant except for benevolence and hedonism values. They correlated positively with SWB across countries, regardless of HDI levels. In low HDI countries, as hypothesized, the social-focused values (except benevolence) related negatively to SWB. In high HDI countries, as hypothesized, the social-focused values (except security) related positively to SWB, but the universalism and conformity correlations were not significant. Openness to change values related positively to SWB across countries, more so in low HDI countries, as hypothesized. Self-enhancement values related negatively to SWB in high HDI countries, and achievement related positively in low HDI countries. Contrary to the hypothesis, power values related negatively to SWB in low HDI countries. This study demonstrated that the socioeconomic context moderated eight of the ten associations between values and SWB. However, several findings did not fit the theorizing based on the social versus person focus, especially in high HDI contexts.

In their study presented above, Sortheix and Schwartz (2017; Schwartz, 2012) also addressed the variation in direct value-SWB associations across countries. They proposed that the cultural values that prevail in a society moderate the associations. Cultural values refer to society's normative system of value emphases. Specifically, they proposed Cultural Egalitarianism as the critical moderator. This cultural value emphasizes cooperative behavior out of personal choice, thereby preserving the social fabric (Schwartz, 2006, 2014). In egalitarian cultures, people are socialized to engage voluntarily in collaborative, productive work, based on internalized commitments, and to view all people as morally equal.

Sortheix and Schwartz (2017) generated moderation predictions by combining an analysis of the cultural context in societies low versus high in Cultural Egalitarianism with the implications of pursuing person-focused versus social-focused values. They asked whether pursuing each basic value might help compensate for what the cultural context fails to provide and whether the cultural context could compensate for what individuals' values cannot provide. They argued that person-focused values confer an advantage in low egalitarian societies. Such societies provide few resources, so, in order to succeed, individuals must exploit their own capacities and resources and take self-assertive initiatives. This can compensate, at least partially, for what is lacking in the non-supportive and threatening circumstances of low egalitarian societies. They, therefore, hypothesized: In low versus high Cultural Egalitarianism societies, (a) openness to change values relate more positively to SWB and (b) self-enhancement values relate less negatively to SWB.

In contrast, pursuing social-focused values is less likely to motivate behavior that can compensate for the instability, uncertainty, and selfishness that characterize low egalitarian societies. Conservation values, grounded in anxiety, are unlikely to motivate the energy, skill, and self-assertiveness to cope with the prevailing difficult circumstances. The needs of others, the concern of self-transcendence values, are liable to be more intense and disturbing in low egalitarian societies. Moreover, these values motivate harmony rather than the assertiveness and competitiveness that can overcome a lack of resources. They therefore hypothesized: In low versus high Cultural Egalitarianism societies, (a) conservation values relate more negatively to SWB and (b) self-transcendence values relate less positively to SWB.

The cross-level interactions that tested these hypotheses were all significant, and they confirmed all four hypotheses. This supported the theorizing about how person- versus social-focused values affect the

ability to cope with the difficult conditions in low egalitarian societies. Moreover, Sortheix and Schwartz (2017) compared the strength of Cultural Egalitarianism versus HDI as contextual moderators of value-SWB associations. The cultural variable of Egalitarianism was the stronger moderator for nine values, though not for power.[3]

Boer (2017) proposed that cultural factors and environmental threats (e.g., disease, wars) may singly or jointly moderate associations of values with affective well-being. She argued that economic, climatic, or safety threats strengthen the associations between affective well-being and the values that protect against threats (e.g., conservation values). Moreover, threat also interacts with culture. Adequate cultural responses to threat (e.g., cultural embeddedness) can diminish the impact of threat on value–well-being associations. Boer (2017) obtained some support for her views, using country as a proxy for the level of threat and of the type of culture. She compared small student samples from four countries. To assess her theorizing requires research that measures threat levels and types of culture directly and uses larger, more representative samples.

Value-Environment Congruence and SWB

The second approach to understanding relations of values to SWB emphasizes the extent to which people's values are congruent with (i.e., similar to) those in their environment, whatever the motivational content of their values. Sagiv and Schwartz (2000) proposed three mechanisms through which person–environment value congruence influences SWB.

The first mechanism refers to the opportunities and constraints that the environment affords for goal-attainment. *Environmental affordances* (Gibson, 1977) are likely to be more favorable to goal-attainment when a person's values are congruent with those prevailing in the environment. The second mechanism refers to the positive or negative *social sanctions* likely to be experienced in the environment. When people share similar values, these values take on normative force. Expressing congruent values promotes SWB because others validate them and provide social support. Expressing non-congruent values undermines SWB because others disapprove or even punish. The third mechanism refers to *internal value conflict*, conflict within one's own value system that may diminish SWB. This happens if values internalized from the environment contradict the values a person already espouses.

The studies of context as a moderator of direct value-SWB associations applied two of these mechanisms to explain moderation effects. These studies hypothesized and tested how variation in aspects of the context (HDI or Cultural Egalitarianism) affected the environmental affordances that constrained or facilitated attaining the goals of particular values. The environmental affordances moderated the associations of those values with SWB. In addition, Sortheix and Schwartz (2017) referred to the social sanctions mechanism to explain why power values relate negatively to SWB regardless of cultural values.

Researchers have applied the mechanisms that account for the effects of value-environment congruence on SWB to many environments (e.g., family, friends, organization, profession, and community). We discuss a selection of these.

Congruence with Reference Groups

Sagiv and Schwartz (2000) studied congruence between the values of business and of psychology students with the values prevalent in the departments in which they had chosen to study. They assumed that power values are more important than benevolence values in Israeli business schools, but the reverse is true in psychology, an assumption supported in Gandal, Roccas, Sagiv, and Wrzesniewski (2005). As expected, those who endorsed values congruent with the environment had higher well-being. Endorsing power values related positively to SWB among business students, but not among psychology students. Endorsing benevolence values related positively to SWB among psychology students, but not business students.

Studies of business students in Singapore (Kasser & Ahuvia, 2002) and Belgium (Vansteenkiste, Duriez, Simons, & Soenens, 2006) did not show the congruence effect, however. These studies measured extrinsic and materialist values in the self-determination theory tradition, not the power value. They found that business students had lower well-being the more importance they ascribed to materialist values. The opposing findings might reflect differences in the index of values, the actual values prevailing in the various business schools, national cultures, or something else. Further research is needed to clarify this.

Later studies operationalized value congruence objectively, correlating individuals' values with their group's average values. Sortheix and Lönnqvist (2015) found that students in Argentina, Bulgaria, and Finland whose values were more congruent with students in their discipline (psychology or business) had higher life satisfaction and positive affect and lower negative affect. Moreover, value congruence led to better interpersonal relationships, which partially mediated the value congruence - SWB association. In a longitudinal study, Sortheix, Olakivi, and Helkama (2013) found that Finns whose values were more congruent with those of others in their small community had better psychological health.

In a Russian national sample, Khaptsova and Schwartz (2016) found greater life satisfaction among those whose values were more congruent with others with similar socio-demographic characteristics (age, gender, education, and ethnicity). Thus, the value congruence effect extended even to an implicit reference group with which one did not interact directly.

Numerous organizational studies demonstrate beneficial effects on SWB of sharing values with colleagues or with the organization. For example, perceived compatibility between individual and organizational values was critical in predicting higher work well-being (Leiter & Maslach, 1999). Congruence between personal values and the core values of one´s profession may also protect against poor well-being. Social work is a profession that emphasizes benevolence and universalism values as opposed to power and face (prestige) values (cf. NASW Code of Ethics, 2008). Tartakovsky (2016) found that the more social workers endorsed benevolence and universalism values and the less they endorsed power and face values, the less exhaustion and burnout they experienced.

Value Congruence Among Marital Couples

Research using difference scores and profile correlations to measure value congruence found that Israeli couples' overall value similarity correlated with their relationship satisfaction (Gaunt, 2006). A study of Finnish couples examined similarity on each of the ten values separately (Leikas, Verkasalo, Ilmarinen, Vartiainen, & Lönnqvist, 2017). The relationships between value similarity and relationship satisfaction depended on gender. For men, similarity with their spouse in self-direction values related positively to satisfaction. For women, similarity with their spouse in conformity values related negatively to satisfaction. For both men and women, similarity with their spouse in hedonism values related positively to satisfaction. However, value similarity mattered less for couples' satisfaction than similarity in political attitudes and religiosity, variables that are influenced by underlying values (Leikas et al., 2017).

Value Congruence with the Societal Culture

If individuals strongly identify with the society in which they live, we might expect that congruence between their values and those in the society would affect SWB. Zilberfeld (2010) assessed this possibility in a study of ultra-orthodox students in Israel. Ultra-orthodox society emphasizes the embeddedness of the person in the group and rejects autonomous thought and action. As expected, SWB correlated positively with endorsing conformity values and negatively with endorsing self-direction values. This pattern of correlations did not replicate among students from the wider Israeli society that does not share the same cultural value emphases.

On the broader societal level, however, there is little support for the hypothesis that similarity between individuals' values and those of their country promotes SWB. Schwartz (2012) tested this hypothesis with data from representative samples from 32 European Social Survey countries. Contrary to the hypothesis, congruence with the average value in the country increased the negative correlations of conservation values with SWB and decreased the positive correlations of openness to change values with SWB. Research on cultural estrangement also questions the positive role of congruence between individuals' values and those in their society. Cultural estrangement is the inverse of congruence. It refers to the discrepancy between personal values and perceived societal values (Bernard, Gebauer, & Maio, 2006). The congruence hypothesis would predict a negative association between cultural estrangement and mental health indicators. However, Bernard et al. (2006) found no association between value discrepancies and psychological outcomes.

Perhaps value congruence with one's society enhances SWB only when individuals are aware of the prevailing cultural values and identify strongly with the society. This is a topic for future research.

Caveat

A problem overlooked in some similarity studies is that apparent similarity effects may be due to the value scores of the individuals and/or groups compared. To uncover unique effects of similarity requires first controlling for the actual value scores. Such controls may eliminate similarity effects (e.g., Dyrenforth, Kashy, Donnellan, & Lucas, 2010) or leave them unchanged (e.g., Khaptsova & Schwartz, 2016; Sortheix & Lönnqvist, 2015).

Attaining Valued Goals and SWB

This third approach is concerned with the process through which values lead to SWB. It proposes that the link between a value and SWB depends upon the successful attainment of the goals the value motivates a person to pursue. Unlike the healthy values approach, it does not assume that holding particular values (e.g., self-direction) is conducive to SWB. Rather, it assumes that people experience high SWB to the extent they attain the goals they. Some evidence suggests that simply attaining a valued goal is sufficient to enhance SWB (e.g., Oishi, Diener, Suh, & Lucas, 1999). Other evidence suggests that the

effect on SWB depends on the nature of the goal that is attained (e.g., Sheldon & Kasser, 1998).

In a study by Oishi et al. (1999), students reported daily for 23 days how satisfied they were with their achievements and their social life. They also reported whether it was a good or bad day. Subsequently, they completed a measure of the importance they ascribe to the ten basic values. Students' goal attainment (indicated by their daily satisfaction with their achievements and social life) predicted their daily well-being. Except for achievement, their values did not (Table 2). But their values did moderate the effect of goal attainment. Satisfaction with achievements predicted well-being more strongly for those high in achievement values than for those low in achievement values. Likewise, satisfaction with their social life predicted well-being more strongly for those high in benevolence values than for those low in benevolence values.

Another analysis showed that various activities were more or less satisfying to the extent that they were consistent with individual's important values (Oishi et al. 1999). For example, the more people valued power, the more satisfaction they gained from performing power-related activities (e.g., buying expensive clothes). Findings were similar for the effects of achievement, universalism, benevolence, and stimulation/hedonism values on the satisfaction gained from their related activities. Moreover, the more importance individuals attributed to a value, the less satisfaction they gained from activities related to the values on the opposite side of the value circle. For example, the more people valued universalism, the less satisfaction they gained from power-related activities. The third analysis in Oishi et al. (1999) showed that values also moderated relations between satisfaction in particular life domains and global life satisfaction. For example, satisfaction with grades related more strongly to life satisfaction the more important achievement values.

In sum, values led to increased SWB when the goals they motivated were successfully attained. This process applied to all values in Oishi et al. (1999). However, other research suggests that not all goal attainment is beneficial for SWB. Most of this research is grounded in self-determination theory and does not measure the ten basic values explicitly, but we can nonetheless extrapolate from it.

In three studies of adolescents and young adults, Kasser and Ryan (1993) examined associations of individuals' aspirations with various indexes of well-being. Aspirations for financial success (i.e., power values) related negatively to well-being, fitting the healthy values expectation. Significantly for the goal attainment approach, anticipating attainment of the desired financial success also led to poorer well-being. In a diary study of students, Sheldon and Kasser (1998) examined whether students' goal progress during a semester promoted their well-being. Those who made more progress toward their goals experienced increased SWB over time. However, this occurred only if the goals they pursued were high in self-determination and/or in intrinsic orientation. Such goals largely express growth values. Attaining extrinsic (power-related) goals did not affect SWB. Kasser and Ryan (2001) reported similar findings. They found that attainment of intrinsic goals related to increased well-being, but the attainment of extrinsic goals did not.

The different outcomes of attaining achievement and power-related goals in Oishi et al. (1999) and the research based on the self-determination theory discussed above (see also, Kasser & Ahuvia, 2002; Vansteenkiste et al., 2006) points to the need for further research. Such research could measure both the ten basic values and the intrinsic/extrinsic values explicitly. It could identify the circumstances under which each value motivates goals whose attainment does or does not promote SWB. It would also be instructive to examine relations between the ten basic values and people's intrinsic and extrinsic aspirations.

Future Research

Moderation and Mediation Studies

A clear message of this chapter is that value-SWB associations vary across contexts. We saw that both a socioeconomic (HDI) and a cultural (Cultural Egalitarianism) characteristic of societies moderated these associations. Other potential societal moderators also merit investigation. For example, researchers might consider levels of democracy, social expenditure, corruption, and rural/urban differences, on the one hand, and cultural values like embeddedness, hierarchy, and harmony, on the other. Studies in non-Western societies might reveal other patterns of moderation. Theoretical analyses could suggest how espousing each value might enhance or undermine successful coping with the environmental demands, constraints, opportunities, and sanctions associated with variation on potential moderators.

Less research attention has been paid to characteristics of individuals that may moderate value-SWB associations. One potential moderator for which there is some support is people's social identities (Sagiv, Roccas, & Oppenheim-Weller, 2015). Identities provide different opportunities and constraints for attaining valued goals. Whether particular values are likely to promote SWB may depend, therefore, on which of a person's social identities he or she is enacting. For example, endorsing power values may

enhance SWB for a person when enacting her manager identity but undermine SWB when enacting her friend identity. Identities may also mediate relations of values to SWB. Espousing values consonant with a social identity (e.g., self-direction values, but not conformity values, with an artist identity) may enhance SWB by validating the identity. Links between values, identities, and SWB are a fruitful domain for future research. Studies of self-esteem suggest that internal conflict or confusion between the values one espouses in different contexts may also damage SWB (e.g., Daniel, Boehnke, & Knafo-Noam 2016).

No research we found treated age or gender as possible moderators of value-SWB associations. We analyzed data from the representative samples from 27 countries in the first three rounds of the European Social Survey to assess whether considering these ubiquitous individual characteristics might be worthwhile. We categorized age into four groups: 15-29, 30-45, 45-65, and 65+ years. Correlations of values and SWB revealed monotonic trends across age groups for eight of the ten values. With increasing age, openness to change values correlated more positively with SWB, whereas conservation and self-enhancement values correlated more negatively. Although these findings are based on cross-sectional data, they suggest that theorizing about why age acts as a moderator assessing possible explanations is worthwhile. Findings for gender also revealed significant moderation. Openness to change and self-transcendence values correlated more positively with SWB among women than among men, whereas conservation and power values correlated more negatively. So, moderation by gender also deserves further study.

Taken together, two cross-national studies suggest that emotions may mediate relations of values to SWB. One study revealed that people's values influence the emotions they desire to feel (Tamir, et al. 2016). For example, people who endorse benevolence values want to feel more empathy or love and people who endorse power values want to feel more anger or hatred. The second study (Tamir, Schwartz, Oishi, & Kim, 2017) found that people who experience the emotions they desire to experience, whether pleasant (e.g., empathy or love) emotions or unpleasant (e.g., anger or hatred) emotions, are happier. Thus, people are happier the more they experience the emotions that their own values promote, whatever the content of their values.

We found only one study that examined both values and personality traits together as predictors of SWB. Haslam, Whelan, and Bastian (2009) found that one or more Big 5 traits fully mediated relations of four values to SWB in a sample of Australian students. For example, extraversion mediated relations of stimulation and self-direction with SWB. Further studies should examine joint effects of values and traits in larger and more representative samples. Might there be additive effects? Or might they interact in their effects on SWB?

Causality in Value-SWB Relations

Throughout this chapter, we have spoken of relations or associations between values and SWB. Long-term longitudinal studies are required to establish whether value change affects subsequent change in SWB and/or vice versa. Because values change quite slowly and only in response to major changes in life conditions whereas SWB is more volatile, it seems more plausible to expect causality to flow primarily from values to SWB. Three studies by Kasser et al. (2014) examined change in SWB and materialism values (related to power value) in different age groups and cultures. In all three studies, decreases in materialism values led to increased SWB whereas increases in materialism lead to decreased SWB. Moreover, changes in well-being predicted changes in materialism. The SWB to materialism effect was weaker, as our reasoning suggests, but it does indicate some reciprocal causality.

Experimental studies have examined causality in short-term relations between various types of well-being and materialism values. Some primed materialist values and observed the impact on well-being (e.g., study 4 in Kasser et al., 2014), others manipulated well-being and observed the impact on state materialism (e.g., Solberg, Diener, & Robinson, 2004). The findings support reciprocal causality between values and SWB.

These studies all examined materialism values. It is important to study value-SWB causality for other values both longitudinally and experimentally. The strength and direction of causality between values and SWB may depend upon the specific values in question.

Different Aspects of SWB

In reviewing the various studies, we have not distinguished among different aspects of SWB. Although values usually relate to most aspects of SWB similarly, there may be some systematic differences worth studying. For example, social well-being, defined as a sense of integration, cohesion, acceptance, and contribution to society (Keyes, 1998), correlated positively with conformity and negatively with self-direction among Iranian students (Joshanloo & Ghaedi, 2009). These findings may reflect unique characteristics of this sample or of Iran. However, it also possible that the relationships of conformity and

self-direction values to the social aspects of SWB differ from relations to other aspects of SWB in some conditions.

The studies of value-SWB associations we reviewed investigate satisfaction with life, happiness, and positive and negative affect. These SWB indicators correlate positively with meaning in life, but the association is far from perfect (Baumeister, 1991; Oishi & Diener, 2014). Meaning is an important aspect of well-being. Research on relations of the basic values to meaning in life and on the environmental and individual characteristics that moderate them would provide an important addition to our understanding of how values affect the quality of life.

Recent Value Developments

We have focused on the ten basic values identified by Schwartz (1992). Recent theorizing and research (Schwartz et al., 2012; Schwartz, 2017) has refined these values and introduced two others (humility and face) that are recognized across cultures that may yield worthwhile new insights.

Implications for National SWB

National levels of SWB have become a tool to evaluate the progress of countries and to inform public policy (Diener, Lucas, Schimmack, & Helliwell, 2009). Most countries with the highest levels of SWB are in Scandinavia and West-Europe (Helliwell, Layard, & Sachs, 2012). These countries provide a favorable context of high Cultural Egalitarianism and socio-economic level. Countries with low levels of SWB tend to be low in Cultural Egalitarianism and socioeconomic level. Our findings imply that change in basic values would have different consequences for national SWB in more versus less favorable contexts. Increased emphases on self-transcendence and conservation values may enhance SWB in favorable contexts but may weaken SWB in unfavorable contexts. Increased emphases on self-enhancement values may weaken SWB in favorable contexts, but in less favorable contexts, achievement values could even enhance SWB. It is, therefore, necessary to consider the context when anticipating the kinds of value change that may help to improve people's well-being.

Conclusion

The literature reviewed here suggests that some values are healthier than others, though not under all circumstances. Theorizing based on combining the social- versus person-focus and the growth versus self-protection orientation of values explains direct value-SWB associations well. However, these associations vary across context. The context may refer to family, friends, neighborhood, organization, demographic peers, society, and more. Sharing values (congruence) with those in close social contexts enhances SWB. In both close and broad societal contexts, the opportunities and constraints the environment provides for attaining valued goals moderate value-SWB associations. We can understand variation across cultures and countries in the associations of particular values with SWB by identifying characteristics of the context that promote or block attainment of these values. With the recent flourishing of research on value-SWB relations, we anticipate many new insights.

Footnotes

[1]Recently, Schwartz and colleagues (Schwartz, et al. 2012; Schwartz, 2017) split the same circle into 19 more narrowly defined values in their refined value theory.

[2]We discuss the exceptions for business and psychology students in Sagiv and Schwartz (2000) below, under 'value-environment congruence'.

[3]This study also examined associations between values and depressive affect. Hypotheses were the mirror opposite of those for life satisfaction. All main effect hypotheses were confirmed. Cultural Egalitarianism moderated the associations with depressive affect for only four values in the predicted manner, however.

SOCIETAL DIFFERENCES AND POLICY

Happiness comes Naturally: Engagement with Nature as a Route to Positive Subjective Well-Being

By Ethan A. McMahan, Western Oregon University

Abstract

Empirical research consistently indicates that contact with the natural world is associated with broad psychological and physical benefit. Of particular interest are findings indicating that exposure to natural environments improves subjective well-being, suggesting that interacting with nature may be one route by which individuals may achieve and maintain a durable sense of happiness. In the current chapter, key concepts and influential theories concerning the effects of nature on well-being are described. Empirical research detailing the salutogenic effects of nature is then reviewed, with emphasis placed on four main areas of inquiry: (1) exposure to natural environments; (2) connectedness to nature and well-being; (3) physical proximity to nature; and (4) green exercise. Current limitations in the extant literature are discussed, and priorities for future research are outlined. Based on the present state of research in this domain, it is concluded that ample evidence documents the positive effects of nature on subjective well-being. However, additional research examining group differences in responses to nature, causal mechanisms accounting for the relationship between nature and well-being, and environmental factors impacting the effects of nature on well-being, among other topics, is necessary to develop a comprehensive and more nuanced understanding of the myriad ways in which happiness may be achieved through engagement with the natural world.

Keywords: Nature, Natural environments, Subjective well-being, Happiness

A large body of literature examining subjective well-being now exists, and scholars and laypeople alike are becoming more familiar with the factors that contribute to individual happiness. Of these factors, contact with nature and natural entities seems to be a particularly powerful route by which subjective well-being can be improved. For centuries, it has been observed that people experience happiness and, more broadly, positive feeling and functioning through connection with nature. Indeed, the notion that engaging with nature improves both psychological and physical well-being has been articulated in numerous ways by many notable individuals across recent history (Selhub & Logan, 2012). For example, John Muir, American naturalist and author, encouraged people to "Climb the mountains and get their good tidings," and by doing so "nature's peace will flow into you," (1901). Frederick Law Olmstead, architect of Central Park in New York City, espoused the importance of nature for optimal psychological functioning, stating that "the enjoyment of [natural] scenery employs the mind without fatigue and yet exercises it; tranquilizes it and yet enlivens it," (1865). Henry David Thoreau suggested that "we need the tonic of wilderness," (1854) explicitly recognizing the healing powers of nature, while Edward Abbey similarly articulated a need for natural environments, noting that "wilderness is not a luxury but a necessity of the human spirit," (1968).

Complementing and building upon the qualitative sentiments provided by well-known authors, scholars, and others regarding the importance of nature, a robust and growing body of scientific literature also indicates that contact with nature has salutary value for individual well-being. This research indicates that engaging with the natural environment is associated with increased positive affect and decreased negative affect (McMahan & Estes, 2015), higher levels of satisfaction with life (Biedenweg, Scott, & Scott, 2017), improved cognitive functioning (Berman et al., 2012), a sense of meaning in life (Passmore & Howell, 2014a), improved physiological functioning and physical health (Bowler, Buyung-Ali, Knight, & Pullin, 2010), and increased self-esteem (Zhang, Howell, & Iyer, 2014), among other positive outcomes. Thus, although contact with nature is of course not a panacea for all ills, evidence suggests that engagement with the natural environment exerts broad positive effects on human functioning, and further empirical investigation of the effects of nature would thus seem to be an important area of positive psychological inquiry.

Despite the seeming relevance of research on the beneficial effects of contact with nature for positive psychology, development of these two areas has occurred largely in parallel with little systematic exchange or explicitly identified connection between the two fields. Research on the effects of nature has

been conducted largely within the areas of environmental psychology, public health, urban planning, landscape aesthetics, and medicine (Bratman, Hamilton, & Daily, 2012), and has thus been guided by and interpreted with reference to the dominant theoretical perspectives in those fields. And although positive psychological research has focused heavily on interventions, activities, and behaviors that improve subjective well-being (e.g., gratitude exercises, practicing mindfulness; see Sin & Lyubomirsky, 2009), a dearth of this research recognizes contact with nature as a route by which individuals can increase well-being. The current chapter emphasizes the relevance of nature research for positive psychology and, more specifically, research on subjective well-being. By explicitly recognizing and integrating these two areas of research, a more comprehensive, nuanced, and accurate understanding of the role that nature plays in facilitating human well-being can be achieved.

In what follows, a brief overview of the primary theories regarding the effects of nature on psychological functioning is provided. Existing empirical literature on the effects of nature on subjective well-being is reviewed, with focus placed on four primary areas of inquiry: (1) exposure to natural environments; (2) connectedness to nature and well-being; (3) physical proximity to nature; and (4) green exercise. Limitations of the extant literature are then identified, and opportunities for research that will move the study of the beneficial effects of nature forward are described. Before turning to the above, however, working definitions of nature and subjective well-being are provided.

Definitions of Terms and Scope of Review

The concept of "natural" and the more narrow definition of what makes a natural environment differ depending on history, culture, and the individual doing the defining (see Bratman et al., 2012; Proctor, 1998). Evidence suggests that what is considered to be natural is largely subjectively determined, and there is no widely-agreed upon definition of this construct. Because of this lack of clarity, the majority of research in this area has avoided explicitly labeling environments as natural versus unnatural in favor of a comparative approach whereby one environment is compared to another, with one of these environments being clearly more natural within the context of the research (e.g., a nature preserve versus a city center). Thus, "naturalness" is typically operationally defined as a matter of degree, rather than being categorically determined.

A common, perhaps key attribute of natural environments is that they contain elements of living systems, including flora and fauna. Beyond this commonality, however, natural environments are a broad and heterogeneous class of environments that can differ along several important dimensions (see Hartig, Mitchell, de Vries, & Frumkin, 2014). Natural environments can vary in their degree of human contact, management, and influence, with some natural environments being relatively free of human impact (e.g., wilderness areas) and others being created and heavily managed by humans (e.g., urban green spaces; McMahan, Cloud, Josh, & Scott, 2016). Moreover, by incorporating natural elements within built environments (e.g., placing potted plants within an office space), even artificial environments (i.e., those created by humans) can be more or less natural. To accommodate this heterogeneity, a broad definition of natural environments is adopted in the current review, where natural environments are defined as those that include a relatively high concentration of living systems, including those of both human and non-human origin, that exist across a range of scales and level of human development.

Whereas definitions of nature vary and are in some cases nebulous, definitions of subjective well-being are widely agreed upon, consistent, and precise. Subjective well-being involves subjective assessments of the nature and quality of individuals' lives and includes both affective and cognitive components (Diener, 1984). In practice, subjective well-being is typically defined as a combination of the relative frequency of positive and negative affect and self-reported life satisfaction, with a preponderance of positive over negative affect and high life satisfaction being indicative of high subjective well-being (Diener, 2000; Diener, Suh, Lucas, & Smith, 1999). Notably, subjective well-being is domain-general in the sense that it typically concerns the quality of one's life as a whole, rather than being reflective of satisfaction with a specific domain of functioning, and is often considered to be roughly synonymous with the less formal term "happiness."

Few studies have examined the effect of contact with natural environments on subjective well-being per se and instead typically focus on the effects of contact with nature on the factors that constitute subjective well-being (e.g., positive affect). Accordingly, the current review includes studies that have addressed these factors, either as a sole indicator of well-being or in combination with other positive outcomes. Additionally, while focusing on studies that assessed positive and negative affect and life satisfaction, the current review also includes literature that assessed positive outcomes that are clearly relevant to affective states (e.g., vitality), as well as cognitive assessments of well-being that are in some way conceptually similar to life satisfaction (e.g., subjective happiness).

Contact with Nature and Well-Being: Primary Theories

Three primary theories provide the foundation for the majority of research examining the effects of contact with nature on well-being: the biophilia hypothesis, psychoevolutionary stress reduction theory, and attention restoration theory. The biophilia hypothesis states that ancestral humans' well-being was integrally tied to engaging with the natural environment (e.g., for obtaining resources such as food and water), and in result, the desire to be in contact with nature was selected during our evolutionary history (Kellert & Wilson, 1995; Wilson, 1984). Despite the fact that modern humans no longer need to directly interact with nature in order to ensure survival, it is believed that we retain this deeply-engrained, biologically-based desire. Moreover, because the majority of human history took place in natural environments and regular contact with built environments is only a relatively recent development, it is predicted that people will tend to prefer and respond more positively to natural versus built environments. A number of studies provide indirect support for the biophilia hypothesis, finding that people prefer visual representations of natural environments over built environments (Kaplan, Kaplan, & Wendt, 1972; Ulrich, 1983; van den Berg, Koole, & van der Wulp, 2003) and that the preference for natural environments is observed across cultures (Newell, 1997; Ulrich, 1993) and evident from an early age (Balling & Falk, 1982; Falk & Balling, 2010; Kahn, 1997).

Psychoevolutionary stress reduction theory (SRT) similarly posits that humans evolved to respond positively to nature and states that contact with the types of environments that contain evolutionarily significant resources (e.g., those with vegetation, water sources, and expansive views) elicits a physiological and psychological response characteristic of stress reduction (Ulrich, 1979; 1981). Because natural environments, relative to built environments, contain a greater concentration of features that signal the presence of these resources, people should evince this response when in contact with nature. In support, empirical research indicates that short-term exposure to natural environments is associated with increased positive affect and decreased negative affect (Hartig, Evans, Jamner, Davis, & Garling, 2003), lower heartrate, reduced cortisol levels, and improved immune functioning (Tsunetsugu, Park, & Miyazaki, 2010), and more rapid recovery from stress inductions (Ulrich et al., 1991). Further, evidence suggests that these salutogenic effects of nature also operate over extended periods, as more positive health profiles are observed among those with a history of regular and frequent contact with nature (Korpela et al., 2017a) and those who have greater access to nature (Maas, Verheij, de Vries, Spreeuwenberg, Schellevis, & Groenewegen, 2009; Maas, Verheij, Groenewegen, de Vries, Spreeuwenberg, 2006).

Finally, attention restoration theory (ART; Kaplan, 1995) focuses primarily on cognition and proposes that modern urban environments tax directed attentional systems, which leads to cognitive fatigue and higher levels of stress and irritability. In contrast, natural environments contain a high concentration of elements that are inherently fascinating, draw on directed attentional systems only modestly, reducing cognitive load and thus allowing for both cognitive and affective restoration (see also Kaplan, 2001). In support, empirical work indicates that those exposed to natural environments show greater improvements in various aspects of both cognitive and affective functioning relative to those exposed to urban environments (Berman, Jonides, & Kaplan, 2008; Berman et al., 2012; Berto, 2005). ART also draws from evolutionary perspectives and proposes that the well-documented human preference for natural over built environments is the result of nature's ability to reduce attentional fatigue, a process which would presumably aid in survival (Joye & van den Berg, 2011).

Although the above theories differ in several respects, they each converge on the notion that humans evolved to respond positively to nature. Notably, each of the theories predicts that contact with nature either directly or indirectly impacts aspects of subjective well-being (e.g., by increasing positive affect), suggesting that engaging and connecting with nature may be one route by which happiness can be cultivated. Evidence supporting this suggestion is provided perhaps most directly by research examining the effects of exposure to natural environments via nature interventions.

Empirical Findings

Exposure to nature and nature interventions. Much of the research examining the various positive effects of nature has focused on the affective consequences of exposure to natural environments. As indicated by a recent meta-analysis of over 30 experimental studies conducted within the last 50 years (McMahan & Estes, 2015), exposure to natural environments, relative to built environments, is associated with both moderate increases in positive affect (r = .31) and smaller, but consistent decreases in negative affect (r = -.12). Similar findings were observed in a meta-analysis comparing the effects of exercise in nature versus in built environments (e.g., a gymnasium), with consistently higher levels of positive affect and lower negative affect observed among those exercising in nature (Bowler et al., 2010). More generally, each of these meta-analyses, as well as several other systematic reviews (e.g., Barton & Pretty, 2010), indicate that being in nature is associated with more positive emotional outcomes.

Importantly, findings from this area of research have been replicated under a variety of

experimental conditions and within a variety of contexts. For example, positive affective outcomes have been observed following brief exposure to natural environments (Hartig et al., 2003; Mayer, Frantz, Bruehlman-Senecal, & Dolliver, 2009; McMahan, Estes, Murfin, & Bryan, 2017; Nisbet & Zelenski, 2011), as well as after longer-term exposure to nature (Korpela et al., 2017a; Passmore & Holder, 2017; Passmore & Howell, 2014b). Similar effects have been observed among those exposed to both manicured natural environments (e.g., parks, green spaces; Berman et al., 2008; Johansson, Hartig, & Staats, 2011) and wilder, less managed environments (e.g., nature preserves; Lee, Park, Tsunetsugu, Kagawa, & Miyazaki, 2009; Lee et al., 2011). Findings further suggest that in addition to improving affective states in non-clinical samples, nature may have a therapeutic effect among those diagnosed with depression (e.g., Berman et al., 2012). Moreover, empirical evidence indicates that technologically-mediated or virtual exposure to nature (e.g., viewing images of nature or nature simulations) is also associated with improved affect (e.g., McMahan et al., 2017; Valtchanov & Ellard, 2010), although effect sizes are generally smaller than those observed following in-person exposure to real natural environments (see Kahn, Severson, & Ruckert, 2009; McMahan & Estes, 2015).

Although the bulk of the research in this area has focused on the effects of exposure to natural environments on affective state, several studies have examined other positive outcomes that result from engagement with nature. For example, engagement in outdoor activity has been found to be positively associated with satisfaction with life in multiple independent studies (e.g., Biedenweg et al., 2017; Mert, Zurnacı, C., & Akgün, 2015; Wolsko & Lindberg, 2013). In a recent study utilizing experience sampling methodology in a group of 20,000 participants, higher levels of subjective happiness were reported when participants were in natural environments versus built environments (MacKerron & Mourato, 2013). Additionally, Ryan and colleagues (2010) observed higher levels of vitality – subjective feelings of energy and vigor – when participants engaged in activities that involved nature. Notably, Ryan and colleagues also found increased vitality among participants who were instructed to simply imagine themselves in nature. Further, participation in wilderness-immersion programs has been associated with increased self-esteem, among other positive outcomes (e.g., Passarelli, Hall, & Anderson, 2010).

Given strong empirical support for the benefits of engaging with natural environments, nature-based intervention programs have been developed recently, and initial evidence suggests these programs are effective at promoting well-being. As one of the largest of such interventions, the David Suzuki Foundation's 30x30 Nature Challenge is a month-long program encouraging participants to spend 30 minutes per day in nature. Evaluations of this program indicate significant reductions in stress and improved mood and vitality among participants (Nisbet, 2014). On a smaller scale, Passemore and Holder (2017) found increased positive affect, sense of connectedness, and prosocial orientation among participants in a two-week intervention program encouraging increased attention to natural environments. The Mood Walks Initiative is a nature hiking program for older adults with serious mental illness, and preliminary findings regarding the outcomes of the program indicate higher levels of happiness and decreased anxiety among those participating in the program (Mood Walks, 2015). Additionally, a number of nature-based youth development programs have been developed, and much of the evidence suggests that these programs are effective at improving multiple facets of well-being (e.g., Collado, Staats, & Corraliza, 2013; Norton & Watt, 2014; Passarelli et al., 2010). In general, findings regarding the effectiveness of nature-based intervention programs at improving well-being are promising. However, these programs are relatively few in number, and a priority for future work should be to develop additional empirically-based programs aimed at utilizing nature as a means for promoting well-being among multiple populations.

Connectedness to nature and subjective well-being. A great deal of research documents the benefits of direct contact with the natural world. Complementing this research are findings indicating that the degree to which individuals report feeling connected to the natural environment is also associated with well-being. Nature connectedness is a trait-level construct reflecting the degree to which one feels this subjective connection to the natural world (Capaldi, Dopko, & Zelenski, 2014). Like other trait-level constructs, nature connectedness is relatively stable across time and situations (Mayer & Frantz, 2004) and consistently predicts relevant outcomes, such as endorsement of pro-environmental attitudes and engagement in pro-environmental behaviors (Mayer & Frantz, 2004; Nisbet, Zelenski, & Murphy, 2009; Tam, 2013). Notably, the term nature connectedness is used broadly in the current chapter to refer to several constructs that have been offered in previous literature, such as connectedness to nature (Mayer & Frantz, 2004), nature relatedness (Nisbet et al., 2009), inclusion of nature in self (Schultz, 2001), emotional affinity towards nature (Kals, Schumacher, & Montada, 1999), connectivity to nature (Dutcher, Finley, Luloff, & Johnson, 2007), and environmental identity (Clayton & Opotow, 2003), among others (see also Capaldi et al., 2014). Although the above constructs differ in their specifics, there exists considerable conceptual overlap, and empirical findings suggest an underlying common construct (Tam, 2013).

Numerous studies have found nature connectedness to be associated with higher levels of subjective

well-being. For example, when developing the Connectedness to Nature Scale (CNS), Mayer and Frantz (2004) found higher levels of life satisfaction among those who feel more connected to nature and, in later work, that nature connectedness mediated the effects of contact with nature on positive affect (Mayer et al., 2009). Zelenski and Nisbet (2014) found that after controlling for feelings of connectedness to other entities (e.g., connectedness to family, to friends), nature connectedness was positively associated with multiple indicators of well-being, such as positive affect, subjective happiness, satisfaction with life, and vitality. Similarly, while Howell, Passmore, and Buro (2013) found higher levels of happiness and emotional well-being, as well as greater meaning in life and psychological well-being, among those reporting feeling strongly connected to nature, Tam (2013) observed that multiple indicators of nature connectedness (e.g., nature relatedness, emotional affinity toward nature, etc.) were positively associated with subjective happiness, affect balance, and satisfaction with life. Indeed, the general finding that nature connectedness is positively associated with indicators of positive feeling and functioning has been replicated multiple times (e.g., Cervinka, Roderer, & Hefler, 2012; Korpela, Savonen, Anttila, Pasanen, & Ratcliffe, 2017b; Wolsko & Lindberg, 2013), and correspondingly, a recent systematic review of the relevant literature found a small, but significant association between nature connectedness and indicators of subjective well-being (r = .18; Capaldi et al., 2014).

Given the connection between nature connectedness and subjective well-being, a number of investigators have attempted to elucidate the factors that facilitate and contribute to the development of a strong sense of connection to the natural world. One such factor seems to be early childhood experiences in nature, as those who report spending more time in nature as children tend to show higher levels of nature connectedness as adults (e.g., Ward Thompson, Aspinall, & Montarzino, 2008). For instance, research indicates that those who grew up in rural environments report higher levels of nature connectedness than their urban-raised counterparts (Hinds & Sparks, 2008). In fact, the consistently found association between childhood nature experiences and nature connectedness has led some investigators to suggest that childhood may be a sensitive period for the development of strong connections to the natural world (e.g., Orr, 1993). If this is the case, encouraging children to interact with nature and providing them with the resources to do so may be an effective strategy to increase nature connectedness and, in turn, the positive outcomes associated with feeling connected to nature.

However, the effect of frequent contact with nature on nature connectedness is not unique to earlier developmental periods, and even brief exposure to natural environments has been found to temporarily increase self-reported nature connectedness among samples of adults (e.g., Nisbet & Zelenski, 2011; Schultz, 2001; Zelenski & Nisbet, 2014). Moreover, Mayer and colleagues (2009) found that the salubrious effects of nature exposure are mediated by short-term increases in nature connectedness, indicating that feeling that one is connected to the natural world may be one mechanism by which nature positively impacts subjective well-being. Findings such as these highlight the importance of regular and frequent contact with natural environments for the development and maintenance of a strong connection to nature and, in turn, positive well-being. But, ready access to natural environments is not equally distributed, with some areas providing greater access to nature while others less so (e.g., rural versus urban environments). This disparity in nature accessibility is a critical factor in determining whether individuals can take advantage of the benefits of nature exposure, a point we now turn to in the following section.

Nearby nature: Physical proximity to natural environments. For many years, it has been believed that access to natural environments promotes well-being. Indeed, this belief was a primary factor motivating the development of urban park systems in many Western nations during the 19th and 20th centuries (Forbes & Kendle, 2013; Hamilton-Smith & Mercer, 1991; Walker & Duffield, 1983), and the development of green spaces within built and urban environments in the 21st century is largely the result of an increased understanding of the role that natural environments play in the facilitation of public health (Ward Thompson & Travlou, 2007). Moreover, the idea that contact with nature promotes health, broadly conceived, has been used as justification for the preservation of natural areas outside of cities as well (Maller, Townsend, Pryor, Brown & St. Leger, 2006). In short, proposals for the development of natural areas within built environments and the preservation of natural areas outside of built environments are largely predicated on the notion that having access to and utilizing these environments will in some way improve the quality of life of nearby populations.

Given the empirical research indicating that even brief contact with nature promotes well-being, a number of studies conducted in multiple locations across the world have examined whether having ready access to natural areas, such as green spaces, parks, and wilderness reserves, is associated with positive outcomes (see Maller et al., 2006). Much of this research is epidemiological in nature and indicates in general that people with access to nearby natural settings enjoy higher levels of well-being than those without easy access to nature (Kaplan & Kaplan, 1989). For example, in a large sample of Dutch survey respondents, de Vries, Verheij, Groenewegen, and Spreeuwenberg (2003) found that percentage of

greenspace (e.g., urban greenspace, agricultural greenspace, nature areas) and 'blue' space (i.e., environments with a dominant natural water feature) within three kilometers of one's residence was positively associated with higher levels of perceived health and decreased psychiatric symptoms. Similarly, physical distance from local greenspace has been found to predict self-reported stress and health, with those living more than one kilometer away from the nearest greenspace reporting higher levels of stress and decreased health-related quality of life than those who are closer to these resources (Stigsdotter et al., 2010). Moreover, long-term relocation of one's residence to an area with greater access to greenspace is associated with increased health-related well-being, while, conversely, moving to a less green area has been found to be associated with decreased well-being (Alcock, White, Wheeler, Fleming, & Depledge, 2014).

Not surprisingly given its epidemiological roots, the bulk of empirical research examining associations between access to nature and well-being has focused primarily on physical health-related outcomes, mortality, and indicators of negative functioning. However, recent work examining associations between nearby nature and indicators of positive psychological functioning has generated results similar to those presented above. For instance, data drawn from the large-scale British Household Panel Survey (BHPS) indicates that those living in urban areas with more greenspace report high levels of life satisfaction than their urban counterparts with less greenspace (White, Alcock, Wheeler, & Depledge, 2013). Similar results were observed in Berlin, Germany (Bertram & Rehdanz, 2014) and Baltimore, Maryland (Vemuri, Grove, Wilson, & Burch, 2011), with residents living in greener neighborhoods of these urban centers reporting higher levels of life satisfaction. Thus, although research addressing associations between nearby greenspace and indicators of subjective well-being is in its infancy, existing findings parallel those found in health-related fields and suggest that people psychologically benefit from living close to nature.

Green exercise. The specific mechanisms that account for associations between access to greenspace and improved well-being are as-of-yet unclear (see Lee & Maheswaran, 2011). However, many outdoor recreation spaces are designed to promote physical activity, and existing empirical evidence consistently indicates that regular physical activity promotes both physical and psychological well-being (Biddle & Asare, 2011; Penedo & Dahn, 2005; Scully, Kremer, Meade, Graham, & Dudgeon, 1998). Those living close to nature may therefore enjoy improved physical and psychological functioning, at least in part, because they are more physically active than those who don't have easy access to these environmental resources (e.g., Coombes, Jones, & Hillsdon, 2010; Mytton, Townsend, Rutter, & Foster, 2012). Yet, research examining whether physical activity mediates associations between greenspace access and well-being has yielded mixed results (e.g., Maas, Verheij, Spreeuwenberg, & Groenewegen, 2008; Richardson, Pearce, Mitchell, & Kingham, 2013), suggesting a more nuanced picture of this relationship, whereby the effects of greenspace access on both physical activity and health depend on various characteristics of both the environment (e.g., greenspace quality, safety) and the person (e.g., age, gender).

Despite this ambiguity, other research clearly indicates that simply being active in nature, whether walking, jogging, or engaging in strenuous physical activity, improves feeling and functioning (e.g., Mitchell, 2013; Pretty et al., 2007). Further, green exercise (i.e., exercising in the natural environment) has been found to yield greater benefits than exercising in built or synthetic environments (e.g., Pretty, Peacock, Sellens, & Griffin, 2005), and among natural environments, higher degrees of perceived environmental greenness are associated with more positive outcomes (Mackay & Neill, 2010). In one recent meta-analysis, Bowler and colleagues (2010) found small to moderate effects of physical activity environment on several distinct affective states (e.g., anger, sadness; d range = .23-.76), where exercising in nature was associated with more positive affective outcomes than exercising in built environments. Additionally, in a multistudy synthesis (n = 1252) of research examining the effects of physical activity in nature using simple pretest-posttest designs, Barton and Pretty (2010) found that being active in nature was associated with moderate improvements in both self-esteem (d = .46) and mood (d = .54). In yet another systematic review, exercising in nature, relative to exercising indoors, was found to be associated with increased feelings of revitalization, positive engagement, and energy, as well as decreased tension, confusion, anger, and depression (Thompson Coon et al., 2011). Findings such as these suggest a synergistic effect of exercise and exposure to nature, where being physically active and engaging with the natural environment produces more positive outcomes than participating in either activity alone (see Pretty et al., 2005).

Notably, the effects of green exercise on indicators of subjective well-being vary depending on environmental and individual characteristics and the nature of the activity (e.g., duration). For example, larger effects are observed in natural environments that include a prominent water feature, and some evidence suggests that the effects of green exercise are more pronounced among younger adults, men, and clinical populations (Barton & Pretty, 2010). Additionally, the effects of green exercise are particularly pronounced after short visits to natural environments (approximately 30 minutes), although further but more modest improvements in well-being are observed for visits of longer duration (Barton & Pretty, 2010;

see also Shanahan et al., 2016). Despite requiring little time for marked improvements in well-being, those who exercise outside, relative to those who primarily exercise in synthetic environments, report greater frequency and duration of exercise (Hug, Hartig, Hansmann Seeland & Hornung, 2009). And, outdoor exercise is associated with higher levels of enjoyment and lower levels of perceived exertion when compared to indoor exercise, despite comparable levels of physiological activity (Akers et al., 2012; Kinnafick & Thøgersen-Ntoumani, 2014). In short, being active in nature requires little time commitment, is more enjoyable, and perceived as less physically taxing than exercising indoors. As a result, green exercise may be a relatively expedient and self-reinforcing activity that effectively improves both physical and psychological functioning, thus representing one promising avenue by which sustainable improvements in well-being can be achieved.

Remaining Questions and Opportunities for Future Research

As the above review indicates, existing research now provides convincing evidence that contact with natural environments promotes positive psychological functioning and higher levels of subjective well-being. However, this area of inquiry suffers from several general limitations that should be addressed in future research in order to gain a more accurate understanding of the ways in which contact with nature produces its salubrious effects. These are (1) a lack of definitional clarity and measurement consistency of major relevant constructs, (2) limited knowledge of group differences, and (3) unclear causal mechanisms. Each of these limitations are described in turn below.

Definitions and consistent measurement. There is a lack of consensus with respect to defining of the primary constructs under investigation, and correspondingly, there exists a high degree of variability in how these constructs are manipulated and/or measured. This is perhaps most obvious, as noted previously, when it comes to defining what it means when we use the terms "nature" or "natural," as these concepts have been defined in manifold ways. Although disagreements regarding appropriate definitions of these constructs might seem like academic squabbling, the absence of broad consensus has allowed the use of several different types of "natural" environments in the empirical literature (e.g., urban greenspace, wilderness areas, campus gardens), and there exists both theoretical and empirical evidence suggesting that exposure to different types of natural environments may differentially impact well-being (e.g., McMahan et al., 2016). However, a paucity of research has explicitly recognized these differences, thus leading to a state of relative ignorance concerning how different natural environments may impact well-being. Developing agreed-upon definitions of "nature" and "natural" that clearly delineate the key factors that constitute these concepts will facilitate more finely-tuned distinctions between different types of natural environments and a higher level of precision when assessing the effects of these environments. In result, a more nuanced understanding of what type of nature works best for improving well-being may be realized.

Relatedly, there exists a high degree of heterogeneity in how well-being and, in particular, indicators of positive psychological functioning are defined and measured in the relevant literature. For example, affective state has been assessed using a multitude of instruments, including the Profile of Mood States (POMS; see Norcross, Guadagnoli, & Prochaska, 1984), the Positive and Negative Affective Schedule (PANAS; Watson, Clark, & Tellegen, 1988), and the Zuckerman Inventory of Personal Reactions (ZIPERS; Zuckerman, 1977), among others. Critically, these instruments differ with respect to their emphasis on positive versus negative affect and the distinct affects assessed, and evidence suggests that associations between nature exposure and affect varies depending on which instrument is used (Capaldi et al., 2014; McMahan & Estes, 2015). This issue is compounded when examining broader constructs, such as psychological functioning, which have been operationalized in many different ways. This state of affairs introduces a high degree of variability in quantitative syntheses of the existing studies and precludes accurate and precise estimates of the size of the effect of nature on a particular outcome. Accordingly, future research should attempt to address this limitation by attempting to maintain consistency in the measurement of specific outcomes.

Group differences. A second limitation concerns the origins and demographics of the samples that are frequently used in this area of research. The majority of studies across all areas reviewed in the current chapter have been conducted on those from relatively affluent, industrialized, Western nations. This is problematic as evidence suggests that cultures differ in how they conceptualize the relationship between humans and nature (e.g., Bang, Medin, & Atran, 2007; Unsworth et al., 2012), and nation-level mean differences in nature connectedness have been observed (Tam, 2013). These culture-related differences no doubt impact how individuals respond to the natural environment and suggest that the benefit of exposure to nature may vary depending on cultural context. Accordingly, future research should attempt to replicate the current findings using samples from diverse cultural and national backgrounds.

Additionally, much of the research, particularly experimental studies examining the effects of contact with nature (e.g., Mayer et al., 2009) as well as studies examining associations between nature

connecteness and well-being (e.g., Zelenski & Nisbet, 2014), has relied primarily on university student samples that are quite homogenous in demographic characteristics, thus limiting the ability to generalize corresponding findings to other populations. However, evidence from epidemiological research examining the effects of greenspace access suggests that some demographic groups may benefit from provision of and exposure to nature to a greater degree than others. For example, younger and older adults have been found to benefit more from greenspace access than middle-aged adults (Kaczynski, Potwarka, Smale, & Havitz, 2009; Maas et al., 2009), associations between greenspace exposure and health are stronger for non-Hispanic Whites relative to other ethnic groups (Kerr, Frank, Sallis, & Chapman, 2007; Scott, Dubowitz, & Cohen, 2009), greenspace access has a stronger impact on the health of lower income groups relative to those with higher incomes (Babey, Hastert, Yu, & Brown, 2008; Maas et al., 2006), and those living in urban areas seem to respond more positively to nearby nature than those living in rural environments (Lachowycz & Jones, 2013). Although suggestive, the above findings are limited in their emphasis on greenspace access, their correlational nature, and their focus on physical health-related outcomes, and corresponding findings generated from experimental research examining potential group differences in the effects of nature exposure on positive psychological outcomes does not exist. A priority for future research in this area is thus to examine how contact with nature psychologically benefits individuals from varying demographic groups.

Causal mechanisms. A dearth of research has addressed potential mechanisms that mediate the effects of nature on well-being, and in result, we know relatively little about how nature exerts its salubrious effects nor the routes by which it does so. Of course, the mechanisms by which nature might affect well-being are numerous and synergistic, and the conditions under which specific mechanisms are elicited and exert their effects likely varies depending on environmental context, an individual's current state of functioning, as well as personal dispositions. A key step moving forward is thus to investigate these potential mechanisms and the situations in which they take on significance in order to develop a more nuanced understanding of the ways in which nature does and doesn't impact psychological well-being.

With that said, several factors represent likely candidates for mechanisms that bridge the divide between nature and happiness. One such mechanism may be the emotion of awe. Awe is defined as an emotional response to perceptually vast stimuli that overwhelm current mental structures (Keltner & Haidt, 2003), and exposure to nature, particularly extraordinary nature (e.g., one involving an expansive view of a large mountain range) is suggested to be a key elicitor of this response (Shiota, Keltner, & Mossman, 2007). Critically, those who experience awe report higher levels of life satisfaction (Rudd, Vohs, & Aaker, 2012), and contact with natural environments may therefore improve life satisfaction via this emotional response. Indirect support for this prediction comes from research examining the differential effects of exposure to particularly beautiful or awesome natural scenes (i.e., those most likely to elicit awe) versus more mundane natural environments, where those exposed to extraordinary nature responded more positively than those exposed to mundane nature (Joye & Bolderdijk, 2015). However, additional research specifically addressing whether awe mediates the association between nature exposure and well-being is still needed.

A related potential mechanism is meaning in life. The experience of meaning in life involves an understanding of who we are, what the world is like, and how we fit in to the grand scheme of things (Steger, 2012) and is consistently associated with higher levels of multiple indicators of well-being (Steger, 2017; Zika & Chamberlain, 1992). Meaning in life results from transcendent experiences (Emmons, 2005) and believing that one's life fits in within a larger context or plan (Wong, 2010), and nature experiences likely facilitate a sense of meaning by providing a salient reminder of one's place in the world and a means by which individuals can connect to something larger than the self. In support, experiences in nature have been found to be a significant source of meaning among adults (O'Connor & Chamberlain, 1996; Reker & Woo, 2011). Additionally, meaning in life has been found to mediate associations between dispositional nature connectedness and well-being (Howell et al., 2013). However, to date, research has not addressed whether the beneficial effects of contact with nature result, at least in part, from increased subjective sense of meaning, and additional experimental research addressing whether brief nature experiences elevate sense of meaning and, in turn, well-being should be pursued.

Positive social experiences are yet another likely mechanism mediating associations between nature and well-being. Several lines of research indicate that natural environments are one context in which social interactions are facilitated and existing relationships are strengthened (e.g., Coley, Kuo, & Sullivan, 1997), and the cultivation and maintenance of positive relationships with others is considered to be a key component of optimal human feeling and functioning (Keyes, 1998; Ryff & Singer, 1998). Indeed, feeling connected to others has been suggested to be a psychological need (Ryan & Deci, 2000). Importantly, the availability of high quality natural environments has been found to contribute to both social cohesion and self-reported health (de Vries, van Dillen, Groenewegen, & Spreeuwenberg, 2013), and one study

conducted in the Puget Sound region of Washington State, indicated that positive social experiences mediated associations between frequency of outdoor recreation and self-reported life satisfaction (Biedenweg et al., 2017). Moreover, Zelenski, Dopko, and Capaldi (2015) found that brief nature exposure increased cooperative behavior, potentially identifying one mechanism by which nature may promote positive social interactions. Yet, as above, experimental research specifically examining whether positive social experiences mediate associations between contact with nature and subjective well-being are lacking, and addressing whether this is the case represents a potentially fruitful area of future inquiry.

Addressing the mechanisms that account for associations between greenspace accessibility and well-being is a particularly complicated task, as these areas could potentially serve many different functions for many different individuals. In fact, these spaces are often intentionally designed to serve a broad section of the local population by providing a diversity of resources and affordances (Eysenbach, 2008). For example, a greenspace may provide opportunities for physical activity (e.g., an extensive path system), quiet places to relax (e.g., solitary benches next to a pond), places to engage in social interaction (e.g., a picnic area), cultural experiences (e.g., a pavilion), and so forth. They may also provide less obvious but beneficial resources, such as better air quality (see Hartig et al., 2014). Utilizing these resources may then in turn positively influence both physical and psychological functioning to varying degrees, depending on the nature of the activity in question. Additionally, it is likely that individual-level characteristics (e.g., dispositions, acute states of functioning) impact the significance and utilization of these resources. For instance, a quiet place to relax may be particularly valuable for an individual who is experiencing significant work-related stress, and utilization of this resource may be particularly important and impactful for stressed individuals versus those who are not experiencing significant stress. In support, a number of empirical studies indicate that the positive effects of passive nature exposure are particularly pronounced for those in need of psychological restoration (see van den Berg, Hartig, & Staats, 2007). Taken together, the above indicates that not only should research consider the mechanisms by which nature improves well-being, but also the conditions under which it does so.

Other questions. The above identifies a few major limitations in the current literature concerning the effect of natural environments on well-being. But, this is by no means an exhaustive account of these limitations, and there exist many other questions that should be addressed in order to develop a more complete understanding of the role that nature plays in the promotion of positive human feeling and functioning. For example, most of the existing research has exposed participants to pleasant natural environments (e.g., nature preserves) or natural environments specifically designed for human use (e.g., urban greenspaces), and in result, less is known about how unpleasant natural environments and those that are not well-suited to human use and habitation affect well-being. Similarly, how individuals' well-being is affected by different natural environs (e.g., boreal forests, deserts, temperate rainforests) is unclear. While a substantial amount of research documents preferences among different natural environments, finding that individuals tend to prefer savannah-like environments, those that contain water features, and familiar natural environments (e.g., Falk & Balling, 2010), little research has addressed whether exposure to these environments differentially benefits individuals. In a related vein, a dearth of research examines variability in outcomes associated with exposure to different built environments. Like natural environments, built environments are a heterogeneous class of environments that differ in many respects (e.g., a parking lot versus an outdoor mall). These differences are likely of practical import when investigating the manner in which a given built environment may or may not impact psychological functioning.

While a great deal of research documents the short-term effects of nature exposure on indicators of subjective well-being, limited research has addressed the potential long-term effects of repeated or frequent nature exposure. That which does exist has done so using retrospective or cross-sectional research designs, thus precluding firm conclusions regarding causality. Relatedly, at current, we know relatively little regarding how long the effects of nature last, the ideal dose of nature, the degree to which person-related factors impact the effects of nature, or how more specific elements within natural environments (e.g., low-level visual features) enhance or perhaps hinder these effects. The rigorous investigation of these questions, as well as those presented above, should take the forefront in future research in this area.

Final Remarks

Despite the above-listed gaps in relevant research, the existing empirical evidence unambiguously indicates that contact with natural environments in some way positively impacts human feeling and functioning. These findings thus validate the literary and artistic sentiments of those who have across history espoused the importance of nature for our happiness. Relative to previous generations however, people are now spending less time in nature (Clements, 2004; Hofferth, 2009; Soga & Gaston, 2016) and the majority of their daily lives indoors (MacKerron & Mourato, 2013). In result, the myriad benefits of interacting with nature go largely unrecognized and thus unrealized (see Nisbet & Zelenski, 2011). The vast majority of individuals have access to some form of nature, be it a local park, a large urban greenspace, or

a national forest, and utilizing these resources seems to be a relatively easy and low-cost means by which subjective well-being can be improved. Indeed, mental health practitioners are becoming increasingly aware of the potential clinical importance of natural environments, and applied research focusing on the promotion of mental health via exposure to nature is therefore likely to be in increasing demand (Mantler & Logan, 2015). Moreover, evidence suggests that interaction with nature promotes conservation-oriented behaviors (e.g., Zelenski et al., 2015). Engaging the natural world and regularly visiting natural environments may therefore promote positive behaviors aimed at improving the well-being of our planet, in addition to providing an effective route by which individual happiness and positive human health can be achieved.

Geographical Variation in Subjective Well-Being

By Peter J. Rentfrow, University of Cambridge

Abstract

Research on subjective well-being has shown that there are geographical differences in well-being. Drawing on theory and research in social-personality psychology, economics, and geography this chapter reviews research concerned with the geographical distribution of well-being, and how individual characteristics, social institutions, and the physical environment influence that distribution. Findings from several studies conducted at multiple levels of analysis strongly suggest that selective migration, social influence, and ecological influence are key mechanisms responsible for the geographical clustering of subjective well-being. Cross-national studies and analyses of regional differences in the U.S. indicate that the average level of subjective well-being in geographical areas is related to a range of economic, social, and health indicators. Moreover, evidence suggests that personality traits interact with features of the environment to influence individual differences in subjective well-being. More work is needed to understand the causal nature of the relations between subjective well-being and the macro environment.

Keywords: Regional Differences, Geographical Psychology, Well-being, Social Indicators

For decades, psychologists have been concerned with understanding the relations between the environment and psychological health. Through the years, countless studies have investigated how features of the social and physical environment affect various indicators of mental health, from depression to happiness. Although that work has proven to be immensely valuable to our understanding of well-being, researchers' conceptualizations of the environment have typically been rather narrow and focused on proximal environmental features. Consequently, considerably less attention has been given to the impact that macro-level factors may have on well-being. However, a growing body of research that conceptualizes environments in terms of geographical units is beginning to broaden our understanding of the links between the environment and psychological well-being.

The relevance of geography for understanding social and behavioral processes has long been recognized by geographers, political scientists, economists, sociologists, and epidemiologists. For example, political scientists often examine geographical variation in polling data and their relationships to demographic, educational, and economic indicators (Heppen, 2003; Hero, 1998); macro-economists investigate geographical variation in labor statistics and how they relate to income, migration flows, and human capital (Krugman, 1991; Martin, 1999); and epidemiologists study geographical variation in rates of disease incidences and their associations with demographic, lifestyle, and economic indicators (Borhani, 1965; Glymour, Avendaño, & Berkman, 2007; Lanska, 1993). What is abundantly clear from research in those fields is that people's values, aspirations, and health are strongly related to features of where they live. It therefore seems reasonable to expect geography to add to our understanding of subjective well-being.

Indeed, a great deal of interest has emerged over the past few years concerned with geographical variation in psychological phenomena and how that variation relates to various macro-level indicators (Rentfrow, 2014). Much of the research in geographical psychology is concerned with mapping the spatial organization of psychological characteristics, identifying the mechanisms responsible for their organization, and understanding how the spatial organization of psychological characteristics relate to political, economic, social, and health variables. This chapter reviews research concerned with geographical variation in well-being.

The Geography of Subjective Well-Being

Subjective well-being is a psychological construct that reflects a person's cognitive and affective evaluation of the quality of their life (Diener, Suh, Lucas, & Smith, 1999; Diener, Lucas, Schimmack, & Helliwell, 2009). Because it is based on people's subjective perspectives, it can be measured easily and reliably using self-report measures, and scores on such measures can provide valid information about the extent to which people find their lives enjoyable, rewarding, and positive overall. The bulk of research on subjective well-being aims to develop an understanding of basic human functioning. Indeed, research on subjective well-being has greatly informed our understanding of the ways in which social, economic, and

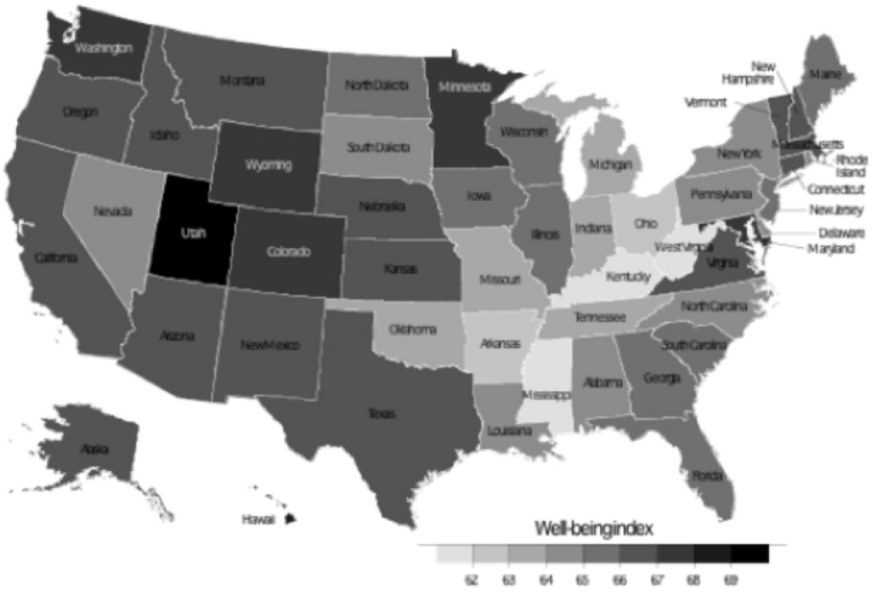
psychological factors interact to influence well-being. For example, subjective well-being is positively associated with income, productivity, sociability, and physical health (Lyubomirsky, King, & Diener, 2005).

Although most research on subjective well-being has examined individual-level processes, researchers are beginning to examine how it plays out at broader geographical units of analysis, such as nations, states, counties, and cities (Diener, Helliwell, & Kahneman, 2010; Lawless & Lucas, 2011; Lucas, Cheung, & Lawless, 2014; Oswald & Wu, 2010; Plaut, Markus, & Lachman, 2002; Rentfrow, Mellander, & Florida, 2009). Interest in the geography of well-being is based, in part, on developing an understanding how local and national culture, society, politics, and economics might feed into people's subjective evaluations of life quality. There is value for psychology and economics researchers to examine such issues because it can reveal distal causes of subjective well-being, and there is also value for policy makers who could use such information to guide decisions about policies. To that end, researchers have begun to examine geographical variation in subjective-well-being by measuring individual differences in subjective well-being using very large samples of people from around the world. The level of well-being in a place (i.e., nation, state, county, or city) is typically based on the average subjective well-being score derived from a sample of people who live in the same place. Thus, to say that the state of Utah is high in well-being means that the average level of subjective well-being taken from a sample of people who live in Utah is high compared to the average level of well-being in other states. In this way, researchers are able to make comparisons of well-being between geographical regions. And the evidence indicates that well-being is not uniformly distributed, but geographically clustered.

A considerable amount of research on geographical variation in subjective well-being has been done at the national level (e.g., Inglehart & Klingemann 2000; Lynn & Steel, 2006; Steel & Ones, 2002; Veenhoven, 1993). Findings from international studies consistently reveal mean differences in subjective well-being across nations. For instance, results consistently show that residents of Canada, Denmark, Switzerland and the US score near the top on measures of subjective well-being whereas residents of Eastern European and African countries score near the bottom (Diener, 2000; Veenhoven, 1993).

National variation is not the only way to examine geographical variation. Within many nations, including the U.S., there is considerable variation in the social, economic, and political landscape within the country. Thus, mapping regional variation within nations has value for further understanding the nature of subjective well-being and the factors that affect it.

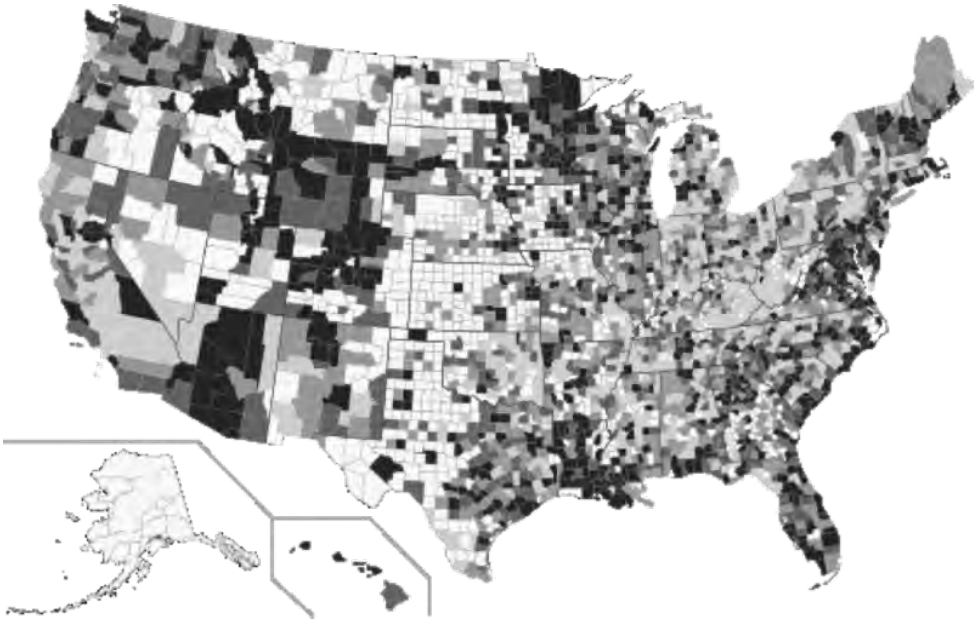
Figure 1. Statewide differences in subjective well-being. Source: Rentfrow, P. J., Mellander, C., & Florida, R. (2009). Happy states of America: A state-level analysis of psychological, economic, and social well-being. *Journal of Research in Personality, 43*, 1073-1082.



Using well-being data collected by the Gallup Organization, Rentfrow et al., (2009) investigated regional variation across states throughout the U.S. The results shown in Figure 1 display the state-wide

well-being differences reported in that research. The map of state-level well-being clearly shows that well-being is not uniformly distributed across the country, but geographically clustered. Specifically, states in the mountain and west coast regions scored highest in well-being. In fact, most of the states that ranked in the top-half on well-being were from the mountain and west coast regions. Well-being was comparatively lower in states along the east coast, and well-being was lowest in states in the Midwest and deep south.

Figure 2. **Map of county-level life satisfaction across the United States. Counties in white have no data; darker shades of gray reflect higher levels of subjective well-being. Source: Lucas, R. E., Cheung, F., & Lawless, N. M. (2014). Investigating the subjective well-being of United States regions. In P.J. Rentfrow (Ed.) Geographical Psychology: Exploring the interaction of environment and behavior. American Psychological Association.**



Many states in the U.S. are large and diverse. For example, California, is home to approximately 40 million people, with six cities with more than 500,000 residents and 286 towns with fewer than 1,000 residents. Thus, it is useful to consider whether well-being varies at even more granular geographical levels of analysis. Using data from the Behavioral Risk Factor Surveillance System, administered by the Centers for Disease Control and Prevention, Lucas et al., (2014) examined regional variation in well-being across roughly 2,400 counties in the United States. The county-level maps of well-being are displayed in Figure 2. Although the data source is different to the one used by Rentfrow and colleagues (2009) to map state-wide well-being, the geographical pattern appears very consistent. Indeed, high levels of well-being appear clustered in the mountain and west coast regions, and low levels of well-being appear in the Midwest and in many counties in the south. Furthermore, close inspection of the map shows considerable variation within states. For example, both Texas and California have counties that score very high and very low in well-being.

In summary, there is compelling evidence from a number of large-scale studies that subjective well-being varies between nations, states, and counties. These findings are important because they strongly suggest that features of the environment may contribute to people's levels of well-being. However, understanding how the environment may influence well-being first requires consideration of how geographical variation in well-being emerges in the first place. What are the causes responsible for geographical differences in well-being?

What are the Mechanisms Responsible for Geographical Variation in Subjective Well-Being?

Recent work in geographical psychology has identified three mechanisms that could contribute to geographical differences in psychological characteristics. Selective migration is one mechanism. Drawing on interactionist theories, which posit that people seek out environments that satisfy and reinforce their psychological needs (Buss, 1987), selective migration assumes that people selectively migrate to places that satisfy their needs. Research on the links between personality and migration decisions indicates that people high in Openness are likely to move away from their home state to a different state and that people high in Extraversion are likely to migrate and that residential mobility has adverse health consequences for people

low in Extraversion (Jokela, 2009; Jokela, Elovainio, Kivimäki, & Keltikangas-Järvinen, 2008; Oishi, 2010; Oishi, Miao, Koo, Kisling, & Ratliff, 2012; Oishi & Schimmack, 2010; Rentfrow, 2011). In addition, work by Lucas et al., (2014) indicates that U.S. counties where residents are high in subjective well-being experience significantly higher levels of population growth compared to areas where well-being is low. Although the causal nature of the relationship is unclear, it raises important questions about what it is about places undergoing high in-migration and where residents are high in well-being.

Another mechanism that contributes to geographical variation in psychological characteristics is social influence. The conceptual basis of the social influence mechanism is essentially an extrapolation from experimental social psychology research showing that people's thoughts, feelings, and behaviors are influenced by those around them. Although most of the evidence for social influence comes from experimental investigations, there is considerable evidence contagion effects within large social networks (e.g., Bourgeois & Bowen, 2001; Fowler & Christakis, 2008). For instance, results from the Framingham Study shows that positive affect spreads through social relationships. More specifically, one's levels of happiness can be predicted by the happiness level of friends three times removed (Fowler & Christakis, 2008).

A third mechanism that could give rise to geographical variation in psychological characteristics is ecological influence. Ecological influence is based on the assumption that aspects of the physical environment influence behavior. More specifically, there is empirical evidence suggesting that temperature, rainfall, green space, crowding, and pathogen prevalence can significantly influence many aspects of human behavior, which over time, can influence the thoughts, feelings, and values of people in the area. As such, the physical environment can influence the prevalence of particular psychological traits. One example of ecological influence comes from work by Schaller and colleagues, which suggests that national levels of Openness and Extraversion are low in parts of the world that have had historically high levels of infectious disease (Schaller, 2006; Schaller & Duncan, 2007; Schaller & Murray, 2008). The explanation for the associations is the high risk of spreading disease led people to become more closed off, skeptical, and exclusive, so that traits associated with these qualities were reinforced. Another example comes from work by Oishi, Talhelm, and Lee (2015), which suggests that there is a link between geographical terrain and well-being. Specifically, people high in Extraversion appear to show a strong preference for oceans whereas people low in the trait show a stronger preference for mountains. Moreover, people appear more content when in their preferred environments. The explanation for the link is that the ocean side is more conducive to socializing, which is desirable among extraverts, whereas mountains are more conducive to reflection, which is more desirable among introverts.

Selective migration, social influence, and ecological influence are three mechanisms hypothesized to contribute to geographical variation in psychological characteristics. Although there is limited direct evidence that conclusively shows the impact that each mechanism has on geographical differences, there is a wealth of indirect evidence, which makes it reasonable to maintain the view that the mechanisms are important. It also seems highly likely that the mechanisms do not work independently but in combination.

One example of how the mechanisms might work in combination to affect geographical variation in well-being comes from recent research on the psychological legacy of the Industrialization Revolution. Industrialization had far-reaching social and economic effects, especially in the old coal regions of Britain, where entire towns were built to mine the coal that fueled the factories. However, with technological advances and shifting economic structures, the value of coal plummeted, leaving entire populations unemployed. Today, the old coal regions continue to have high levels of unemployment and low income and rank near the bottom on measures of well-being (Obschonka et al., in press).

To understand how the rise and fall of industrialization in coal regions influenced the well-being of residents in coal regions, Obschonka and colleagues (in press) examined the links between the historical employment share in large-scale coal-based industries and current levels of well-being. The findings suggested that the prevalence of coal-based industries was significantly related to high anxiety and depression, and low well-being. Analyses of the mechanisms responsible for these associations suggested that a combination of selective migration (with people high in well-being leaving the coal regions) and social influence (where persistent economic hardship restricted opportunities) played important roles.

Thus far, we know how well-being differs across geographical areas and we have good ideas about the mechanisms that are responsible for the differences. But how important are geographical differences in well-being? Are they related to important outcomes? Investigating the links between geographical differences in well-being and various geographical indictors will not only inform our understanding of the importance of these differences, it will also help us understand how features of the environment contribute to well-being.

Are Geographical Differences in Well-being Linked to Important Outcomes?

To understand if geographical levels of well-being are associated with important outcomes, it is first useful to consider the processes through which psychological characteristics, such as subjective well-being, become expressed on geographic social indicators. There are at least two ways through which macro-level indicators of psychological characteristics and social indicators become linked. One way is through a "bottom-up" process, in which the psychological characteristics lead to demonstrative behaviors, which are then represented on conceptually relevant social indicators. This process implies that geographical differences in social indicators are an additive effect of the psychological characteristics of residents. Research on the behavioral manifestations of personality provides evidence for a bottom-up perspective (Bogg & Roberts, 2004; Ozer & Benet-Martínez, 2006; Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). Another way psychological characteristics could become expressed in social indicators is through a "top-down" process, in which structural and institutional factors influence the prevalence of psychological and behavioral processes by shaping the experiences, opportunities, and expectations of residents. This process implies that geographical differences in psychological characteristics are a result of social and institutional differences. Support for this perspective comes from research in social and cultural psychology showing that norms influence people's attitudes and behaviors (e.g., Cohen, 1996; Hofstede, 2001; Triandis & Suh, 2002).

These processes are complementary and intended to provide insight into the ways in which psychological characteristics become represented on social indicators. To date, research on the geographical correlates of subjective well-being cannot pinpoint causality, so it is not possible to say that certain associations are due to bottom-up processes while others are based on top-down processes. Nonetheless, it is helpful to keep these processes in mind while interpreting the links between geographical levels of subjective well-being and the social indicators.

National-level correlates of subjective well-being. To develop an understanding of why some nations consistently score highly in well-being, it is helpful to examine the cultural correlates of well-being. This approach has illuminated a number of important findings. Specifically, it appears that nations with high levels of well-being are have more individualistic cultures where citizens place considerable value on personal independence and autonomy (Diener, Oishi, & Lucas, 2003; Hofstede, 2001). One interpretation of the association is that individualistic societies, compared to collectivistic societies, afford people more opportunities to pursue personal interests and to express themselves, so people have a greater range of opportunities and sense of freedom. There is also evidence that nations with high levels of well-being score high on measures of human rights and social justice. These findings suggest that in nations where the rights of all citizens, irrespective of gender, race, ethnicity, or sexual orientation, the population as a whole is effectively able to enjoy the freedom to pursue a meaningful life.

Several studies have observed positive associations between national levels of subjective well-being and median income, suggesting that residents of wealthy nations are more satisfied with their lives compared to people in less affluent nations (Diener et al., 2003; Diener & Suh, 1997; Easterlin, 1995; Schyns, 1998; Stevenson & Wolfers, 2013). The explanation for this association is that in wealthy nations, basic needs, like electricity, plumbing, shelter, healthcare, and the like are, are available, so life is much easier for residents than it is for people who live in nations where such needs are not easily met. Moreover, there is evidence that the benefits of national wealth to subjective well-being is greater to citizens of low-income nations than it is to residents of post-industrial and high-income nations (Mellander, Florida, & Rentfrow, 2011).

Cross-cultural studies of personality have also added to our understanding of national differences in well-being. There is evidence that nations high in subjective well-being are also high in Extraversion, Agreeableness, and Openness, and Emotional Stability (McCrae & Terracciano et al., 2005, Steel & Ones, 2002). These patterns of associations are generally consistent with individual-level research and raising interesting ideas about the nature of national differences in well-being. One idea is that places where there are disproportionate numbers of sociable, enthusiastic, friendly, and stable people causes people to feel accepted, appreciated, and hence satisfied with their lives. Another idea is that cultural characteristics, like individualism-collectivism, freedom, and social justice, interact with the personality traits with the people in the culture to affect subjective well-being. At present, we lack the data to understand precisely how culture, money, and personality interact to affect national variation in well-being.

Regional-level correlates of subjective well-being. Analyses of the correlates of regional differences in well-being has identified a number of patterns of results that are consistent with nation-level analyses and also offer more nuanced information. Studies concerned with regional variation across the U.S. have shown that well-being is linked to a range of economic, occupational, social value, and personality indicators.

Wealth is important for regional differences in well-being. Both states and counties that score high

on measures of well-being also score high on various measures of wealth. Specifically, regional levels of well-being are related to median income, per capita GRP, and house prices (Florida, Mellander, & Rentfrow, 2013; Lucas et al., 2014; Rentfrow et al., 2009). However, the nature of the association between well-being and income does not appear to be linear, as money generates diminishing returns for well-being. That is, as regions become wealthier the benefits to well-being become marginal at best. Given the strong association between wealth and well-being, it is customary for researchers to control for the effects of wealth on well-being.

Regional differences in well-being are also related to many occupational indicators. Areas with large proportions of educated and employed residents show high levels of well-being. There is also evidence that regions with large shares of highly educated professionals- or what Florida (2002) refers to as the creative class, also score highly in well-being. These patterns are consistent with the proportion of residents who have working-class professions (i.e., construction and extraction, installation, maintenance and repair, production, transportation and material moving occupations). Regions with comparatively large shares of working class professions score low on well-being.

Just as nations that value freedom and tolerance score high in well-being, so too do states regions. Indeed, Rentfrow et al. (2009) observed evidence that states with large amounts of social and cultural diversity also score highly on measures of well-being. However, it is necessary to point out that these results were not replicated at the county level (Lawless & Lucas, 2011; Lucas, Cheung, & Lawless, 2014). In fact, it appeared that at the county level, sexual orientation and ethnicity were negatively related to well-being.

Statewide differences in well-being are also linked to personality. Specifically, states that score high in subjective well-being also score highly on Neuroticism, which is consistent with research at both the individual and national levels of analysis (Lyubomirsky et al., 2005; Steel & Ones, 2002).

In their analyses of well-being across counties, Lawless and Lucas (2011) observed associations between well-being and the prevalence of married couples. Specifically, areas with large proportions of married couples were significantly higher in well-being, whereas the prevalence of residents who were separated, divorced, widowed, and single were each associated with significantly low levels of well-being. This pattern of results is consistent with research at the individual level (Ben-Zur & Michael, 2009; Gove, Style & Hughes, 1990), and the results lend further support to the argument that social relationships are very important for subjective well-being (Diener & Seligman, 2002).

It may not come as a surprise, but it is important to report that regional variation in subjective well-being is also related to several physical health indicators (Lawless & Lucas, 2011). Specifically, the level of well-being in U.S. counties is significantly related to rates of physical health, obesity, and deaths due to cancer, heart disease, influenza, homicide, and others. These results hold even when the rates are adjusted for age. Thus, it appears that regions where disproportionate numbers of people are physically unhealthy are also places where subjective well-being is low.

Person-Environment Interactions and Subjective Well-being

Another aspect of research in this area concerns the impact that regional psychological characteristics have on the social and psychological processes of individuals. Studies of geographical variation can help us understand how social and physical aspects of the environment influence and interact with various psychological processes and affect subjective well-being. One of the ways research in this area can add to our understanding is by illuminating the choices people make about where to live and whether those choices influence their well-being. What factors do individuals seek out when choosing places to live, and do those choices relate to life satisfaction?

Using data from a Gallup Poll of Americans, Florida (2008) examined the factors that influence people's decisions about where to live. For some people, social relationships are very important and provide a strong source of life satisfaction. Such people therefore rank proximity to friends and family among the most important factors when deciding where to live. Other people derive a great sense of meaning from their careers and structure their lives around work. For people who place such importance on their careers, proximity to work ranks higher than living near loved ones. And for other people, a significant source of pleasure in life comes from spending time in various cultural or natural spaces. For that reason, some people place outdoor amenities, like access to trails, parks, or beaches highly, or urban amenities, like museums, clubs, and restaurants highly. The fact that there are individual differences in place preferences is not surprising, but does living somewhere that satisfies one's preferences promote subjective well-being?

To live in a place that offers opportunities to pursue one's interests seems ideal, and it seems reasonable to expect that living in such a place would contribute to well-being. For instance, living in a

suburban area with quiet streets, good schools, and plenty of green space should enhance well-being for people who value raising a family because such areas provide supportive environments fulfilling that goal. In contrast, living in a big city with famous museums, galleries, and theaters should enhance well-being for people who value cultural experiences because such areas are well equipped to provide them. There is empirical evidence to support such reasoning. Specifically, in a large-scale of 216 London neighborhoods, Jokela, Bleidorn, Lamb, Gosling, and Rentfrow (2015) examined whether subjective well-being is associated with living in a neighborhood that has characteristics that complement people's personalities. The findings indicated that the degree to which personality and place characteristics complement each other does influence well-being. Specifically, the findings showed that people high in Openness had high subjective well-being if they lived in densely populated and culturally diverse parts of London, and that people high in Agreeableness had high subjective well-being if they lived in neighborhoods with large numbers of family-occupied homes, large gardens and parks, and low crime rates. These results suggest that there may not be a single set of environmental factors that enhance well-being (once basic needs are met), but instead that environmental factors differentially affect well-being depending on certain personality traits.

Another way to conceptualize person-environment interactions on well-being is to consider the degree to which people are psychologically similar to the people in their environment. It is abundantly clear that loneliness and isolation have serious consequences for psychological and mental health, so it is not surprising that feelings of belongingness are critical for self-esteem and contribute to subjective well-being (Leary & Baumeister, 2000). Feeling a sense of belonging and connection to others facilitates the development of a shared reality where people's thoughts, values, and emotions are validated, which can contribute to feelings of self-worth (Fulmer et al., 2010). Thus, we can consider the degree to which people are psychologically similar to their neighbors as measure of person-environment fit, and examine whether the degree to which people fit with their neighbors is linked to well-being. Bleidorn et al. (2016) investigated this possibility by studying personality similarity between individuals and the modal personality of the people living in their city. The results from their analyses small but statistically significant fit effects on self-esteem. Specifically, the more similar people were to their city's modal levels of Openness, Agreeableness, and Conscientiousness, the higher was their self-esteem. Although small effects, the results nevertheless suggest that people have a greater sense of self-worth when they share with their neighbors similar levels of curiosity, friendliness, and self-discipline.

Sharing similar values to one's neighbors is also important for well-being. As the level of political polarization dividing regions of the U.S. increases, people are sorting themselves into areas where they will be surrounded by others who share their beliefs. Indeed, regional differences in political ideology are partially driven by people's efforts to share spaces with like-minded others. And the evidence indicates that living with others who have similar ideologies fosters a sense of belonging and group identity (Dixon & Durrheim, 2003; McPherson, Smith-Lovin, & Cook, 2006). For instance, in an impressive series of studies, Motyl, Iyer, Oishi, Trawalter, & Nosek (2014) investigated the consequences of ideological fit within a regional context and found that ideological fit was linked to feelings of belonging, place satisfaction, and the desire to stay in the area. In contrast, people who did not share political or religious values with their neighbors were more likely to want to move and to actually move to another location.

In summary, the social and physical characteristics of places are important to subjective well-being. Whether or not people live in areas that satisfy their needs and have neighbors who share their values and beliefs is important for subjective well-being. Research in this area offers important insights for understanding the complex factors that contribute to well-being and they also have implications for researchers and policy makers concerned with developing programs and initiatives designed to promote psychological well-being. However, it is important to acknowledge that all the research that has focused on geographical variation in well-being is based on samples from predominantly WEIRD nations (white, educated, industrialized, rich, and democratic). The fact is that people in many parts of the world, and in industrialized nations, lack the opportunities or resources to choose where they live. This fact is a limitation of the research and its implications.

Conclusion

Where we live matters: So many important events and all the seemingly trivial routines of daily life occur in the communities, towns, cities, and states in which we live. These are the places where we learn about who we are and what we believe. And finding the right place to live is among the most important life decisions that people make. It should therefore come as little surprise that the study of geographical differences has a lot to contribute to our understanding of subjective well-being. The research carried out thus far provides several important insights about the nature of well-being and offers valuable clues about the social and economic factors that might enhance it. Further investigating the scale and impact that geographical factors have on individual-level subjective well-being has the potential to inform theory and

research in psychology, as well as government and policy initiatives aimed at promoting healthy living.

The Psychology of Life Balance

By M. Joseph Sirgy, Virginia Polytechnic Institute & State University & Dong-Jin Lee, Yonsei University

Citation

Abstract

Life balance is a state of equally moderate-to-high levels of satisfaction in important life domains contributing to overall life satisfaction. Life balance can be effectively achieved through a set of inter-domain strategies. Two sets of inter-domain strategies are identified, namely strategies to prompt greater participation of satisfied domains to contribute to life satisfaction and strategies to increase domain satisfaction and decrease dissatisfaction. Inter-domain strategies designed to prompt greater participation of satisfied life domains to contribute to life satisfaction include: (1) engagement in social roles in multiple life domains (explained by the principle of satisfaction limits), (2) engagement in roles in health, safety, economic, social, work, leisure, and cultural domains (explained by the principle of satisfaction of the full spectrum of human development needs), and (3) engagement in new social roles (explained by the principle of diminishing satisfaction). Inter-domain strategies designed to increase domain satisfaction and decrease domain dissatisfaction include (1) integrating domains with high satisfaction (explained by the principle of positive spillover), (2) optimizing domain satisfaction by changing domain salience (explained by the value-based compensation principle), (3) compartmentalizing domains with low satisfaction (explained by the segmentation principle), (4) coping with domain dissatisfaction by engaging in roles in other domains likely to produce satisfaction (explained by the behavior-based compensation principle), (5) stress management (explained by the principle of role conflict), and (6) using skills, experiences, and resources in one role for other roles (explained by the principle of role enrichment).

Key words: **Balanced Life, Life Balance, Work-Life Balance, Life Satisfaction, Subjective Well-being, Quality of Life. Work-Family Conflict, Work-Family Interference**

Much research has been documented about concepts related to the balanced life in the literatures of organizational/industrial psychology and human resource management. These concepts include work-life balance, work-family balance, work-family interference, and work-family interface (see literature reviews of various concepts related to work-life balance by Allen, Herst, Bruck, & Sutton, 2000; Bulger & Fisher, 2012; Byron, 2005; Casper, Eby, Bordeaux, Lockwood, & Lambert, 2007; Danna & Griffin, 1999; Eby, Casper, Lockwood, Bordeaux, & Brinley, 2005; Eby, Maher, & Butts, 2010; Greenhaus & Allen 2011; Kalliath & Brough, 2008; Kossek & Ozeki, 1998; Lee & Sirgy, 2017; McNall, Nicklia, & Masuda, 2010; Sirgy & Lee, 2016, 2017; Sirgy, Reilly, Wu, & Efraty, 2008; Yasbek, 2004). In the literature of subjective well-being, only a few studies were found addressing life balance. For example, Diener, Ng, and Tov (2008) reported a study involving a representative sample of the world to assess people's affect balance (positive versus negative affect) on the previous day and the various activities they have engaged in. The study found that the most popular activity that most people engaged in is socializing with family and friends. In this context, the study also found a *decreasing marginal utility* of this type activity. That is, to ensure an optimal level of life satisfaction, people attempt to engage in a variety of activities because satisfaction from one type of activity diminishes in time. Sheldon and Niemiec (2006) demonstrated that life balance is achieved not only by the fulfilment of psychological needs (needs for autonomy, competence, and relatedness) but a *balanced effect among the satisfaction of these needs* . Matuska (2012) conceptualized life balance as congruence among both desired and actual time spent in activities and equivalence in the degree of discrepancy between desired and actual time spent across *activities that satisfy basic and growth needs* (needs related to health, relationship, challenge/interest, and identity). The author was able to demonstrate a strong association between life balance and personal well-being. A similar conceptualization was introduced by Sheldon, Cummins, and Kamble (2010). They defined life balance as perceived low discrepancy between actual and ideal time-use profiles. The authors developed a life balance measure based on this conceptualization and were able to demonstrate that life balance is positively related to subjective well-being mediated by psychological need satisfaction.

The first author of this chapter made an attempt to address the concept of the balanced life in his 2002 book on the *Psychology of Quality of Life* (Sirgy, 2002). In Chapter 14 of the book, titled "balance," Sirgy proposed that people make attempts to create balance in their lives to *optimize* life satisfaction (i.e., achieve and maintain an acceptable level of life satisfaction). He made a distinction between two balance

concepts: within-domain balance and between-domain balance. *Balance within a life dom*ain is achieved by striving to experience both positive and negative affect. Positive affect reflects a reward function, namely goals are attained and resources are acquired. In contrast, negative affect serves a motivational function. That is, negative affect helps the individual recognize problems and opportunities for future achievement and growth (cf. Kitayama & Markus, 2000). *Balance between life domains* can be achieved through compensation (i.e., increasing the salience of positive life domains compensates for negative life domains; and conversely, decreasing the salience of negative life domains helps reduce the influence of negative affect from these domains on overall life satisfaction) (also see Sirgy, 2012). The same author with a doctoral student at the time (Sirgy & Wu, 2009) published an article in the *Journal of Happiness Studies* titled "The pleasant life, the engaged life, and the meaningful life: What about the balanced life?" In this article the authors positioned the concept of the balanced life vis-à-vis other popular concepts of subjective well-being, namely "the pleasant life," "the engaged life," and "the meaningful life" (as proposed by Martin Seligman in his 2002 book, *Authentic Happiness*). Seligman has argued that life satisfaction stems from three major sets of experiences in life, namely experiencing pleasantness regularly (the pleasant life), experiencing a high level of engagement in satisfying activities (the engaged life), and experiencing a sense of connectedness to a greater whole (the meaningful life). In response, Sirgy and Wu countered by suggesting that having a balanced life is equally important to life satisfaction. The balanced life is experienced when people are highly engaged in social roles in multiple domains. They explained the effect of balance on life satisfaction using two concepts, namely *satisfaction limits* (i.e., people can derive only limited amount of satisfaction from a single life domain; hence engagement in multiple domains is necessary to optimize life satisfaction) and *satisfaction of the full spectrum of human developmental needs* (i.e., people have to be involved in multiple domains to satisfy both basic and growth needs; both sets of needs have to be met to induce a high level of subjective well-being). This article won the Best Paper in the journal and was reprinted in *Explorations of Happiness* (edited by Delle Fave, 2013).

The goal of this chapter is to identify the major principles of life balance, and as such we introduce to the reader a comprehensive construct of life balance reflective of these principles. We describe how life balance contributes to subjective well-being (life satisfaction or perceived quality of life).

Life Balance

To follow the subsequent discussion, the reader needs to become familiar with some basic concepts of subjective well-being, namely life domain, domain satisfaction, and the bottom-up spillover process of life satisfaction. Let's first define the concept of "life domain" and "domain satisfaction." Then we will tackle the concept of "balance." Andrews and Withey (1976) and Campbell, Converse, and Rodgers (1976) were the main proponents of the life domain approach to the study of quality of life and subjective well-being. Andrews and Withey used multiple regression to predict subjects' life satisfaction scores ("How do you feel about life as a whole?" with responses captured on a 7-point delighted-terrible scale). They found that satisfaction with various life domains explained 52-60% of the variance. These domains are interpersonal relations, self, family, leisure/leisure-time activities, home, friends and associates, neighborhood, job, education, services/facilities, community, economic situation, local government, national government, and life in the U.S. today. Campbell, Converse, and Rodgers used a similar set of life domains, namely leisure/nonworking activities, family, standard of living, work, marriage, savings/investments, friendships, city/county, housing, education, neighborhood, life in the U.S., health, religion, national government, and organizations. Many other quality-of-life/well-being researchers have uncovered other variations of life domains (see literature reviews by Diener, 1984; Diener, Suh, Lucas, & Smith, 1999; and Sirgy, 2012), and the notion of satisfaction in life domains contributing to a life satisfaction judgment has come to be known as *bottom-up spillover theory of life satisfaction*.

Affective experiences are stored in memory in life spheres, and these spheres are organized in a hierarchy of satisfaction. At the top of the satisfaction hierarchy is life satisfaction—a hot cognition reflecting how the individual feels about his or her life overall. Second in line in the satisfaction hierarchy is domain satisfaction. That is, people make judgments about how they feel in certain life domains such as family life, social life, work life, material life, community life, etc. Satisfaction in these life domains influences the life satisfaction judgment, which is at the top of the satisfaction hierarchy—the most abstract hot cognition. At the bottom of the satisfaction hierarchy are concrete hot cognitions related to satisfaction with life events (i.e., concrete and salient events that have occurred and are associated with positive or negative affect). As such, satisfaction judgments related to life events (most concrete hot cognitions) influence satisfaction judgments of life domains, which in turn influence satisfaction with life overall (most abstract hot cognition). The reader should then note that the central tenet of bottom-up spillover theory of life satisfaction is the carryover of affect from subordinate life domains to superordinate ones, specifically from life domains such as leisure, family, job, and health to overall life. Thus, bottom-up spillover implies that subjective well-being (or life satisfaction) can be increased by allowing life domains carrying positive

feelings or satisfaction to spill over unto the most superordinate domain (overall life). The positive affect accumulates in life domains as a direct function of satisfaction of human development needs—physiological needs, safety needs, social needs, esteem needs, self-actualization needs, knowledge needs, and aesthetics needs (Maslow, 1970).

Having explained the concepts of life domains and domain satisfaction, the reader is now ready to appreciate the discussion concerning how people manipulate the interplay life domains and domain satisfaction to increase life balance, which in turn contributes to life satisfaction. That is, to achieve life balance people engage in behavioral strategies to increase life satisfaction by manipulating the interplay among domain satisfaction to prompt greater participation of satisfied life domains to contribute to life satisfaction and increase domain satisfaction and decrease domain dissatisfaction. Inter-domain strategies designed to prompt greater participation of satisfied life domains to contribute to life satisfaction include: (1) engagement in social roles in multiple life domains (explained by the principle of satisfaction limits), (2) engagement in roles in health, safety, economic, social, work, leisure, and cultural domains (explained by the principle of satisfaction of the full spectrum of human development needs), and (3) engagement in new social roles (explained by the principle of diminishing satisfaction). Inter-domain strategies designed to increase domain satisfaction and decrease domain dissatisfaction include (1) integrating domains with high satisfaction (explained by the principle of positive spillover), (2) optimizing domain satisfaction by changing domain salience (explained by the value-based compensation principle), (3) using skills, experiences, and resources in one role for other roles (explained by the principle of role enrichment), (4) compartmentalizing domains with low satisfaction (explained by the segmentation principle), (5) coping with domain dissatisfaction by engaging in roles in other domains likely to produce satisfaction (explained by the behavior-based compensation principle), and (6) minimizing role conflict (explained by the principle of role strain and stress).

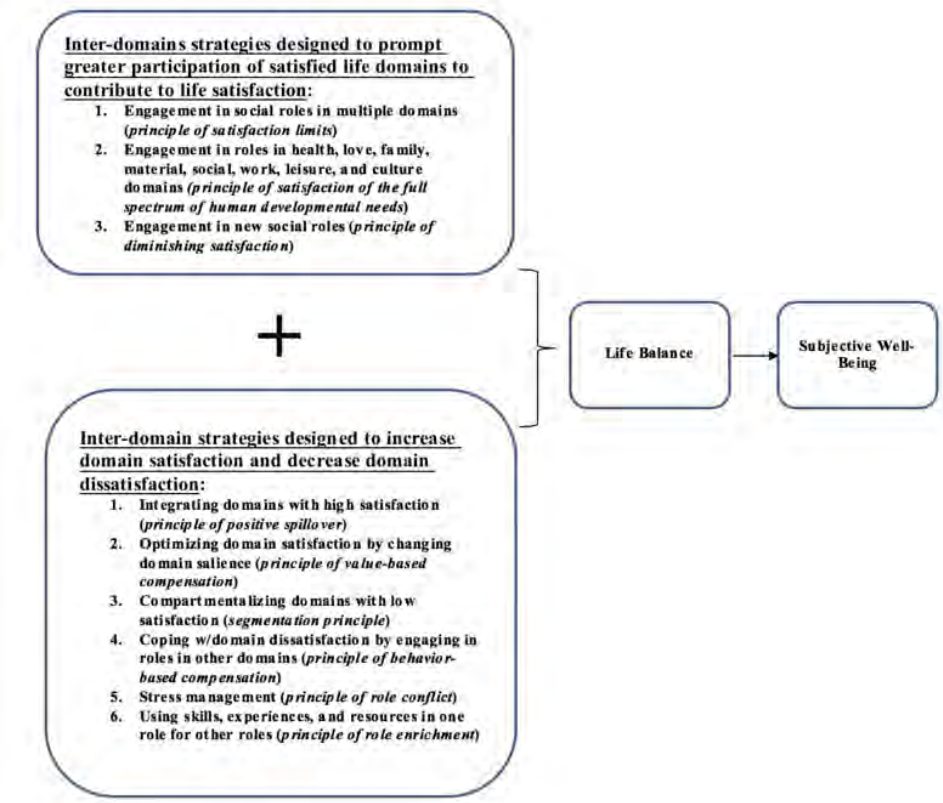
We will begin by discussing those principles related to prompting greater participation of satisfied life domains to contribute to life satisfaction. See Figure 1.

Inter-domain Strategies Designed to Prompt Greater Participation of Satisfied Life Domains to Contribute to Life Satisfaction

As previously mentioned, we will discuss three behavioral strategies people use to achieve life balance by prompting greater participation of satisfied life domains to contribute to life satisfaction. These are (1) engagement in social roles in multiple life domains (explained by the principle of satisfaction limits), (2) engagement in roles in health, safety, economic, social, work, leisure, and cultural domains (explained by the principle of satisfaction of the full spectrum of human development needs), and (3) engagement in new social roles (explained by the principle of diminishing satisfaction).

Engagement in social roles in multiple life domains and the principle of satisfaction limits. Much research has shown that engagement in social roles in work life and nonwork life (family, leisure, social, community, etc.) serves to produce a positive, fulfilling, state of mind characterized as vigor, dedication, and absorption (Schaufeli, Salanova, Gonzalez-Roma, & Bakker, 2002). *Vigor* reflects a high level of energy and mental resilience in role engagement in multiple domains. *Dedication* refers to being strongly involved in one's roles at both work and nonwork by experiencing a sense of significance, enthusiasm, and challenge. *Absorption* is characterized by being fully concentrated and happily engrossed in the task at hand associated with the various roles across life domains (Schaufeli & Bakker, 2004).

Figure 1. Behavioral Strategies of Life Balance



Individuals are likely to achieve a high level of satisfaction in life overall when they are fully engaged in multiple roles in work *and* nonwork life. Further, they are likely to maximize their life satisfaction if and when they become fully engaged in *multiple* roles. Doing so is essentially one way to increase harmony among life domains. Increasing satisfaction in multiple domains ultimately serves to increase life satisfaction at large. The effect of role engagement in social roles in multiple domains on life satisfaction can be explained through the *principle of satisfaction limits,* which we now turn to.

The bottom-up spillover model of life satisfaction proposes that life satisfaction is determined by cumulative satisfaction experienced in important life domains such as satisfaction in work life, family life, social life, leisure life, spiritual life., community life, etc. (e.g., Andrews & Withey, 1976; Campbell, Converse, & Rodgers, 1976). Mathematically speaking, the model states that a life satisfaction score of an individual can be predicted by adding all the satisfaction scores of salient life domains. For example, if one uses an 11-point satisfaction scale (-5=high dissatisfaction to +5=high satisfaction), then an individual (A) registering satisfaction in work life (e.g., "+3"), family life (e.g., "+3"), leisure life (e.g., "+3"), social life (e.g., "+3"), and material life (e.g., "+3") should have a higher life satisfaction score than another individual (B) who registers satisfaction in work life (e.g., "+5"), family life (e.g., "0"), leisure life (e.g., "0"), social life (e.g., "0"), and material life (e.g., "0"). This is due to the fact that the former individual has a total domain satisfaction score of "15" [(+3) + (+3) + (+3) + (+3) + (+3)], whereas the latter has a total domain satisfaction score of "+5" [(+5) + (0) + (0) + (0) + (0)]. Of course, this predictive equation assumes that work life, family life, leisure life, social life, and material life are all equally salient to both individuals. In other words, overall life satisfaction is accrued additively from satisfaction in multiple life domains. Research has demonstrated that satisfaction from a variety of life domains contributes to unique variance in life satisfaction, and that there is some validity to this compensatory model of life satisfaction (e.g., Hsieh, 2003; Rojas, 2006; also see reviews by Diener, 1984; Diener et al., 1999).

The *principle of satisfaction limits* (Sirgy & Wu, 2009) posits that the amount of contribution of domain satisfaction from a single life domain to overall life satisfaction is limited. In the example of the compensatory model described above the limit is +5 satisfaction units in each domain (scale = +5 to -5). In other words, one can achieve only a limited amount of satisfaction from a single life domain (a maximum of 5 satisfaction units). Using the example above, Person A is satisfied in work life ("+3"), leisure life ("+3"), social life ("+3"), material life ("+3"), and family life ("+3"). His life satisfaction (15 units) is based

on a moderate degree of satisfaction in five salient life domains. Person B is satisfied with work life (+5) only. He is not satisfied in family life ("0"), leisure life ("0"), social life ("0"), as well as material life ("0"). His life satisfaction score ("5" units) is based on satisfaction from 1 out of 5 salient domains. In sum, an individual who is highly satisfied in *multiple domains* is likely to experience a higher life satisfaction compared to an individual who is highly satisfied in a single domain. As such, role engagement in multiple life domains produces an additive effect on life satisfaction (e.g., Andrews & Withey, 1976; Campbell, Converse, & Rodgers, 1976: Eakman, 2016; Hsieh, 2003; Rojas, 2006; Sirgy & Lee, 2016; Sirgy & Wu, 2009). That is, high role engagement in a single life domain with little or no role engagement in other life domains cannot contribute much to life satisfaction compared to high role engagement in multiple domains.

Consider the following study: Bhargava (1995) asked study participants to discuss life satisfaction of others. Most participants inferred life satisfaction of others as a direct function of their satisfaction in *multiple* domains. They calculated happiness by summing satisfaction across several important domains—the more positive affect in multiple domains, the higher the subjective well-being. In a work context, individuals engaging in various social roles in nonwork life domains, in addition to roles in work life, are likely to experience a high level of life satisfaction compared to those who are highly engaged only in work life (e.g., Greenhaus & Powell, 2006; Rice, McFarlin, Hunt, & Near, 1985).

In sum, this discussion can be captured as follows: Individuals who have a high level of role engagement in multiple life domains are likely to increase life balance and experience higher life satisfaction than those who have a high level of role engagement in a single domain. This effect may be due to satisfaction limits. Specifically, compared to individuals who are engaged in a single domain, individuals who are highly engaged in multiple life domains are likely to experience more satisfaction in those domains, contributing to life satisfaction. Those who are engaged in a single domain can produce only a limited amount of domain satisfaction (less that those who are engaged in multiple domains) that spills over to life satisfaction. That is, compared to role engagement in multiple domains, role engagement in a single domain is likely to be wholly insufficient to contribute significantly to life satisfaction.

Engagement in roles in health, love, family, material, social, work, leisure, and culture domains; and the principle of satisfaction of the full spectrum of human developmental needs. People try to optimize their life satisfaction (enhance their life satisfaction to an acceptable level) by actively engaging in social roles in multiple domains. The question that arises based on the preceding argument is "which domains?" Life satisfaction is significantly increased when the individual engages in roles in life domains that can satisfy the full spectrum of human development needs (Maslow, 1970). As such, we believe that life balance can be achieved through active engagement in social roles in multiple domains serving to satisfy both basic and growth needs: health, love, family, and material domains serving to satisfy mostly basic needs and social, work, leisure, and culture domains serving to satisfy growth needs. Let us be more specific.

Sirgy and Wu (2009) have argued that subjective well-being is not simply cumulative positive minus negative affect—irrespective of the source. It is the satisfaction of human developmental needs, the full range of needs—not a handful of selected needs. In other words, one cannot substitute positive affect related to one need with another need. To illustrate this point, let us consider the following example. Two individuals, A and B. Person A has "+3" satisfaction units in each of the following domains related to basic needs: health life, love life, family life, and material life. In other words, Person A is satisfied in domains related to his basic needs, a total score of "+8" satisfaction units [(+2) + (+2) + (+2) + (+2)] and the same person is similarly satisfied in life domains related to growth needs (social life, work life, leisure life, and culture life), a total of "+8" [(+2) + (+2) + (+2) + (+2)]. Summing up Person A's domain satisfaction scores, we obtain a total amount of "16" units of domain satisfaction (+8 satisfaction units from domains related to basic needs, and another +8 satisfaction units from domains related to growth needs). Now let us compare this case with Person B who is highly satisfied with basic needs only. Person B is highly satisfied in domains related to his basic needs, a total score of "+20" satisfaction units [(+5) + (+5) + (+5) + (+5)] while is dissatisfied in domains related to his growth needs, a total of "-8" satisfaction units [(-2) + (-2) + (-2) + (-2)]. As such, the total domain satisfaction score for person B is also "+12". We predict that person A is likely to report a higher degree of life satisfaction than person B because person A has *balanced satisfaction* from life domains related to *both basic and growth needs*, whereas Person B has unbalanced domain satisfaction (high satisfaction in domains related to basic needs but low satisfaction in domains related to growth needs).

Let us delve deeper to understand the psychology underling this effect. We will do so by discussing the *principle of satisfaction of the full spectrum of human developmental needs* . This principle posits that individuals who are satisfied with the full spectrum of developmental needs (i.e., satisfaction of growth needs as well as basic needs) are likely to have a high level of life satisfaction relative to those who are less satisfied (e.g., Alderfer, 1972; Herzberg, 1966; Maslow, 1970; Matuska, 2012; Sheldon, Cummins,

& Kamble, 2010; Sheldon & Niemiec, 2006). When people engage in multiple roles across life domains, they are likely to obtain access to psychological and physical resources, which in turn increase opportunities for satisfaction of many basic and growth needs. Seeking to satisfy a specific need in a single life domain does not positively contribute much to life satisfaction (Sirgy et al., 1995). That is, when people engage in multiple roles, they are likely to experience satisfaction of growth needs (i.e., social, knowledge, aesthetics, self-actualization, and self-transcendence needs) as well as satisfaction of basic needs (i.e., health, safety, and economic needs). Satisfaction of growth needs contributes to positive affect, whereas satisfaction of basic needs contributes only to the reduction of negative affect (Herzberg, 1966). Satisfaction of both sets of basic and growth needs contributes significantly and positively to life satisfaction.

Specifically, Sirgy and Wu (2009) have described how people organize their lives to fulfil their developmental needs. To satisfy their biological and health-related needs, people engage in a variety of activities such as eating right, exercising regularly, getting regular check-ups, engaging in regular sex, and so on. The events related to those activities and their outcomes generate a certain amount of satisfaction and dissatisfaction. These affective reactions are organized and stored in memory in certain life domains such as health, love, family, and economic. When a man is asked how he feels about his health life, he is likely to reflect on his affective experiences in relation to health-related activities such as eating right, exercising regularly, having regular check-ups, and so on. When the same person is asked about his love life, he reflects about his affective experiences related to love, romantic relationships, and sex. When asked about his family life, he reflects on those experiences related to the use of his significant others such as spouse and children, his residence, his neighborhood, and community. Financial issues and experiences related to money, income, standard of living, and material possessions also likely to be segmented in material life and mostly related to basic needs. With respect to growth needs (e.g., social, esteem, self-actualization, self-transcendence, aesthetics, and knowledge needs), experiences may be segmented in life domains such as social life, work life, leisure life, and culture life. However, this is not to say that a variety of developmental needs can be met in a single domain. Consider the work domain for example. Many developmental needs, both basic and growth needs, can be met through work life. Through work life, both basic (i.e., economic, health and safety, and family-related needs) and growth needs (i.e., social, esteem, self-actualization, self-transcendence, knowledge, and aesthetics needs) can be met. To reiterate, in every life domain a variety of developmental needs can be met. However, certain life domains are predisposed to meet certain developmental needs more so than others. As such, we argue that health, love, family, and economic domains are likely to reflect satisfaction resulting more from meeting basic than growth needs. Conversely, social life, work life, leisure life, and culture life are domains likely to reflect satisfaction resulting more from meeting growth than basic needs.

Suggestive evidence of this principle comes from a body of evidence showing that materialism is negatively correlated with life satisfaction (see Wright and Larsen, 1993, for a meta-analysis of the research findings). Specifically, materialistic people can be viewed as imbalanced in that they pursue wealth and material possessions to the exclusion of other important goals in life. Materialistic people who are successful hoarding material wealth may feel successful and happy with their material life. Placing undue emphasis on making money (to satisfy basic needs such as biological and safety needs) is likely to lead them to neglect other growth needs such as social, esteem, self-actualization, self-transcendence, aesthetics, and knowledge needs. It is no wonder that the evidence shows that materialism is negatively correlated with life satisfaction.

Furthermore, as previously discussed, Matuska (2012) conceptualized life balance as congruence among both desired and actual time spent in activities and equivalence in the degree of discrepancy between desired and actual time spent across *activities that satisfy basic and growth needs* (needs related to health, relationship, challenge/interest, and identity). The author conducted a study that successfully demonstrated a strong association between life balance and personal well-being.

In sum, the preceding discussion can be captured as follows: Individuals who have a high level of role engagement in life domains related to both basic needs (e.g., health, love, family, and material domains) and growth needs (e.g., social, work, leisure, and culture domains) are likely to experience greater satisfaction among life domains contributing to higher life satisfaction than those who have a high level of role engagement in domains related to only basic or growth needs. This effect may be due to the effect of satisfaction of the full spectrum of human developmental needs. Specifically, compared to individuals who are engaged in roles in select domains, individuals who have a high level of role engagement in multiple domains addressing both basic and growth needs are likely to experience more life satisfaction. Role engagement in health, love, family, and material domains are likely to satisfy mostly basic needs (survival needs such as having enough resources to deal with health and safety issues), whereas role engagement in social, work, leisure, and culture are likely to satisfy mostly growth needs (higher-order

needs such as social, esteem, self-actualization, aesthetics, and knowledge needs). The combined and balanced effects of satisfaction of both basic and growth needs serve to increase life satisfaction. That is, satisfaction of the full spectrum of human developmental needs (balance between basic and growth need satisfaction) produces the highest level of life satisfaction.

Engagement in new social roles and the principle of diminishing satisfaction. Much research in variety seeking supports the notion that successful engagement in new roles is likely to produce more positive affect than successful engagement in well-established roles (e.g., Kahn, 1995; Kahn & Isen, 1993; Levav & Zhu, 2009; McAlister & Pessmier, 1982). That is, engaging and succeeding in new roles tend to produce a jolt of positive affect much more so than engaging and succeeding in well-established roles. Also, much research in industrial/organizational (I/O) psychology has demonstrated the effect of task variety on job performance and employee well-being (e.g., Christian, Garza, & Slaughter, 2011; Pierce & Dunham, 1976). That is, compared to workers who are engaged in repetitive tasks, workers engaging in a variety of tasks tend to feel much more motivated to excel on their jobs, tend to do much better in relation to job performance, and experience higher levels of job satisfaction. One can extrapolate from this research that life balance is not only limited to engagement in social roles in multiple domains satisfying both basic and growth-related needs but also new social roles. This may best be explained using the *principle of diminishing satisfaction.*

This principle states that individuals with life balance are likely to continuously engage in new roles to guard against diminishing satisfaction associated with well-established roles. Why? The intensity of the positive affect in the context of a social role experienced in a given life domain tends to decay with adaptation effects (Helson, 1964). Consider the following scenarios. Person A (woman) is right out of college and starts a new job. She experiences success in her assigned roles. This success is likely to bring much positive affect and satisfaction in work life—+4 units of satisfaction in the work domain—on a 11-point satisfaction scale varying from -5 (very dissatisfied) to +5 (very satisfied). Compare Person A (woman) to Person B (man) who is a seasoned worker—has been on the job for a long time. He is equally successful in his assigned work roles (perhaps a +2 units of satisfaction). That is, the man is not likely to experience the same magnitude of satisfaction compared to the woman. This dampening of positive affect and satisfaction for the man is due to an adaptation effect. That is, positive affect is dampened with repeated successful performance. To guard against this dampening effect and to restore satisfaction in the work life domain, the man has to engage in new roles to maintain the same level of domain satisfaction that was once generated through old and well-established role performance. However, to increase positive affect in the work domain (say from +2 units of satisfaction to +4 units of satisfaction), he needs to engage in new work-related roles successfully.

Research has documented this phenomenon. Specifically, given successful role performance in a particular life domain (e.g., work life) individuals who have not been feeling satisfied in that domain are likely to experience a greater magnitude of domain satisfaction than individuals who are already satisfied in the same domain (e.g., Ahuvia & Friedman, 1998; Diener, Ng, & Tov, 2008; Rojas, 2006). Put succinctly, increases in satisfaction in a life domain serve to increase life satisfaction but at a decreasing marginal rate with repeated experiences.

In sum, we can capture the preceding discussion as follows: Individuals become engaged in new social roles to mitigate decreases in domain satisfaction and life satisfaction overall. This effect is due to the diminishing satisfaction effect. Specifically, individuals who are engaged in social roles experience diminishing satisfaction in a given life domain over time, which in turn detracts from life satisfaction overall. To guard against this diminishing domain satisfaction, they engage in new social roles to generate new satisfaction thereby compensating for the diminished satisfaction related to the old roles.

Inter-domain Strategies Designed to Increase Domain Satisfaction and Decrease Domain Dissatisfaction

In this section we will discuss six behavioral strategies people use to achieve life balance by increasing domain satisfaction and decreasing domain dissatisfaction. These are: (1) integrating domains with high satisfaction (explained by the principle of positive spillover), (2) optimizing domain satisfaction by changing domain salience (explained by the value-based compensation principle), (3) compartmentalizing domains with low satisfaction (explained by the segmentation principle), (4) coping with domain dissatisfaction by engaging in roles in other domains likely to produce satisfaction (explained by the behavior-based compensation principle), (5) stress management (explained by the principle of role conflict), and (6) using skills, experiences, and resources in one role for other roles (explained by the principle of role enrichment).

Integrating domains with high satisfaction and the principle of positive spillover. Life balance can also be achieved by integrating life domains that house high levels of positive affect or satisfaction.

Doing so contributes to life satisfaction overall. Consider the owner of a mom and pop store whose family residence is situated on the top floor of the store. His wife and children help at the store by staffing the checkout stand, maintaining inventory, dealing with suppliers and customers, etc. In this situation, the store owner's work life is highly integrated with his family life, marital life, social life, material life, and perhaps community life too. The store is highly successful in that it has a good stream of patrons, a good reputation in the neighborhood, and it generates a decent income that supports his family and a few other jobs in the community. Success in these varied roles translates into positive affect in work life, family life, marital life, social life, material life, and community life. Thus, life satisfaction is increased by integrating both work and family life, which serves to increase satisfaction in both domains. This phenomenon is essentially known as "positive spillover."

Let us further delve in this discussion of positive spillover. Experiences in work *and* nonwork life may spill over. That is, affect may spill over from work life to nonwork life and vice versa. This is what I/O psychologists commonly refer to as "affect spillover" (e.g., Edwards & Rothbard, 2000; Grzywacz & Carlson, 2007). Affect spillover can be either positive or negative. Positive affect spillover refers to positive mood that transfer from one life domain to another. Conversely, negative spillover refers to negative mood spilling over from one domain to another. *Affect spillover* should be distinguished from *crossover effects*. Affect spillover refers to feelings caused by experiences in one life domain influencing another life domain. It is an intra-individual phenomenon (i.e., within an individual). In contrast, *crossover effect* is an inter-individual construct. It refers to emotional contagion between individuals whereby individuals are influenced by the emotions displayed by those around them (e.g., Demerouti, Bakker, & Schaufeli, 2005; Hatfield, Cacioppo, & Rapson, 1994). Crossover effects are likely to be high when individuals are in physical proximity and in close communications (Barsade, 2002; Neumann & Strack, 2000).

Consider the following case involving two individuals, Person A and Person B. Both individuals experience "+1" units of satisfaction in work life and "+3" units of satisfaction in family life. However, Person B decides to integrate work and family domains (e.g., by doing work at home and taking care of family responsibilities at work). Person B was highly successful in integrating work and family domains. Doing so increased his satisfaction in work life from "+1" to "+3," whereas his satisfaction in family life remained at "+3." Person B achieved work life balance through positive spillover. In contrast, Person A did not bother to integrate the two domains; hence, he remained experiencing "+1" satisfaction in work life and "+3" in family life. In this case, positive spillover through domain integration resulted in greater satisfaction in family life for Person B, and as a result higher subjective well-being.

Individuals are likely to experience spillover of positive affect from one life domain to another when the life domains are interdependent and the roles are integrated (e.g., Greenhaus & Powell, 2006; Ilies, Wilson, & Wagner, 2009). In regard to the direction of spillover of positive affect, individuals are likely to experience spillover of positive affect from a life domain with a strong involvement to another life domain with weak involvement (Frone, Russell, & Cooper, 1992). For instance, for those who are highly involved with work, affect spillover from work-to-family seems to be stronger than family-to-work spillover.

The *principle of positive spillover* posits that positive affect in two life domains that are highly integrated amplify domain satisfaction, which in turn spills over to overall life satisfaction. That is, positive affect that spills over between life domains increases the level of satisfaction in those domains. For example, sharing of positive work experiences increases family satisfaction because sharing of positive events facilitates positive mood among family members and family satisfaction (e.g., Gable, Gonzaga, & Strachman, 2006; Heller & Watson, 2005). Furthermore, positive affect in one role can boost the level of motivation and energy to engage in another role in a neighboring domain. Thus, positive affect in one domain may increase the likelihood of successful performance in a different domain, resulting in increased satisfaction in that domain, which in turn increases life satisfaction overall (Edwards & Rothbard, 2000). In other words, increased satisfaction in the respective domains contribute additively to life satisfaction.

In sum, the preceding discussion can be captured as follows: Individuals who experience positive spillover between two or more life domains through domain integration are likely to experience greater satisfaction in those domains, compared to those who do not experience positive spillover. Such increases in domain satisfaction contribute to increases in life satisfaction overall.

Optimizing domain satisfaction by changing domain salience and the principle of value-based compensation. Consider the following scenario: Person A is satisfied with family life (+3 unit of satisfaction units on a 11-point scale varying from +5 to -5) but not satisfied with work life (-3 satisfaction units). Person A also believes that both family life and work life are equally important (0.8 importance points to each domain on a 1.0-point importance scale varying from "0" as "not important at all" to "1.0"

as "extremely important"). Hence, family satisfaction is "+2.4" [(+3) x (0.8)] and work satisfaction is "-2.4" [(-3) x (0.8)]. Person B is also in the same boat—feels happy with family life but unhappy with work life. Person B also believes that both domains are equally important. Note that in both cases, there is marked satisfaction in family life ("+2.4") and dissatisfaction in work life ("-2.4"). How do people manipulate the interplay between/among the domains to enhance life satisfaction overall?

Person A makes a cognitive change by increasing the salience of family life—increasing importance weight from "0.8" to "1.0," resulting in "+3.0" satisfaction points [(+3) x (1.0)] in the family life and decreasing the salience of work life—decreasing the salience weight from "0.8" to "0.1" resulting in "-0.3" satisfaction units [(-3) x (0.1)] in work life. That is, satisfaction in family life increases—from "+2.4" to "+3.0" [(+3) x (1.0)] and dissatisfaction in work life decreases from "-3.2" to "-0.3" [(-3) x (0.1)]. Person B remains the same. Thus, Person A was able to increase satisfaction in family life and decrease dissatisfaction in work life. Doing so serves to increase life satisfaction overall. Person B remains the same.

This prediction is in line with the research showing a significant correlation between domain satisfaction and domain importance (Hsieh, 2003). That is, domains in which people express high levels of satisfaction are likely to be treated as more salient than domains with low satisfaction (or dissatisfaction). Consider the following study. Scott and Stumpf (1984) collected data on subjective well-being, domain satisfaction, and domain importance using a population of immigrants to Australia. The data clearly revealed a pattern of correlations in which most domain satisfaction scores were significantly correlated with their corresponding domain importance scores—friendship, material possessions, family recreation, and nation. Also consider research in social psychology showing that people report things they are not proficient at to be less important than the things that they are proficient at (e.g., Campbell, 1986; Harackiewicz, Sansone, & Manderlink, 1985; Lewicki, 1984; Rosenberg, 1979). These findings also are in line with the positive correlation between domain satisfaction and domain importance.

The *principle of value compensation* provides an explanation for the association between domain satisfaction and domain salience. People jack up the salience of domains they feel satisfied in and decrease the salience of domains they feel dissatisfied in. Why? They do so to increase life satisfaction or at least prevent life satisfaction from falling below an acceptable level (Sirgy, 2002). Wu (2009) attempted to capture the value-based compensation effect by developing an index that reflects the correlation between have-want discrepancy scores from 12 different life domains and perceived importance scores of these domains—a correlation coefficient at the individual level. Individuals who engage in compensation are those who perceive life domains with high satisfaction to be more important than others. Wu calls this compensation phenomenon the "shifting tendency." Correlations between the *shifting tendency* and life satisfaction (as well as domain satisfaction scores) were positive suggesting that the shifting tendency may be a strategy that enhances subjective well-being.

In sum, the preceding discussion can be captured as follows: Individuals increase domain satisfaction by increasing salience of satisfied domains; and conversely, they decrease domain dissatisfaction by decreasing salience of dissatisfied domains. Life satisfaction is increased by doing so.

Compartmentalizing domains with high dissatisfaction and the segmentation principle. Consider the following scenario comparing two individuals (persons A and B) who are experiencing dissatisfaction at work: -3 units of dissatisfaction on a 11-point scale varying from -5 (very dissatisfied) to +5 (very satisfied). However, both individuals are satisfied with their family life (+3 units of satisfaction). Both individuals are experiencing negative spillover of affect from work life to family life. That is, their dissatisfaction at work (-3 units of satisfaction) is influencing their mood at home causing friction and stress in family life. Person A decides to deal with the high dissatisfaction at work by compartmentalizing his work life to prevent future negative spillover of negative affect from work life to family life. That is, he decides that at home he will not think about work issues, speak of work issues, and do anything related to work. Doing so, Person A manages to maintain his satisfaction in family life to the previous level (+3). Person B does not segment and thus remains to experience decreased satisfaction in the family life as a result of the negative spillover.

Negative affect in one life domain is likely to spill over to other life domains when there is a high level of overlap across life domains in terms of time, space, effort, and resources. In order to prevent spillover of negative affect to other life domains, individuals create and maintain psychological, physical, or behavioral boundaries around their life domains (Ashforth, Kreiner, & Fugate, 2000; Edwards & Rothbard, 2000; Judge et al., 2001; Sonnentag 2012). For example, workers can segment family life domain from work life domain. At home, they do not converse about work experiences. Work-life issues stay at work, and home-life issues stay at home.

Research by Lucas, Diener, and Suh (1996) has demonstrated that the global category of happiness

is composed of separable well-being variables (e.g., work satisfaction, home satisfaction, and life satisfaction). These variables sometime move in different directions over time (cf. Scollon & Diener, 2006). This finding point to the possibility that some people at times are able to prevent spillover of negative affect between life domains. Recent research found that increased use of mobile technologies blur the boundaries between work and family, making segmentation difficult (Chesley, 2005; Park, Fritz, & Jex, 2011).

Let us now delve more into the psychological dynamics concerning the effect of segmentation on life satisfaction in greater detail. Wilensky (1960), I/O psychologist, was the first to describe how people use segmentation to enhance their subjective well-being. He argued that when people feel dissatisfied in one life domain and they realize they have little control in changing that outcome, they make an attempt to "seal off" the domain housing the dissatisfaction. They do so to maintain a certain level of overall life satisfaction (i.e., to ensure that overall life satisfaction does not drop below an intolerable level). He described how affect from one domain "spills over" unto other domains. He described how people "segment" their affect in certain domains preventing affect from spilling over.

As such, the *segmentation principle* posits that individuals who segment life domains can prevent spillover of negative affect across life domains. Segmentation of dissatisfying life domains from other life domains contribute to overall life satisfaction because segmentation of dissatisfying life domain from other life domains protects satisfaction in other life domains. Segmentation of a life domain with negative experiences is important because it serves as a coping mechanism and a buffer for subjective well-being. Much research in work-life balance has documented the segmentation effect (e.g., Edwards & Rothbard, 2000; Michel & Hargis, 2008; Sonnentag et al., 2008).

Based on the discussion, we can summarize the concept of segmentation as a behavioral life-balance strategy. Compared to individuals who do not compartmentalize their dissatisfied domains from spilling over to other domains, those who manage to compartmentalize reduce the likelihood of decreases in life satisfaction overall. That is, compartmentalizing negative affect in one domain serves to protect neighboring domains from negative spillover, thus preventing the neighboring domains from slipping into dissatisfaction, and doing so prevents declines in life satisfaction.

Coping with domain dissatisfaction by engaging in roles in other domains and the principle of behavior-based compensation. Consider the following scenario. Person A is becoming increasingly unhappy with family life—satisfaction in family life drops from +3 units to -2 units. This drop of satisfaction in family life is likely to adversely influence his life satisfaction overall. Person B is similarly unhappy with family life—satisfaction drops from +3 units to -2 units in the last few months. Person A becomes more engaged at work by taking on more responsibility, socializing with his co-workers, and getting more recognition from his boss. That is, his satisfaction in work life jumps from a mere +1 units of satisfaction to +4, a whopping increase of +3 units. This increase of satisfaction in work life serves to offset the decrease of satisfaction in family life. Person B does not do anything about his family situation (-2) and his satisfaction at work is rated +1. Ultimately, Person A's life satisfaction is maintained, while Person B's life satisfaction drops significantly.

Many seminal studies in I/O psychology have documented the fact that involvement at work is negatively correlated with involvement in nonwork (e.g., Cotgrove, 1965; Clark, Nye, & Gecas, 1978; Fogarty, Rapoport, & Rapoport, 1971; Goldstein & Eichhorn, 1961; Haavio-Mannila, 1971; Haller & Rosenmayr, 1971; Rapoport, Rapoport, & Thiessen, 1974; Shea, Spitz, & Zeller, 1970; Walker & Woods, 1976). Other evidence suggests that individuals dissatisfied at work tend to increase their engagement in nonwork roles (e.g., Furnham, 1991; Shepard, 1974; Staines, 1980). For example, individuals in low-status jobs feel dissatisfied with their jobs. To compensate for this dissatisfaction, they become more involved in leisure activities (Miller & Weiss, 1982). Specifically, they stress the importance of prize winning in leisure activities related to organized league bowling.

Also consider the research on materialism. There is much evidence to suggest that materialism (strength of financial aspirations) is negatively related to subjective well-being (see literature review by Richins & Rudmin, 1994; Roberts & Clement, 2007). That is, those who score highly on measures of materialism report lower levels of subjective well-being, and vice versa (e.g., Ahuvia & Wong, 2002; Kasser & Ryan, 1993; Richins & Dawson, 1992; Sirgy, 1998). One explanation provided by Diener and Biswas-Diener (2009) is the notion of shopping therapy. Those who do not have close friends and other social resources tend to *compensate* by shopping. In other words, shopping becomes therapeutic.

According to the *principle of behavior-based compensation*, individuals experiencing dissatisfaction in one life domain are more likely to compensate by engaging in satisfying roles in other life domains. For example, individuals feeling dissatisfied with their jobs invest themselves in more satisfying nonwork activities such as leisure, family, or religion (e.g., Brief et al., 1993; Freund & Baltes, 2002;

Judge, Thoresen, Bono, & Patton, 2001; Tait, Padgett, & Baldwin, 1989).

Best, Cummins, and Lo (2000) conducted a study on the quality of rural and metropolitan life and found that both groups report equivalent levels of life satisfaction. However, metropolitan residents reported more satisfaction with family and close friends, while farmers reported more satisfaction with the community and productivity. The authors explained this finding by suggesting that life satisfaction is maintained through behavior-based compensation. That is, decreases in satisfaction in one domain are compensated by increases in satisfaction in another through role engagement. Specifically, behavior-based compensation occurs when an individual repeatedly experiences dissatisfaction in a life domain allocates much time, energy, and other resources in another life domain to make up for the satisfaction deficiency.

In sum, we can capture the preceding discussion as follows: Individuals who feel dissatisfied in a life domain and engage in successful role performance in another life domain are likely to experience higher levels of life satisfaction than those fail to feel equally dissatisfied but do not engage in other life domains. Engaging in successful role performance in the other life domain serves to increase satisfaction in that domain to compensate for the decrease in satisfaction in the original domain. Doing so serves to maintain an adaptation level of life satisfaction.

Stress management and the principle of role conflict. The compensatory model of life satisfaction does not take into account the interaction of roles between life domains. Consider the following scenario: Person A experiences a moderate level of satisfaction in both work life and family life (e.g., +3 units of satisfaction in each domain). The same person experiences conflict between roles in work life and family life (e.g., family demand interferes with work demand and vice versa). Person B experiences the same levels of domain satisfaction in both work life and family life (+3 units of satisfaction in each). Additionally, Person B does not experience role conflict. The compensatory model of life satisfaction would predict that both individuals are likely to experience the same the level of life satisfaction. However, life balance dictates that role conflict be accounted for in the way domain satisfaction contributes to life satisfaction. By taking into account role conflict we would predict that Person B should experience higher levels of life satisfaction than Person A.

Research has shown that role conflict in life domains has an adverse effect on domain satisfaction and overall life satisfaction (e.g., Kossek & Ozeki, 1998). A high level of psychological involvement in one role is usually associated with increased amount of time and involvement devoted to that role, thereby making it difficult to deal with role demand in other life domains (e.g., Greenhaus & Beutell, 1985). Individuals experiencing role conflict across life domains are likely to experience stress, which in turn reduces overall life satisfaction (e.g., Frone, Russell, & Cooper, 1992). Why would they experience stress? To maintain successful performance in these roles they have to invest much more time and energy in the same roles to maintain an acceptable level of life satisfaction. This allocation of more resources to maintain successful performance in conflicting social roles is essentially induced by psychological stress commonly manifested in terms of general psychological strain, somatic/physical symptoms, depression, substance abuse, burnout, work-related stress, and family-related stress. Positive affectivity is negatively correlated with stress (e.g., Brief et al. 1993; Judge, Locke, Durham, & Kluger, 1998; Watson, 2000; Watson, Clark, & Tellegen, 1988).

Much research has shown that life balance can be achieved when social roles in work and non-work life domains are compatible with minimal conflict (e.g., Greenhaus & Allen, 2011). That is, stress management is typically a suggested approach to deal with the stress generated by role conflict. Role conflict can take multiple forms (Greenhaus & Beutell, 1985). *Time-based conflict* refers to time pressures from one role preventing individuals from meeting expectations in another role or creating a preoccupation with one role while one is physically attempting to fulfil another role. *Strain-based conflict* occurs when tension, anxiety, and/or fatigue from one role affects performance in another role. *Behavior-based conflict* occurs when in-role behavior from one role is incompatible with behaviors expected in another role. As such stress management can be viewed as involving three different set of techniques, techniques to reduce stress from (1) time-based conflict, (2) strain-based conflict, and (3) behavior-based conflict. Examples of stress management techniques dealing with time-based conflict is to plan ahead and schedule tasks and events in ways that do not conflict. In doing so, the individual has to be time sensitive and punctual in starting and completing tasks and attending events on time. Examples of stress management techniques designed to reduce strain-based conflict include breathing exercises, meditation, physical exercise, among others. An example of a stress management technique that can assist in reducing behavior-based conflict is to become more conscious at identifying behaviors that may cause role conflict and to take action to change those behaviors in ways to avoid role conflict.

In sum, the preceding discussion can be summarized as follows: Individuals who successfully manage stress stemming from role conflict are likely to experience higher life satisfaction than those who

fail to manage that stress. Specifically, role conflict brings about much stress—stress stemming from time-based role conflict, strain-based role conflict, and behavior-based role conflict. Stress take a toll on life satisfaction. Stress management to reduce time-based conflict, strain-based conflict, and behavior-based conflict serves to reduce domain dissatisfaction. In doing so, life satisfaction is maintained at acceptable adaptation levels.

Using skills, experiences, and resources in one role for other roles and the principle of role enrichment. Consider the following scenario. A worker experiences imbalanced domain satisfaction in work and family life. That is, his satisfaction at work is +4 units—on a 11-point satisfaction scale varying from -5 (very dissatisfied) to +5 (very satisfied). A few months ago his satisfaction in family life was +3 but now it plummeted to -2 (moderate degree of dissatisfaction in family life). That is, his satisfaction in family life has decreased significantly but his satisfaction at work remained constant. He is experiencing diminished satisfaction in family life due to conflict with his adolescent children. He remembers using conflict resolution strategies at work that were successful in resolving conflict within his project team. He applies the same conflict resolution strategies at home to deal with the family conflict with positive results. Doing so managed to change his satisfaction in family life from a -2 to a +3, thus increasing satisfaction in family life.

There are many situations in which people use skills, experiences, and resources in one role for other roles to enhance balanced satisfaction among life domains. Experiences in a social role can produce positive experiences and outcomes in another other role. Similarly, skills and resources in one role can improve or further enhance performance and satisfaction in another role. For example, work-to-family enrichment occurs when work experiences serve to increase satisfaction in family life; and similarly, family-to-work enrichment occurs when family experiences contribute to heightened satisfaction in work life (e.g., Greenhaus & Powell, 2006; Voydanoff, 2004). Doing so helps workers enhance domain satisfaction. That is, learning occurs in one life domain is easily transferred to other life domains allowing the individual to generate more domain satisfaction through role engagement and goal attainment. And such learning serves to enhance domain satisfaction.

Research has documented the effect of *role enrichment* on overall life satisfaction when two roles are integrated (e.g., Olson-Buchanan & Boswell, 2006), when the skills and resource requirements are similar (e.g., Greenhaus & Powell, 2006), and when role performance in one life domain becomes increasingly interdependent with another (e.g., Hanson & Hammer, 2006; Ilies et al., 2009). High levels of role enrichment serves to improve role performance in work and non-work domains, which in turn contributes to balanced domain satisfaction. That is, skills, psychological resources, and material resources generated in a life domain can be applied to roles in other life domains to improve role performance in those domains (e.g., Hanson & Hammer, 2006). Furthermore, individuals with high role enrichment are less likely to experience stress and anxiety from increased role demand. Such individuals apply their skills and resources across social roles producing more positive outcomes—less psychological distress and anxiety in performing multiple roles and a heightened sense of self-efficacy in those roles.

In sum, we can succinctly capture the preceding discussion as follows: Individuals who use their skills, experiences, and resources in one role for other roles across life domains are likely to experience greater domain satisfaction (in dissatisfied domains) than those who do not. That is, they use skills, experiences, and resources in one domain to increase satisfaction in another domain (or mitigate decreases in satisfaction in another domain), and doing so helps to increase (or preserve) life satisfaction overall.

Conclusion

The key goal of this chapter is to shed more light on the concept of life balance and its effects on life satisfaction. We presented a concept of life balance involving nine behavioral strategies and linked those strategies to subjective well-being and we explained how they impact life satisfaction through a set of psychological principles. The first three of these strategies are designed to prompt greater participation of satisfied domains to contribute to life satisfaction, whereas the remaining strategies are designed to increase domain satisfaction and decrease domain dissatisfaction. As such we believe that there are two sets of strategic requisites of life balance. One requisite is to prompt greater participation of satisfied life domains to contribute to life satisfaction; the second requisite is to increase domain satisfaction and reduce dissatisfaction. These two strategic requisites result in what we call "life balance."

To reiterate, inter-domain strategies designed to prompt greater participation of satisfied life domains to contribute to life satisfaction include: (1) engagement in social roles in multiple life domains (explained by the principle of satisfaction limits), (2) engagement in roles in health, safety, economic, social, work, leisure, and cultural domains (explained by the principle of satisfaction of the full spectrum of human development needs), and (3) engagement in new social roles (explained by the principle of diminishing satisfaction). Inter-domain strategies designed to increase domain satisfaction and decrease

domain dissatisfaction include (1) integrating domains with high satisfaction (explained by the principle of positive spillover), (2) optimizing domain satisfaction by changing domain salience (explained by the value-based compensation principle), (3) compartmentalizing domains with low satisfaction (explained by the segmentation principle), (4) coping with domain dissatisfaction by engaging in roles in other domains likely to produce satisfaction (explained by the behavior-based compensation principle), (5) stress management (explained by the principle of role conflict), and (6) using skills, experiences, and resources in one role for other roles (explained by the principle of role enrichment).

The reader should note that we have construed life balance in terms of two sets of conjoint behavioral strategies. We identified at least three principles to capture the psychological dynamics of the first set and six other principles capturing the psychology of the other set. Within each set there may be more. We encourage researchers to make a concerted effort to identify more behavioral strategies of life balance within each set. For example, one can argue that people who have a balanced life are adept in organizing their lives. That is, they use organizational skills to help them do the best they can in various social roles across a variety of life domains. This may be a principle involving the second set of inter-domain strategies—strategies designed to increase domain satisfaction and decrease dissatisfaction. Another behavioral strategy that may involve the second set is efficiency. Perhaps people with a balanced life tend to use efficiency skills. To be efficient is to try to generate as much output with as little input. Efficiency skills require to be creative in engaging in tasks that manage to "kill two birds with one stone." For example, a person is efficient in planning to shop for office supplies (i.e., work life) and family meals (i.e., family life) at the same time. How about making decisions in one social role in a particular life domain by taking a whole-life perspective—by considering the effect of that decision on satisfaction in other life domains? Could this be a behavioral strategy of life balance characteristic of the second set (inter-domain strategies designed to increase domain satisfaction and decrease dissatisfaction)?

Much of what we discussed in this chapter have focused on behavioral strategies of life balance in relation to life satisfaction. Future studies should examine the relative efficacy of these strategies affecting life balance and life satisfaction. Future studies should empirically test the conceptual model presented in this study.

Understanding the dimensions of life balance and the theoretical mechanisms linking life balance with life satisfaction should help practitioners and policy makers formulate programs that can enhance subjective well-being. Armed with this greater understanding, therapists, life coaches, human resource managers, and policy makers can develop better programs to help their own constituencies achieve greater balance in their lives.

Subjective Well-Being and the Law

By Peter H. Huang, University of Colorado Law School and Visiting Scholar, Loyola LA Law School

Abstract

This chapter analyzes legal implications of subjective well-being (SWB) research. Law can and should learn much from SWB research because the law can and should care about people's SWB. An incomplete list of legal doctrinal and subject areas in which law professors have applied SWB research includes administrative law, alternative dispute resolution, business law, civil procedure, conflict resolution, contracts, constitutional law, corporate law, criminal law, development law, employment discrimination law, family law, immigration law, international law, negotiations, legal ethics, securities law, securities litigation and enforcement, tax law, tort law, and trusts and estates. Some legal scholars have repeated or contributed to existing concerns, debates, and disagreements among non-law scholars about how to measure SWB. For example, some law professors continue to assume that SWB is one-dimensional, despite the large amount of empirical psychological research finding that SWB is multi-dimensional and has distinct components. Some law professors also continue to ignore the conceptual difficulties with aggregation, interpersonal comparisons, and intertemporal comparisons of multi-dimensional SWB measures. In addition, law often requires societies to make contested normative value-judgments over which there lacks consensus. Some law professors and policy makers advocate using SWB metrics to evaluate legal policies, procedures, and regulations. Others argue that hedonic adaptation implies legal interventions have little, long-run SWB impact. This argument ignores short-run impacts which might be irreversible or have spillover effects, including changing individual preferences and social norms. The unique history and current sociology of the American legal academy has resulted in American legal scholarship applying SWB research focusing perhaps unexpectedly primarily on legal education and law practice. Perhaps quite surprisingly, at least to SWB researchers, is that law professors have applied SWB research most, and by a quite far margin, to analyze how to utilize SWB evidence-based research to sustainably improve the alarmingly, perennially, and persistently negative SWB of many law students and lawyers.

Keywords: Law, Legal Scholarship, Law Professors, Legal Education, Law Practice

The United States Declaration of Independence stated in 1776 that a self-evident truth is that people have the right to pursue happiness. It is notable the statement is a right of pursuing happiness instead of a guarantee of achieving happiness (Schubert, 2012). Some American law professors have applied SWB research to analyze legal rules and institutions. A partial inventory of the areas in legal doctrine where law professors have written articles based upon SWB research includes administrative law, alternative dispute resolution, business law, civil procedure, conflict resolution, contracts, constitutional law, corporate law, criminal law, development law, employment discrimination law, family law, immigration law, international law, negotiations, legal ethics, securities law, securities litigation and enforcement, tax law, tort law, and trusts and estates. This is not and should not be a surprising collection of legal topics because SWB research findings are relevant, for both descriptive and prescriptive reasons, to law. Part of legal scholarship describes how law impacts human behavior. Another part of legal scholarship considers how to design socially optimal legal rules and institutions. The notion of social optimality requires a benchmark by which to measure and evaluate alternative legal arrangements. SWB is one such yardstick. More precisely, SWB is a dashboard or portfolio of metrics, including life satisfaction, positive affect, negative affect, and time use (Brulé & Maggino, 2017; Krueger, 2009; Wheatley, 2017). There are also anticipated, experienced, and remembered SWB measures (Kahneman, 2013; Huang, 2014).

A natural area of legal scholarship based on SWB research is to analyze whether and if so, then how law can foster economic development and growth. A common belief and folk theory is that acquiring sufficient wealth causes happiness. People, countries, and the media therefore often use wealth as an imperfect proxy for happiness. The numerous difficulties and problems with measuring countries' well-being using traditional economic indicators as Gross Domestic Product (GDP), or even Net Economic Welfare (NEW), are well-known to economists (Fleurbaey, 2013; Jones & Klenow, 2016) and others, including an oft-cited speech that Robert F. Kennedy (1968) famously made about some of the shortcomings GDP has in measuring what matters.

In the Report by the Commission on the Measurement of Economic Performance and Social Progress, that President Nicolas Sarkozy of France commissioned, 2001 economics Nobel laureate Joseph Stiglitz, 1998 economics Nobel laureate Amartya Sen, French economist Jean Paul Fitoussi, and other leading economists (Stiglitz, Sen, & Fitoussi, 2010) advocated measuring social progress by SWB in place of the more traditional GDP. Many countries, cities, and communities have adopted SWB measures to inform policy decision-making. Anti-fracking ordinances, regional or city planning, environmental impact regulations, land use restrictions, open space laws, water use limitations, and zoning laws are just some examples where simply changing the criteria of policy evaluation from unfettered economic development and growth to SWB measures has drastic implications. As 1972 economics Nobel laureate Kenneth Arrow observed in discussing the importance of organizational agendas (1973, p. 47), placing full employment on the United States federal government's agenda, which the Full Employment Act of 1946 accomplished, had real, albeit slow, social and policy consequences.

Many legal doctrinal areas have this common structure: law can change people's incentives to take certain relevant actions. Law can provide negative incentives, such as fines, imprisonment, penalties, or taxes. Law can provide positive incentives, such as monopolies, rents, subsidies, or tax deductions. In business law, relevant actions include choice of business organization, partnership dissolution, and partnership formation. In corporate law, relevant actions include acquisitions, appropriation of corporate opportunities by a company's directors and officers, corporate oversight, incorporation, mergers, and self-dealing of a company's directors and officers. In contract law, relevant actions include breach of and reliance on a contract. In civil procedure, relevant actions include the decisions to file, drop, continue, and settle lawsuits. In criminal law, relevant actions include crime commission and crime prevention. In family law, relevant actions include marriage, divorce, and having children. In immigration law, relevant actions include legal immigration, illegal immigration, and immigration enforcement. In international law, relevant actions include agreeing to and breaking accords, conventions, and treaties. In legal ethics, relevant actions include awareness, care, record-keeping, and social media use. In negotiations, relevant actions include offers and counteroffers. In property law, relevant actions include acquisition, development, innovation, investment, pollution, and upkeep. In securities law, relevant actions include disclosures, insider trading, and securities fraud. In tax law, relevant actions include compliance, fraud, and reports about income, expenses, or profits. In tort (accident) law, relevant actions include care, precaution, and activity levels. In trusts and estates, relevant actions include bequests and charitable donations.

Much of legal analysis determines how civil liability and criminal penalties can achieve socially optimal magnitudes of relevant actions. Socially optimal monetary civil liability damages or criminal penalties involve wealth reallocations to achieve socially optimal compensation, deterrence, and risk allocation (Cooter, 1991). Such legal analysis hinges crucially on the notion of social optimality employed. Wealth or more generally economic and financial metrics of social optimality are only proxies of what people ultimately care about (Oswald, 1997). After all, money has instrumental, not intrinsic, value. Most economists view money to have three functions: a medium of exchange, a store of value, and a unit of account. Some anthropologists, communication scholars, marketing scholars, philosophers, political scientists, psychologists, and sociologists view money to be much more in the sense of signals or symbols expressing beliefs, class, connection, emotions, family, friendship, gratitude, hope, identity, intimacy, meaning, morals, power, relationships, security, sentiments, status, success, and trust (Bandelj, Wherry, & Zelizer, 2017; Zelizer, 2017). People, popular culture, and the media often conflate and confuse money with SWB.

Changing the meaning of socially optimality to include or be SWB rather than some other more traditional normative criteria such as wealth can dramatically change the design of legal rules and institutions (Huang, 2010) and in the regulation of risk (Huang, 2008a). For example, current tax law is based upon optimal tax theory, which utilizes a neoclassical welfare economics approach to assess and evaluate policy (Kaplow, 2010). A key assumption of neoclassical welfare economics is that people exhibit declining marginal utility of income. Modern American income tax law and arguments for progressive taxation are premised on that assumption. There is empirical evidence that some individuals experience increasing marginal utility of income, which would lead a tax policy based on welfare economics analysis to redistribute income from poor to rich people (Lawsky, 2011). If tax analysis replaces the criterion of maximizing social welfare, defined to be some weighted sum of individual welfare, with the criterion of maximizing experienced SWB, then SWB research supports progressive taxation policies that redistribute income from rich to poor people, because a study by psychologists of 54 countries found progressive taxation is associated with higher SWB (Oishi, Schimmack, & Diener, 2012).

In business law areas, such as corporate law and securities regulation, for example, metrics used to evaluate the social desirability of economic outcomes and legal interventions include corporate stock market value and shareholder wealth. Huang (2005a, 2005b, 2008b, 2011) examines other possible metrics

for evaluating business law and securities regulations, including career satisfaction, consumer confidence, economic stress, financial anxiety, investor exuberance, market moods, meaning at work, shareholder empowerment and participation, trust in financial markets, and work-life balance. People's financial health and mental health are interrelated and influence each other. Economist Graham (2017) draws on research linking inequality and SWB to show how a growing prosperity gap leads to gaps in people's aspirations, beliefs, hopes, and optimism. Poverty has emotional costs in terms of depression, despair, desperation, hopelessness, misery, insecurity, and stress.

Blumenthal and Huang (2009) propose and advocate the notion of positive parentalism to foster more positive individual and social outcomes based on applying insights from positive psychology. For example, governments can help people learn and develop their signature strengths so that individuals can seek and craft work to be more fulfilling and view that work to be a calling instead of a career or job (Huang, 2008c; Wrzesniewski, McCauley, Rozin, & Schwartz, 1997). If light paternalism is analogous to therapy that corrects for and remediates cognitive and emotional disturbances that detract from individual SWB (Loewenstein & Haisley, 2008), then positive paternalism is analogous to positive therapy (Leffert, 2017) that improves decision-making capabilities or processes via helpful thinking styles that raise individual SWB. Positive parentalism is related to policies that boost people's competencies to exercise agency by making choices (Grune-Yanoff & Hertwig, 2016; Hertwig & Grune-Yanoff, 2017). Both positive parentalism and boosts empower people to make better decisions (Huang, 2015b).

A famous area of SWB research concerns hedonic adaptation (Brickman & Campbell, 1971). Natural applications to law of SWB research about hedonic adaptation include analysis of civil lawsuit settlements (Huang, 2008d; Swedloff, 2008), economic development (Clark, 2012), emotional paternalism (Blumenthal, 2005, 2007), roles of decision versus experience utility in public policy (Loewenstein and Ubel 2008), and tort damages for pain and suffering (Swedloff & Huang, 2010). The debate over the legal relevance and significance of hedonic adaptation is ultimately a disagreement over three sets of issues. First, reasonable people differ over whether SWB is the only thing people and society care about and should care about (Etzioni, 2016; Swedloff, 2014). Second, the robustness of hedonic adaptation varies across contexts and individual demographic variables, such as age, ethnicity, and gender. Third, the distributive, ethical, and normative implications of hedonic adaptation are complex and unresolved.

Another legal area where SWB research about hedonic adaptation has relevance is employment discrimination damages (Moss & Huang, 2009). A psychological theory of affective adaptation due to Timothy Wilson and Daniel Gilbert posits that people attend to unexplained events, react to them and if they can explain them, adapt emotionally to and attend less to them (Wilson & Gilbert, 2008). People who lose their jobs due to illegal discrimination are less likely to adapt to such losses than people who lose their jobs for non-discriminatory causes because illegal discrimination is illegitimate, invidious, and results from animosity and hatred. A legal implication of this, other happiness research, and the endowment effect is that courts should award higher damages for illegal firing of a long-term employee than for illegal failure to hire.

The strand of SWB research that has had the most impact in areas of law has been that about mindfulness and the legal areas that have most whole-heartedly adopted SWB research about mindfulness are those of conflict resolution: negotiations, meditations, and alternative dispute resolution (Huang, 2018a; Riskin, 2002, 2010, 2012; Riskin & Wohl, 2015). Although practicing mindfulness can apply to every area of law (and life), law professors and lawyers practicing in the areas of conflict resolution have been at the forefront of applying the insights from SWB research about mindfulness. Why this has been the case is unclear. Perhaps one reason is that conflict resolution is emotionally charged and mindfulness about emotions can be seen to be a form of emotional intelligence.

Many law professors, law students, and lawyers view much of legal education and law practice as being analytical, cognitive, and logical, instead of also being affective, emotional, and psychological (Robbennolt & Sternlight, 2012). Many law professors, law students, and lawyers often use the phrase "thinking like a lawyer" to describe the goal of legal education. Rarely do law professors, law students, and lawyers talk about feeling like a lawyer or feelings in general. Yet many in the public view and many clients view (even their own) lawyers as being aloof, arrogant, robotic, uncaring, and unfeeling. Huang and Rosen (2015) borrow the popular culture metaphor of a zombie apocalypse to describe what happens to many American law students in law schools and lawyers in practice. Many law professors are coming to realize the competitive advantage and importance that emotional intelligence in the form of empathy, compassion, emotional regulation, and mindfulness offers lawyers in their professional development (Austin & Durr, 2016; Fruehwald, 2015; Kiser, 2017; Linder & Levit, 2014; Martin, 2014).

Practicing mindfulness in the form of developing and exercising self-compassion may increase attorney SWB and gender diversity (Mangan, 2016). Mindfulness has now become pervasive in legal

education and law practice (Huang, 2015a, 2016, 2017, 2018b; Martin, forthcoming). To fully appreciate why this has become so, it helps to better understand the unique history and current sociology of American law, legal scholarship, law professors, and the legal academy. Although American law professors, law students, and lawyers know much of this information only all too well, professors who do not teach in law schools are likely to find the next section surprising, if not shocking, because law schools differ so much culturally and structurally from other parts of universities, including economics, psychology, and marketing departments which are the academic homes of many SWB researchers. The next section also partially explains what parts of SWB research law professors, law students, and lawyers find most fascinating and useful.

Law, Legal Scholarship, and Law Professors

Law is often a blunt and crude instrument of social policy. Societies design and enforce laws to achieve hopefully legitimate and worthy ends. Legal scholars approach the study of law from various perspectives. For example, an economics approach to law may view law as creating incentives to avoid anti-social behavior through a menu of civil liabilities and criminal penalties. An expressive approach to law may view law as being aspirational in changing social norms, expressing shared value-judgments, and fostering pro-social individual preferences. An approach to law as instruments or levers implies some criterion or set of criteria to assess how well the law is doing. Neoclassical economic approaches to law use the criterion of Pareto efficiency (Calabresi, 1991) or Kaldor-Hicks efficiency (Hicks, 1939; Kaldor, 1939) to evaluate legal interventions. Modern legal theory and legal education has become infused with the language of microeconomics and finance, including these concepts: adverse selection, compliance, cost-benefit analysis, deterrence, discounted present value, diversification, efficiency, error costs, expected value, externalities, incentives, informational efficiency, insolvency, internalization, moral hazard, network externalities, opportunity costs, public bad, public good, risk allocation, risk aversion, social welfare, standardization, tradeoffs, transactions costs, and utility.

Because happiness and SWB are related to, although distinct from, the notions of utility and welfare in modern economics (Benjamin et al. 2014a, 2014b), SWB offers a potential alternative framework to evaluate how well the law is doing. Utilizing SWB as a legal metric requires the balancing of simplicity against validity. For better or worse, the gatekeepers to policy are often economists and lawyers. SWB researchers can influence economists through happiness economics. SWB researchers can influence lawyers through happiness law and economics. Some legal scholars view SWB research as providing a different and more realistic foundation than neoclassical economics for performing legal analysis. The question some legal scholars analyze is whether a particular legal policy, procedure, or rule increases a measure or a (weighted) set of measures of SWB. How to weigh distinct components of SWB is a concern and something over which reasonable people can disagree.

Some legal scholars have reargued the debates over whether SWB is a one-dimensional or multi-dimensional measure. Empirical research finds that SWB is multi-dimensional and includes evaluative, experienced, and eudaimonic aspects of well-being (Stone & Mackie, 2013). The multiple dimensions of SWB also raise the issues of incompleteness and intransitivity of making comparisons based upon SWB. There also are all too familiar political economy concerns that policy makers have multiple opportunities and powerful incentives to cherry pick and manipulate SWB measures (Frey & Gallus, 2013).

Because of the particular path-dependent history of American legal scholarship, some legal scholars are suspicious that SWB is just economists' old notion of utility or welfare dressed in psychological garb. It is helpful to briefly review the history of American legal scholarship. The former dean of Yale Law School, Anthony T. Kronman (1993, p. 167), expressed his opinion that law and economics has been the intellectual movement with the greatest influence on American academic law in last twenty-five years of the twentieth century. Today's dominant "law and economics" movement started with the work of economics Nobel laureates Ronald Coase and Gary Becker, Henry Manne, Guido Calabresi, and Richard Posner. Economic analysis of law has now become a routine part of jurisprudence, judicial opinions, and law school classes. In spite of, or perhaps because of, the influence of law and economics, there have been and remain today many criticisms of the law and economics approach and movement. Critics point out how "classical" law and economics pays little attention to human rights, distributive justice, and the importance of situations in shaping human choice and behavior. More recent incarnations or versions of law and economics incorporate considerations about cognition, fairness, and contexts by drawing upon research from anthropology, neuroscience, psychology, and sociology. These newer developments in economic analysis of law apply insights from behavioral economics, game theory, neuroeconomics, and socio-economics. Behavioral economics and its application to law, known as behavioral law and economics, are currently very popular analytical tools among many legal scholars.

The above historical backdrop explains why some law professors think of SWB research,

particularly happiness economics, as just more of the same old law and economics. For these law professors, the small difference is that happiness economics, instead of neoclassical economics, has now become the analytical tool for evaluating legal rules and institutions. Some law professors view allusions to happiness to be merely a way to make look modern Jeremy Bentham's (1749/1948) old moral philosophy of utilitarianism. Some law professors are understandably suspicious and wary of articles and popular trade books that include the word "happiness" in their titles with scant discussion about positive psychology or SWB in their books.

The above historical backdrop also explains why some other law professors view SWB research in the form of hedonic psychology or positive psychology as challenging the prevailing law and economics orthodoxy because of SWB research focusing on people's anticipated, experienced, and remembered SWB as opposed to neoclassical economics' revealed preference theory, which assumes people have unobservable preference orderings, which their observed choices reveal. For these law professors, SWB research differs fundamentally and radically from behavioral economics. While behavioral economics finds that many people have cognitive biases and utilize heuristics, SWB research finds that people may not choose what maximizes their SWB (Benjamin et al., 2012) and people having high SWB may be satisficing, instead of maximizing any objective function (Schwartz et al., 2002). These law professors view SWB research to have pervasive and far-reaching legal policy implications, such as advocating for changes in (tax) law and policies to reduce American consumerism (Ritzer, 2013) and materialism (Kasser, 2003).

It is also helpful to briefly review the sociology of American legal scholarship. Most American law professors have a professional degree, namely the doctor of jurisprudence or juris doctor (J.D. or JD). Most American law professors do not have a Ph.D. These two facts mean that most American law professors have neither the knowledge involved with nor experience of writing a Ph.D. dissertation. These twin facts also mean that most American law professors lack Ph.D.-level expertise in economics, psychology, or any other discipline. Finally, most American law professors have little, if any, training in probability and statistics. In fact, many American law professors, law students, and lawyers lack much numeracy (Cheng, 2014; Milot, 2013; Obama, 2011), though some law students have a surprisingly high amount of mathematics skills (Rowell & Bregant, 2014). The significance of the above observations is that many American law professors, law students, and lawyers are unable to directly evaluate the validity of empirical and experimental SWB research. Certainly, most American law professors, law students, and lawyers are consumers, not producers, of SWB research.

Most American law professors publish exclusively in American law reviews, which are not peer-refereed. Instead, second-year and third-year law students decide which of the many article submissions they receive to publish. American law professors make simultaneous and multiple article submissions. Upon acceptance, American law professors typically try to trade up their accepted article to a higher-ranked law review. American law schools have a flagship or general law review in addition to several other legal subject matter specialized law reviews. There are several rankings of law reviews that generally track the U.S. News & World Report ranking of law schools. Most law reviews also do not require anonymous submissions.

Many American law professors often engage in over-claiming of the scholarly contributions of their law review articles. Some law professors are notorious for repeatedly publishing multiple, yet only slightly different, versions of essentially the same article. Because law reviews are mostly, if not exclusively, run by law students, there is little institutional memory. There are two submission cycles or seasons, one in mid-February after new law student editorial boards have been chosen and the other in mid-August when law students return from their summer jobs. Law reviews typically publish a couple of issues per annual volume with each issue consisting of a couple of articles. For those slots, most law reviews will typically receive several thousand submissions because simultaneously submitting the same article to multiple law reviews is the norm. Many law review editors have neither the desire, interest, motivation, time, or training to read, let alone carefully and thoughtfully, that many unsolicited manuscripts, each approximately 25,000 words or 50 double-spaced pages. Law review editors often choose which articles to publish based on a catchy, pithy title and the first several pages of a manuscript. Some law review editors use the name, affiliation, and past publications of authors as imperfect proxies of quality. Many authors claim their article is the first and only one to address an undertheorized important legal topic. A recent law review article provides a parody and satire of law review articles generally (Schlag, 2017).

This publication system perversely selects for publication many law review articles that are grandiose, overly complex, and verbose. There is often a disproportionate number of law review articles that draw upon interdisciplinary and multi-disciplinary research because such law review articles are more complicated, impressive, and interesting than the traditional legal analysis of judicial opinions and statutes. The above sociology of the legal academy partially explains what law review articles law student law

review editors chose to publish. As to why law professors publish, there are many reasons, including feeling pride, getting tenure, influencing policy, being invited to scholarly conferences, and experiencing joy (Anaya, 2017).

Improving Legal Education Based on SWB Research

There is currently a well-known crisis in legal education on many levels (Lewinbuk, 2015, pp. 5-7; Tamanaha, 2012). Since 2011, there have been historic lows in the number of American law school applicants, students, graduates, and jobs that involve law practice or require the professional J.D. degree (Bernstine, 2014). Legal education commentators and observers disagree over whether these changes are cyclical or structural and temporary or permanent. An area of justifiable interest to law students and law professors is legal education reform. Some other law school stakeholders, such as law school alumni, administrators, and law student wellness specialists, also have understandable incentives to advocate for legal education reform.

The portrayal of American legal education in popular culture is and has been usually very negative with many films and television programs featuring a cruel, inquisitional version of the so-called Socratic method of teaching in which law professors continually and unsympathetically question law students into submission, crying, and/or throwing up (Papke et al., 2012b). Even prior to the current legal education crisis, some law school administrators engaged in dishonest and fraudulent actions to get a higher position in the highly influential and very competitive annual law school rankings the magazine U.S. News & World Report publishes each spring (Huang, 2012).

Although most students entering American law school have slightly higher SWB than the population average, by the end of the first semester of law school, many law students report statistically significant lower SWB and mental health, with little recovery during law school or afterwards (Sheldon & Krieger, 2004, 2007). A 2014 SWB study (Organ, Jaffe, & Bender, 2016) surveyed over 11,000 law students at fifteen law schools and found that 37% screened positive for anxiety, 17% screened positive for depression, 53% drank enough to become drunk at least once in the prior thirty days, 43% binge drank at least once in the prior two weeks, 22% binge drank more than two times in the prior two weeks, and 14% in the prior year used prescription drugs without a prescription. Sadly, the survey also found that over 60% expressed concern that seeking help is a potential threat to bar admission or finding a job, about 23% sought help for mental health problems, and only 4% of students had sought help for alcohol and drug problems. These disturbing statistics may not even reveal the depths of the SWB crisis among American law students because of underreporting and self-delusion.

Undoubtedly, many American law students are suffering mentally and emotionally throughout their time in law school. To cope temporarily with precipitous declines in SWB, many law students are developing bad and unsustainable strategies of drinking alcohol and self-medicating (Austin, 2013, 2015) instead of learning to eat healthily (Austin, 2017). Many factors can account for the sharp drop in SWB in the first semester of law school, including an exclusive focus on analytical and critical thinking, amorality or value-neutrality of legal analysis, the mandatory, competitive, and hierarchical grading curve of many law schools with required means, medians, or distributions (Heffernan, 2014), a dominant language of law school (Mertz, 2007), or a shift from such intrinsic values as learning, helping others, and public interest to such extrinsic values as class ranking, grades, and starting salaries (Peterson, 2014).

What is clear is that a SWB crisis exists in American legal education. Because unhappy students are likely to become unhappy lawyers, a SWB crisis also exists in American law practice, as the next section discusses. A nationwide task force (with representation from the American Bar Association, Association of Professional Responsibility Lawyers, National Conference of Chief Justices, National Conference of Bar Examiners, and National Organization of Bar Counsel) issued a 73-page report detailing changes that bar associations, judges, lawyer assistance programs, law schools, legal employers, and regulators each can undertake to promote SWB in legal education and law practice (National Task Force on Lawyer Well-Being, 2017). Many of the recommendations of that report are based on positive psychology research, including examples in Appendix B of that report discussing possible topics to teach law students about how to sustainably increase SWB.

Law schools can increase law student SWB in many ways, including enabling law students to make better academic and career choices based on a more realistic vision of the realities of lawyers' professional lives, teaching students about different attribution styles (Felder, 2014; Rosen, 2011), and not fostering learned helplessness (Levit & Linder, 2010). A law professor and his daughter, who earned a master's degree in applied positive psychology, co-authored an important article about how and what legal educators can learn from positive psychology to slow the current epidemic of law student depression (Peterson & Peterson, 2009).

A new field of study, positive legal education, (Austin, forthcoming; Huang, Brafford, Austin, &

Knudson, 2018) proposes to apply research from positive psychology and positive education to transform American legal education focusing on law students' SWB. This project intends to analyze whether: (1) current American legal education adversely alters brain structure and function; (2) current American legal education impairs character development, compassion, and ethical decision-making; and (3) neuroscience and positive psychology-based interventions can mitigate the harmful effects of current American legal education. Ultimately, this project aims to develop sustainable positive legal education interventions that cultivate and foster character development, compassion, and ethical decision-making by American law students.

This project will be a longitudinal, multi-year study of law students that includes the collection of spit samples to test for cortisol levels and the neuroimaging of law students in August, December, and May of the first year of law school to test for structural and functional brain changes. This project also plans to conduct brain scans while law students make decisions in ethical dilemmas and play economic trust games (Huang, 2009) to determine if current American legal training encourages unethical behavior (Huang, 2013) and impairs the quality of decision-making, as well as during memory tasks to discover whether current American legal education harms law students' memory (Austin, 2013). The team plans to investigate whether such positive psychology interventions as mindfulness or compassion meditation can change law students' brain functioning, brain structure, and charitable donation behavior, as is the case for a study involving non-law students (Ashar et al., 2016). The project also plans to investigate if teaching other SWB interventions enhances law school academic performance, similar to related research about improvements on standardized tests (Adler & Seligman, 2016).

Improving Law Practice Based on SWB Research

The practice of law in America today is less of the noble profession it once was and more of a competitive, cutthroat, and pressure-filled business, like many other former professions, such as accounting, advertising, and medicine. Automation, outsourcing, and rapid technological upheaval are only happening at ever increasing rates. While there is no shortage of lawyers for those who can afford the best legal representation that money can buy, there is and has been a chronic shortage of lawyers for people who cannot afford to hire lawyers to vindicate their legal and human rights (Bok, 1983).

Many clients are unsatisfied with many aspects of law practice, including the billable hour system of compensation. Many law firm junior associates are unhappy about work-life balance. Many law firm partners are disillusioned by the unrelenting stresses of the business of law practice. Many in the general public see lawyers as well-paid corporate lackeys and parasites profiting off of others' misfortune and miseries. Lawyers have many external public relations issues and internal quality-of-life problems. Lawyers are often portrayed as flawed humans, if not outright villains, in movies (Asimow, 2000) and popular culture (Papke et al., 2012a). Lawyer jokes are ubiquitous and seemingly never-ending (Galanter, 2005).

Many lawyers are prone to poor mental and physical health, alcoholism, anxiety, depression, drug abuse, suicide, and unhappiness (Brafford, 2014, 2017). A 2016 study found that 20% of attorneys abused alcohol and about 30% had symptoms of depression (Krill, Johnson, & Albert, 2016). Despite these and many other depressing statistics about lawyer SWB (Krieger & Sheldon, 2015), there is hope for change for the better at both the level of individual attorneys and the level of legal organizations (Brafford 2014, 2017; Huang & Swedloff, 2008).

Individual attorneys can employ many positive psychology strategies to boost their SWB. One such strategy is to cultivating optimism as part of a larger strategy to boost an attorney's "psychological capital" or "PsyCap," a positive mental capacity, which is akin to what is colloquially called mental toughness. PsyCap consists of these four psychological resources: hope, optimism, resilience and self-efficacy (Gruman & Saks, 2013; Knudson, 2015; Luthans, Youssef, & Avolio, 2006). Empirical research reveals significant positive links among PsyCap and engagement, job performance, and job satisfaction and negative links with anxiety, stress, and turnover (De Waal & Pienaar, 2013; Gruman & Saks, 2013). Other positive psychology evidence-based strategies that individual attorneys can easily incorporate into their daily lives include acts of kindness, gratitude activities, and savoring (Lyubomirsky, 2007). These activities can help boost positive emotions, and in turn resilience and SWB.

Brafford (2014, 2017) offers a carefully designed, detailed blueprint for how law firms can become positive organizations. Brafford (2014, 2017) makes a compelling business case for why positive law firms are likely to enjoy competitive advantages: 1) higher profitability, 2) desirable, extra-financial business outcomes, and 3) successfully recruiting and retaining Millennials. Brafford (2014, 2017) proposes creating a law firm SWB index with metrics for lawyers, staff, clients, law firms, and communities. Such an index would be a welcome counterpoint and supplement for the currently dominant and well-known profits-per-partner metric. Widespread adoption of a law firm SWB index would facilitate comparisons across law

firms and encourage law firms to raise their SWB index scores to attract like-minded talent and clients.

Some Concluding Thoughts

SWB research can and should inform law. Humans make laws, which means that humans can change laws. Laws differ across countries at any one point in time. Laws differ across time in any one country. People today are often shocked by some of the past laws in their country or other countries. Examples abound involving laws that discriminated against people solely because of their age, ethnicity, gender, sexual orientation, race, and religion. Because laws come and go, there is hope laws that decrease SWB will be overturned and laws that increase SWB will stand the test of time. There is no guarantee of course that will happen at all or quickly. Laws have their own inertia. Laws can thus be quite sticky.

This chapter has considered only some of the vast and growing body of legal scholarship based on SWB research. Merely replacing economic notions of efficiency and metrics of welfare by SWB has potentially radical implications for the optimal design of legal rules and institutions. For better or worse, currently most of the legal applications of SWB research are devoted to improving legal education and law practice. To those outside of the legal academy and legal profession, such a focus may seem to be self-absorbed and self-indulgent. Non-lawyers can legitimately ask why not study the SWB of psychologists, economists, educators, adolescents, nurses, veterinarians, and many others?

There are, at least, twelve responses that come to mind. First, researchers can and should analyze the SWB of all people. Second, researchers can and should analyze the SWB of all professions. Third, and more on point, dramatic, rapid, and permanent declines in the SWB of law students can interfere with the legal education of those students. Fourth, dramatic, rapid, and permanent declines in the SWB of law students can interfere with the legal education of their peers. Fifth, and even more importantly, lawyers with low SWB are less effective advocates for their clients. Sixth, and also importantly, lawyers today are often powerful leaders in many societies. Seventh, and also significantly, lawyers can collaborate with non-lawyers to address many of the critical domestic and international problems facing humanity, including climate change, inequality, injustice, poverty, and prejudice. Eighth and perhaps most importantly, lawyers can make a difference to individual and societal SWB in societies under the rule of law. Ninth, lawyers who have high SWB have the power to do good and help those who cannot help themselves. Tenth and conversely, lawyers who have low SWB have the power to do harm and hurt those who cannot help themselves. Eleventh, because lawyers are gatekeepers to policy making in America, lawyers who have high SWB can improve the quality of U.S. policy making. Twelfth and conversely, lawyers who have low SWB can impair the quality of U.S. policy making.

Abstract

This chapter focusses on the question of how formal institutions, like those governing the level of freedom and the generosity of the welfare state, affect self-reported well-being. The evidence suggests, for example, that more freedom, as well as government structures which encourage civic engagement, participation and trust, have positive effects. Many studies, however, use cross-sectional data with small sample sizes, often due to institutions being measured at the country level with limited variation over time. As a consequence, further work is needed to test robustness. Stronger results hold with respect to particular types of welfare state institutions, like unemployment benefits, which are subject to quite frequent changes within nations. Increases in unemployment benefits are associated with higher levels of well-being for all workers, probably due to greater income security. However, doubt still persists as to their overall impact, due to the extent to which well-being is adversely affected by the higher taxes needed to support a more generous welfare state.

Keywords: Well-being, Freedom, Partisan Happiness, Welfare Benefits, Taxes.

This chapter is about how formal institutions in a nation affect the well-being of its people. Douglass North (1990) defines institutions as *"the humanly devised constraints that structure human interactions. They are made up of formal constraints (rules, laws, constitutions), informal constraints (norms of behaviour, conventions, and self-imposed codes of conduct), and their enforcement characteristics"*.

In North's theory, formal rules are created by the polity, whereas informal norms maybe part of the heritage that is often referred to as "culture" and includes characteristics like "social trust". This chapter focuses mostly on formal institutions, and we leave it to other authors in this book to discuss how informal norms affect well-being.

The chapter is structured as follows. In section 2 we study how the nature of the political system in a country affects well-being. Do the citizens of a country gain pleasure from having more political freedoms and civil liberties? In addition to the degree of freedom of its citizenry, we ask whether the quality of other government structures affect happiness. Does corruption of public officials lead people to experience more negative feelings? Is there a relationship between the size and quality of the regulatory state and well-being?

This section also emphasizes the importance of formal institutions that facilitate greater engagement with the political process and reinforce social networks. Is it the economic outcomes that systems yield, or the degree to which their decision-making processes are inclusive, which matter the most? The section concludes with a discussion of the role of partisan politics. Is, for example, political competition more like a team sport whereby one gets pleasure from being a supporter of the winning side, aside from the policies which actually end up being implemented?

Section 3 focusses mostly on government spending and taxes. It seeks to answer questions like whether or not countries with more generous welfare states and greater job security have higher well-being. Do the 'happiness studies' on this topic take into account the fact that countries with high public spending tend to tax their citizens more? On the other hand, can "sin taxes" like on cigarettes, actually increase well-being? The final section concludes.

The Effect of Political Systems on Well-being

The Effect of Freedom on Well-being

First, we ask the question of how formal institutions governing the level of civil, political and economic freedoms affect well-being in nations. Most of the institutions governing these kinds of freedoms change only slowly over time which is probably why much of the work in this field has relied on exploiting cross-sectional variation.

Many authors have sought to test the hypothesis that freer countries have higher levels of self-reported well-being (SWB).[1] Greater choice is typically regarded as a good thing. In particular, democratic freedoms are often viewed as being vital to monitor and control politicians, and to bring the decisions of government closer to the wishes of the citizenry.

Of course, not all theories highlight the positive effects of freedom. For those who have self-control problems, like eating or smoking too much, constraints on behaviour may be helpful. It is often argued that the 'right to bear arms' should be restricted. There are also many rules imposed on children, which include not having the right to vote, even in western democracies. Some people may voluntarily place restrictions on themselves by joining a strict religion, due a belief in the supernatural or desire to be a member of a close-knit group.

It should also be noted that economic freedoms are nearly always regulated, usually in the name of increasing social welfare. Free markets are not to be mistaken with unregulated markets. Even *"unfettered competitive markets are based on a set of laws and institutions that secure property rights, ensure enforcement of contracts, and regulate firm behaviour and product and service quality"* (see Acemoglu, 2009).

The "happiness studies" on this topic tend to use data at the national level and their findings are still in need of greater validation. As an early example, Veenhoven (1993) uses a cross-section of 23 countries from the World Values Survey (WVS) in the 1980s. He argues that there "*is a clear correspondence between average happiness in nations and the degree to which these nations provide material comfort, social equality, freedom and access to knowledge*" (pg 32). Freedom is measured, in this instance, by the Estes Index of Political Participation and also the degree to which the country has a free press.

In a later study, Veenhoven (2000a) used a cross-section of 38 countries and a single index combining political, civil and economic freedoms to again argue that freedom and well-being are positively correlated.

However, Inglehart and Klingemann (2000) found that their Freedom House democracy score was not significant in a SWB regression, after controlling for other variables, when using a cross-section of 105 countries. This result led these authors to conclude that "*the interpretation that democracy causes well-being does not stand up: other factors – particularly the number of years of communist rule and the society's level of economic development – seem to play much more powerful roles*" (pg 181).

The uncertainty underlying this debate is heightened by the controversy over whether even the level of development itself influences well-being. The time-series of SWB data for many nations do not appear to support this proposition (see Easterlin, 1974) and the growth rate of GDP has often been argued to matter more (see Di Tella, MacCulloch & Oswald, 2003).

One approach to better identify the relationship between freedom and well-being has been to use within-country data. For example, Frey and Stutzer (2000) study the role of direct democracy (via initiatives and referenda) using a cross-section of 26 Swiss cantons between 1992 and 1994. A shift from the canton with the lowest direct participation rights (i.e., Geneva) to the one with the highest (i.e., Basel land) is associated with an 11 percentage point higher probability of declaring oneself completely satisfied with life (on an eight point scale ranging from "completely dissatisfied" to "completely satisfied").

These authors argue that the institutions of direct democracy have two effects on well-being. One maybe to generate better policy outcomes. The other is to expand the possibilities of citizens to participate in political processes and procedures.

The relative sizes of these two effects can be identified since their data set includes foreigners living in Switzerland who can share in the outcomes of direct democracy, but who are not able to gain utility from participation in the process, which is only available to citizens. Consequently Swiss nationals are hypothesised to gain more from direct democracy, compared to foreigners. It turns out that about two thirds of the total gain in SWB is due to a more favourable process in political decision-making whereas one third is due to more favourable outcomes.

The robustness of the Frey and Stutzer (2000) results has, however, been questioned. For example, Dorn, Fischer, Kirchgässner and Sousa-Poza (2008) use surveys conducted between 2000 and 2002 by the Swiss Household Panel to re-evaluate the relationship between cantonal direct democracy and well-being. Their study introduces new controls for cultural determinants of life satisfaction such as languages and religion. Once these controls are included, these authors are unable to find a robust relationship.

Furthermore, Blume, Muller and Viogt (2009) are also unable to detect a correlation between direct democracy and happiness scores, although they revert to using cross-country data with a sample of 54

observations taken between 1996 and 2005.

Another approach to help better identify the relation between freedom and SWB has been to bring a time series dimension to the question. For example, Inglehart, Foa, Peterson and Welzel (2008) use different waves of the World Values Surveys, taken between 1981 and 2007. They correlate changes in SWB (measured by both self-reported happiness and life satisfaction) from the first to the last available survey for each country, with changes in two proxies for freedom, as well as changes in GDP per capita.

One of their freedom proxies is the level of democracy, measured by the Polity IV project. The other is a survey question taken from the WVS which asks, *"Some people feel they have completely free choice and control over their lives, while other people feel that what they do has no real effect on what happens to them. Please use this scale where 1 means "no choice at all" and 10 means "a great deal of choice" to indicate how much freedom of choice and control you feel you have over the way your life turns out".*

Of these two proxies, the Polity IV measure of democracy is not significant. Inglehart et al (2008) instead argue that their results do *"show that a growing feeling that one has free choice was by far the most important influence on whether SWB rose or fell".* The positive correlation which these authors report between changes in SWB and changes in feelings of free choice is an important one, although its implications are somewhat unclear.

First, there is a degree of ambiguity as to what the above survey question is capturing. For example, people in many countries, including Qatar, reported higher average levels of *"free choice"* and *"control over their lives"* than the United States (see WVS, 2010-2014). Yet Qatar is ranked as being "not free" by Freedom House.

Second, the WVS survey period from 1981 to 2007 covers the end of the Cold War in 1989-90 when, for example, the threat of East-West conflict was believed to be falling. The positive emotions and reduced fear around this time may have led people to both tick up their happiness scores and report feeling freer.

Third, Stevenson and Wolfers (2009) report that the subjective well-being of women in the United States fell between 1972 and 2006, both absolutely and relatively to that of men, notwithstanding a great expansion of women's opportunities over this time.

In summary, the heavy use of cross-sectional data sets, limited time-series evidence, small number of observations and widely differing proxies for freedom used across different studies, taken together, point to a need for more work to help better identify the relationship between freedom and self-reported well-being.

The Effect of Government Quality and Processes on Well-being

In additional to the freedom of its citizenry, the quality of other government structures may affect the well-being of a nation. For example, Italy achieved the top score of 1 (out of 7) for its Political Rights and Civil Liberties in 2017 from Freedom House, yet many of its institutions are perceived to be mired in corruption.

Helliwell and Huang (2008) exploit the cross-sectional variation in life satisfaction data from 75 countries taken between 1981 and 2000 by the World Values Survey to test the relationship between the quality of government and well-being. The quality variable is measured by an average of four indices that measure governmental effectiveness, regulatory quality, rule of law, and control of corruption.

Their results show that increasing the overall quality of government by about one standard deviation would have a similar effect on life satisfaction, for a typical respondent, as moving at least halfway up the income distribution within one's own country (measured in deciles).

The World Happiness Report (Helliwell, Layard, & Sachs, 2016) uses a larger sample of 156 countries, surveyed between 2005 and 2015, from the Gallup World Poll. The results focus mostly on cross-sectional variation. This report finds evidence of a significant and large negative correlation between SWB and an index of corruption. Well-being is measured by the Cantril "ladder of life" survey question which asks respondents to rank their lives on a 0 to 10 scale, where the worst possible life is a 0 and the best possible life is a 10.

The argument found in Frey and Stutzer (2000) that formal institutions, like referenda, may increase well-being due to the satisfaction that comes from the process of participating, aside from the actual outcomes that are produced, has important implications.

For example, Helliwell (2011) uses a case study of Singapore's Prison Service reforms which he believes exemplifies lessons from well-being research that emphasizes the positive role of processes (such

as engagement in a shared purpose). The reforms which he studies were begun in 1998 and emphasized the building of connections and trust so as to combine prisoners, staff and the public in collaborative commitments to improve the lives of all.

The outcome of these reforms appear to have been impressive, having helped contribute to a one-third drop in recidivism, as well as improved staff morale and better social connections between prisons and the rest of society.

More generally, Helliwell and Putnam (2004) use the World Values, US Social Capital Benchmark and Canadian "Equality, Security and Community" surveys to study the relationship between social networks and well-being. Marriage and family, closeness to friends, workplace ties, civic engagement, trust and trustworthiness are independently and robustly positively correlated with an individual's happiness and life satisfaction.

At the macroeconomic level, Aghion, Algan, Cahuc and Shleifer (2010) find that measures of trust are negatively correlated with the level of government regulation whereas Djankov et al. (2002) find a positive relationship between corruption and regulation.[2] Hence, the above types of findings, taken together, suggest that countries with a smaller regulatory state and higher levels of citizen participation in decision-making, as well as a greater degree of social connectedness and trust, may experience higher levels of well-being.

However, work on the topic of how specific regulations affect well-being is still quite scarce, probably due to the difficulty of obtaining comparable measures of rules, both across nations, and even within the same country over time.

The Effect of Political Affiliation and Political Parties on Well-being

Another question relates to how an individual's political affiliation, whether it be left-wing or right-wing, as well as the partisan stance of the government, affects well-being. Di Tella and MacCulloch (2005) find that the same outcomes affect people's life satisfaction differently, depending on which party they support, and that these differences cannot be traced back to income differences. A panel of 10 countries is used from 1975 to 1992 to help identify the results by exploiting the time series variation in the data.

This kind of evidence favours the partisan approach to modelling business cycles: right-wingers tend to care more about inflation and left-wingers seem to be more concerned with unemployment. In other words, the same economic outcomes that are associated with a particular set of institutions may be associated with different levels of well-being across individuals, depending purely on their ideological inclination.

Respondents also declare themselves to be happier when the party in power has a similar partisan inclination to themselves, even after controlling for key economic performance indicators such as unemployment, inflation and income.

The effect is quite large: a right-wing person living under a Socialist Party leader, like President Hollande of France, would have been willing to put up with an increase of 11 percentage points in the inflation rate in order to have a Conservative Party leader, like Prime Minister Theresa May, in the United Kingdom. This trade-off is derived by regressing a measure of well-being on a set of explanatory variables that include how far into the ideological right is the government and also the inflation rate, where the data are divided into two sub-samples made up of those who identify themselves as being either right-wing or left-wing.

One interpretation is that some non-economic variables may affect the two constituencies differently. Examples in America may be a party's position on gun control or abortion. Another interpretation is that voters experience happiness when the party they support is in power, regardless of its policies, due to the personal charisma of the leader (which maybe attractive only to the party's constituency). Alternatively, there could be a pure "victory effect", whereby individuals care that the party which they support is in power (regardless of the leader or the policies which he or she enacts).

Furthermore, Pierce, Rogers and Snyder (2016) use daily data on the SWB of over 300,000 people before and after the 2012 US election which was won by (former Democratic) President Obama. The happiness of those individuals who identified themselves as partisan losers (i.e., Republican supporters) dropped significantly in the days immediately after the election. The drop in their in their SWB was twice as large as respondents living in Boston experienced in the aftermath of the Boston Marathon bombings. On the other hand, the SWB of the partisan winners (i.e., Democrat supporters) was not affected by the election.

Not only do economic and political outcomes affect SWB, but causality may also work in the opposite direction. Using an unbalanced panel of 15 European Union members from 1973 to 2012, Ward

(2015) finds a positive correlation between voters' SWB and their propensity to re-elect incumbent governments. He includes a range of macroeconomic control variables, like GDP growth, inflation and unemployment, as well as country and year fixed effects. A one standard deviation increase in SWB is associated with an 8.5 percentage point (86% of a standard deviation) swing in the vote share enjoyed by the governing coalition.

Liberini, Redoano and Proto (2013) also find that a drop in a person's SWB makes them less likely to vote in favour of the ruling party, even if the reason is an event for which the government has no influence. They use British Household Panel Survey Data on just over 4,200 individuals who were interviewed between 1996 and 2008.

To summarize, these findings appear to lend more support to the idea that well-being is not driven solely by the outcomes which formal institutions generate. The success of one's own "team", as well as participation in the electoral process, increase well-being, independently of the policies actually implemented. In addition, although there are still few studies on the topic, lower SWB may lead to a desire to change the government, regardless of its political colour.

The Effect of the Welfare State and Taxes on Well-being

In this section we study how another set of formal institutions, namely those relating to the government expenditure and taxation system, affect well-being in nations. We focus in particular on those programmes that enhance income security.

The Welfare State and Well-being

An increasing body of work has explored whether certain forms of welfare state institutions, like unemployment benefits, affect well-being. For example, Richard Easterlin (2013) states that *"If society's goal is to increase people's feelings of well-being, economic growth in itself will not do the job. Full employment and a generous and comprehensive social safety net do increase happiness"*.

Some people argue that the unemployed voluntarily choose not to find a job since they don't find work attractive. If this is the case then unemployment may not be associated with much mental distress, leading policy-makers to opt for a less generous benefit system to reduce the attractiveness of being out-of-work.

However, a large body of evidence from 'happiness' studies has now shown that the unemployed are far less happy than those that have work. Becoming unemployed has a larger negative effect than divorce, according to many data sets. This result has led some economists to argue that governments should bias their policies toward providing a comprehensive social safety net.

Di Tella, MacCulloch and Oswald (2003) study the effect of unemployment benefits on national well-being, as well as on different sub-groups, like the unemployed and employed. They use a sample of 271,224 people living in 12 nations between 1975 and 1992 who were surveyed by Euro-barometer. Their "happiness regressions" exploit the time-series variation in these data by controlling for country and year fixed effects, as well as country specific time trends.

People are willing to forgo GDP growth rates of 2.5% to see an increase in unemployment benefits, as a proportion of wages, equal to 3 percentage points, ceteris paribus. This trade-off is derived by regressing a measure of well-being on a set of explanatory variables that include GDP and unemployment benefits. The above change in benefits is equivalent to a shift from the Irish level to the French level (i.e., from 0.28 to 0.31). The employed and unemployed experience an increase in SWB of similar magnitude. However, doubt still persists as to the overall impact of more generous benefits, due to the potential adverse effects on well-being of the higher taxes and unemployment which they may cause.

More generally, a number of political scientists have focussed on the question of whether the welfare state facilitates higher levels of well-being due to its capacity to allow people to uphold a "socially acceptable" standard of living, independent of market participation. In this spirit, Esping-Andersen (1990) creates a "decommodification" index, which measures the extent of "emancipation" of labour from market dependency summarized across three domains: pensions, income maintenance for the ill or disabled, and unemployment benefits.

Pacek and Radcliff (2008) use Euro-barometer data from 1975 to 2002 for 11 nations to test whether the "decommodification" index is correlated with SWB. In regressions controlling for country fixed effects, they find that decommodification is positively correlated with life satisfaction, significant at the 5 percent level. A shift from the minimum to maximum value of the former variable is associated with three-quarters of a standard deviation increase in SWB. These authors conclude that the "welfare state contributes to human well-being".

The above kinds of studies appear to build a strong case supporting a positive association between

a social safety net and SWB. However, Veenhoven (2000b) argues that public welfare may crowd out private provision by friends, families and private organizations, as well as lead to a loss in individual freedoms. Due to the positive correlations noted in the previous section of this chapter between SWB and participation in private networks, the possibility of adverse effects due to crowding out do need to be investigated further.

Related to these concerns, there is still much debate regarding the question of the effect of overall government size on well-being. For example, Bjørnskov, Dreher, and Fischer (2007) correlate general government consumption spending, as a fraction of GDP, with life satisfaction using the third and fourth waves of the WVS, taken between 1997 and 2001, which cover 120,000 individuals in 74 countries. These authors find that SWB is negatively related to government consumption, although they mainly exploit cross-sectional variation by only controlling for a set of region dummies (i.e., Sub-Saharan Africa, North Africa, Middle East, Asia, Pacific and Latin America) rather than country dummies.

In summary, whereas the evidence is supportive of a positive relationship between particular dimensions of the welfare state, such as unemployment benefits, and well-being, the effect of aggregate government size is subject to much disagreement. One reason for the difficulty in assessing the overall impact of government spending on SWB is discussed in the next section.

Taxes and Well-being

The papers discussed above seek to explain well-being using measures of the generosity of government programmes. However they do not directly consider the impact of the higher taxes needed to fund them. Akay et al. (2012) use 26 waves of the German Socio-Economic Panel, which has surveyed about 25,000 individuals between 1985 and 2010, to correlate life satisfaction with each person's net income, as well as the level of taxes they pay. Individual and year fixed effects are included in their regressions.

Net income is significantly positively linked with SWB whereas, conditional on net income, taxes have a positive effect. The authors interpret these findings as meaning that taxes have separate two effects on SWB: a negative effect to the extent they subtract from gross income; and a positive effect most likely due to the benefits that tax revenues provide by helping to fund public goods and social insurance programmes.

One of the few papers which correlates SWB with direct measures of both government spending and taxes at the national level is Grimes, Ormsby, Robinson and Wong (2016). They use data on 171,804 people living in 35 nations between 1981 and 2012, collected in six waves of the WVS. Taxes are divided into two categories: "non-distortionary", defined as indirect taxes on goods and services; and "distortionary", which include income taxes, social security contributions, and property taxes. They control for country and year fixed effects, GDP per capita, inflation, unemployment, and personal characteristics.

Higher taxes are found to be associated with lower SWB, whereas the reverse is true for public expenditures. Grimes et al (2016) main result is that non-distortionary taxes lower well-being more than distortionary taxes. Increasing the latter by 10 percent of GDP, funded by a same sized cut in the former, leads to a rise in SWB of 25% of a standard deviation, similar to the effect of getting married in many 'happiness regressions'. They also find that devolving central government expenditure to a more local level leads to higher SWB.

Another paper which attempts to distinguish between different types of tax structures is Oishi, Schimmack and Diener (2012). Their sample is a cross-section of 54 countries from the 2007 Gallup World Poll in which the Cantril "ladder of life" question was asked to 59,634 people. These authors find that countries with more progressive income tax systems (i.e., where the tax rate increases more steeply as taxable income rises) tend to have higher levels of SWB. They argue that the mechanism occurs by virtue of a "fairer distribution of wealth" and the provision of more "quality public goods".

Aside from taxes which are used purely to help raise revenues for the government, some taxes may instead be used to discourage addictive forms of behaviour. These are sometimes referred to as "sin taxes". Gruber and Mullainathan (2005) find that higher cigarette taxes increase the SWB of smokers, on average, compared to non-smokers, presumably by helping them give up.

In summary, research determining the impact of taxes on SWB is still in its infancy. There is already some evidence suggesting that different kinds of taxes affect well-being differently. Few, if any papers, have been able to successfully identify the net effect of government programmes on SWB, taking into account the full impact of the taxes needed to finance them.

Conclusion

The aim of this chapter is to describe how formal institutions, like the political system in a country,

as well as the rules surrounding the welfare state and taxes, affect well-being. There are many studies suggesting that more freedom, as well as government structures which encourage civic engagement, participation and trust, have positive effects. However since freedom-related variables have typically been measured at the national level and often vary only slowly over time, further work is needed to test robustness.

One theme of this research agenda is that processes may matter at least as much as outcomes. For example, people appear to experience higher levels of well-being from the act of participation in a referendum, regardless of the policies that actually get implemented. Similarly, the evidence points to political competition being somewhat like a team sport in which one gets pleasure from supporting the winning side. In other words, there appears to be a pure "victory effect", whereby individuals care that "their" party is the one holding power, regardless of the policies which are enacted.

A growing body of research using country level panel data also supports the view that a comprehensive social safety net is associated with higher levels of well-being for all workers, both employed and unemployed. However, doubt still persists as to the overall impact of a generous welfare state, due to the extent to which well-being may be adversely affected by the higher taxes needed to support it.

Topics regarding the impact of (slow-moving) formal institutions on well-being opens up the question of the advantages, but also the limitations, of using happiness data to help evaluate public policies. First, there is uncertainty about the time horizon used by people in framing their survey responses. Second, since people may adapt over time, there is doubt as to the short-run versus the long-run effect of institutions on well-being. Third, there is still much disagreement as to whether a person's well-being can even be summarized by a single number or whether there are different dimensions of well-being that cannot be aggregated.

Footnotes

[1]Examples of survey questions that have been used to measure self-reported well-being and which will be referred to in this chapter include the "happiness" question, which asks, "*Taking all things together, would you say you are: very happy; quite happy; not very happy; not at all happy?*", and the "life satisfaction" question, which asks, "How satisfied are you with your life as a whole these days?", with responses ranging from "*completely dissatisfied*" to "*completely satisfied*". Another example is the "ladder of life" question which asks "*Please imagine a ladder with steps numbered from zero at the bottom to 10 at the top. The top of the ladder represents the best possible life for you and the bottom of the ladder represents the worst possible life for you. On which step of the ladder would you say you personally feel you stand at this time?"*

[2]Aghion et al (2010) use a measure of trust from the World Values Surveys, collected between 1981 and 2003, which they correlate with the level of regulation (measured by the number of steps that an entrepreneur must complete to open a business legally) across 57 countries. Respondents in the WVS were asked, *"Generally speaking, would you say that most people can be trusted, or that you can't be too careful in dealing with people? What would it be today?"* and also *"To what extent do you trust the following institutions: government, banks, foreign companies?"*

Abstract

Measures of subjective well-being have gained substantial attention in economics as quantitative approximations of individual welfare. They allow researchers to study relevant determinants of welfare on an individual as well as on a societal level. These determinants might not to be easily detectable in observable behavior. By referring to the recent well-being literature, we provide a selection of determinants of well-being that are important for public policy and show how the analysis of subjective well-being is applied as a complementary analytical tool for policy evaluation. We highlight the use of these measures for guiding public policy in areas that might involve suboptimal behavior. We also discuss some challenges for future research that are associated with the choice of evaluation metrics, the role of aspiration and adaption in evaluations, and utility misprediction.

Keywords: Subjective Well-Being, Determinants of Welfare, Policy Evaluation, Bounded Rationality

It is self-evident that public policy *should* be oriented towards the well-being of the people. It is similarly evident that views differ regarding what well-being means and what contributes to well-being. Moreover, we see that public policy *is* used (but also abused) to affect the allocation and redistribution of resources and thus well-being. In order to gain a better understanding of such normative and positive issues regarding the relationship between public policy and subjective well-being, several questions need to be addressed. First, there is the question of what well-being is. In an empirical context, survey research has derived several measures of subjective well-being that capture facets of what people consider a good life. Second, there is the question about the determinants of well-being. Third, we would like to know how these measures of subjective well-being can be analyzed to learn about the welfare consequences of alternative policy arrangements. From a constitutional perspective, we would like to understand what basic rules can be implemented to secure well-being-enhancing public policies and, thereby, create environments that make people better off.[1]

In this chapter, we provide an overview of some recent reactions to these questions and illustrate how insights from research on subjective well-being can provide guidance for a well-being evidence-based public policy.[2] Studying covariates of subjective well-being helps us to understand the critical determinants of individual welfare, which involve both tangible and non-tangible (psychological) aspects. Based on measures of subjective well-being, it is possible to uncover welfare consequences that are partly unobservable when using traditional measures of economic and social progress such as national income. However, even with a better understanding of the determinants of well-being, an institutional perspective on public policy reminds us that it is not possible to simply trade-off the different contributors to well-being. Instead, we advocate that subjective well-being measures should be applied in comparative analyses in order to learn about the consequences of alternative institutional and policy arrangements.

In particular, we see two major benefits of well-being research for policy evaluation. First, it facilitates evaluations which analyze numerous, potentially countervailing effects of policies, thus allowing the researcher to study their net effects on individual welfare. Well-being research thus helps to identify institutions that enable individuals to better meet their preferences. Furthermore, it offers a promising alternative method (often called *Life Satisfaction Approach*) for directly evaluating the benefits provided by public goods. Second, subjective well-being research provides an alternative approach for policy evaluation in areas that might involve suboptimal behavior. With regard to the insight commonly applied in behavioral economics (and also a popular adage) that people do not always behave in their own best interest, we emphasize the need to weaken the assumption of consumer sovereignty in rational choice analyses and the strong (or exclusive) reliance on observed behavior as a welfare criterion. If some behavioral choices are suboptimal from an individual's perspective, research can then seek to identify the conditions under which such choices are less likely. Data on subjective well-being can provide a valuable input for the discourse and people's limitations in pursuing their ideas of the good life. This empirical research on subjective well-being provides a tool for policy evaluation in areas where decision utility (as reflected in behavior) systematically diverges from experienced utility.

There are, of course, many open issues and challenges to the use of subjective well-being for public policy. First, the well-being approach involves the choice of a concrete evaluation metric: the metric that is used to elicit people's judgments. Depending on the applied measure, different (policy) conclusions might be inferred. Second, hedonic adaptation and the aspiration treadmill have potentially great consequences for the assessment of the nexus between public policy and individual well-being. And third, studies in the field of economics and psychology suggest that people systematically mispredict the utility they derive from some circumstances in the future. This might lead to suboptimal decisions. However, up to now it is rather difficult to derive policy implications from the results in the literature.

The remainder of this chapter is organized as follows. In section 2, we start with the measurement of individual well-being for public policy and provide some examples of policy-relevant covariates of subjective well-being. Section 3 discusses different aspects and examples of policy evaluations based on subjective well-being data, including the life satisfaction approach to value public goods. A separate section 4 addresses the potential of individual ex post welfare judgements for policy evaluations in areas that might involve suboptimal behavior. In section 5, we take up three challenges for well-being evidence-based public policy. Section 6 offers concluding remarks based on a constitutional perspective.

Policy-Relevant Determinants of Subjective Well-Being

Subjective Well-Being as a Complementary Welfare Measure

Over the past two decades, economists have rediscovered their interest in the concept of utility as a measurable quantity, as it had been abandoned with the ordinal revolution in economics on the basis of general skepticism regarding subjective measures. The same holds for most other social sciences, but not for psychology where already in 1999 Diener, Suh, Lucas, and Smith reviewed "three decades of progress" after a first review of the topic by Wilson in 1967. In this recent counter-movement of "happiness research" (as termed colloquially), data on subjective well-being is used as an empirical approximation of utility and individual welfare.[3] This approach bases judgements of individual welfare on people's self-evaluations of the quality of their lives rather than on a decision utility that is inferred from observed choices (Kahneman, Wakker, & Sarin, 1997). In contrast to the traditional choice-based approach, the experience or survey-based approach explicitly adopts and makes reference to (unobservable) psychological content, such as a person's beliefs, desires, or emotional states (e.g., Hands, 2009). It can therefore be argued that the experience or survey-based concept of utility captured by measures of subjective well-being is broader and more accurate and appropriate in identifying what people care about.

Subjective well-being can also serve as a welfare indicator from an aggregated perspective. It has various advantages over traditional measures of economic activity which reflect only the monetary value of goods and services trades in formal markets. Subjective well-being goes beyond measuring market transactions by incorporating non-material aspects, such as the welfare derived from social relationships, the experience of autonomy and competence, the absence of insecurity, or grievance derived from perceived inequality. Moreover, measures of happiness consider *outcome* aspects of components already included in the gross national product (GNP) via input measures. This holds, in particular, for the vast area of government activity (measured in GNP by the cost of material and labor). The statistics based on these subjective well-being measures are generally used to complement the traditional measures of aggregated welfare, such as GNP per capita.[4]

In sum, subjective well-being may serve as an alternative welfare indicator which allows the researcher to directly study relevant determinants of welfare both on an individual and on a societal level. The identification of the determinants of individual well-being can then provide some guidance when considering basic rules and defining the relevant space for public policy. By referring to the recent well-being literature, we highlight in the following examples for determinants of subjective well-being that matter for public policy.

Examples of Policy-Relevant Covariates of Subjective Well-Being

Unemployment and inflation. The view that considered unemployment to be a social bad changed with the advent of the new classical macroeconomics perspective in which all unemployment is considered to be voluntary. According to this view, the important reasons why people decide not to work are that unemployment benefits are too attractive relative to the salaries achieved on the market, or simply that the going market rate is below the reservation wage. However, the results of subjective well-being research show that the scope of this position is too narrow.

First, unemployment reduces the individual well-being of those personally affected, even if the lower income available to them is statistically taken into account. For example, Kassenboehmer and Haisken-DeNew (2009) find that entering unemployment has a negative causal effect on life satisfaction. They identify this effect by studying a sample of people in Germany who experience an exogenous transition

into unemployment due to plant closure. Based on their findings, they conclude that the non-pecuniary costs of unemployment are dramatic, particularly for women during their first year in unemployment.

Second, unemployment reduces the subjective well-being not only of the individuals who are actually unemployed, but also of those who currently work. Luechinger, Meier, and Stutzer (2010), for example, find that an increase in regional unemployment substantially reduces the reported life satisfaction of the people who currently work. However, with regard to people who work in the public sector and who usually enjoy extended protection from dismissal, the negative effect is about a third lower than for private sector employees. The results suggest that general unemployment is accompanied by increased economic insecurity and that this is an important component of the psychological costs of general unemployment.

Besides unemployment, inflation is another economic variable that affects individual welfare and has strong policy implications. A one percentage point increase in inflation is often considered to result in the same welfare loss as a one percentage point increase in the rate of unemployment (this view is reflected, for example, in the so-called misery index). However, research has shown that the negative well-being effects of inflation seem to be relatively less severe than those from unemployment (Di Tella & MacCulloch, 2006). The size of this relation varies between studies, though. Using data for 12 European countries over the period from 1975 to 1991, Di Tella, MacCulloch, and Oswald (2001) report that people would trade off a 1 percentage point increase in the rate of unemployment for a 1.7- percentage point increase in the rate of inflation. With data for a longer time period from 1975 to 2013 and for a larger set of EU member countries, Blanchflower, Bell, Montagnoli, and Moro (2014) find the same direction of relationship. However, their estimates imply that unemployment has a much stronger negative impact. They report that a one percentage point increase in the rate of unemployment lowers well-being more than five times as much as a one percentage point increase in the rate of inflation.

Income and income inequality. People obviously care about their income, but they also care about others' incomes, as well as income inequality within a society. Based on a repeated cross-section of Americans over a 37-year period, Oishi, Kesebir, and Diener (2011) find a direct negative effect of income inequality on happiness. Americans were, on average, happier in years when relative national income was comparatively more equally distributed than in years when it was less equally distributed. They further find that this relationship cannot be explained by lower household income, but that it is moderated by psychological factors, i.e., a decrease of perceived fairness and trust.

Schwarze and Härpfer (2007) present evidence for Germany that people of all income classes report lower life satisfaction when regional income inequality increases. This may be due to inequality aversion and/or empathy for the poor. Similarly, if economic shocks increase unemployment, people may care about the fate of the people who experience unemployment, reducing their own sense of well-being (over and above the effect of the increase in economic insecurity discussed above).

Another explanation for the negative impact of income inequality is the importance of relative position or status as a determinant of people's well-being. The empirical well-being literature documents that an individual's well-being level is reduced when the average income of other individuals increases.[5] For example, Stutzer (2004) studies residential communities and finds that the average income level in the community of residence is significantly positively related to people's income aspirations and negatively correlated with people's life satisfaction. Luttmer (2005) reports a negative correlation between self-reported happiness (and other indicators of well-being) and income in the neighborhood. Dynan and Ravina (2007) confirm the general finding that beside the positive effect of an absolute income increase, there is a positive relationship between people's income positions relative to that of their neighbors and self-reported happiness. In their study for the United States, they further show that this relationship is stronger for individuals who have above-average incomes. This finding highlights the fact that an income-based analysis of the evolution of aggregate welfare in a society might be insufficient.

Further aspects. Beside these prominent economic determinants of subjective well-being, recent literature has identified a broad range of other relevant aspects that are directly or indirectly linked to public policy. This includes aspects such as social capital and quality of social relationships, religious faith, exposure to crime, and access to technology, as well as, of course, health and health care. Picking out an example, van den Berg, Fiebig, and Hall (2014) provide evidence for a relationship between caregiving and self-reported life satisfaction. Based on Australian panel data, they find that weekly informal care time is associated with reduced life satisfaction for the care-giving person. As the authors argue, this finding is important given that the development of sustainable long-term care systems is one of the main challenges for public policy in high-income countries.

Subjective Well-Being for Policy Evaluation

Inherent Risk of Premature Policy Proposals

If research provides information about outcomes linked to individual well-being, it is tempting to suggest policy interventions that strengthen positive outcomes and diminish negative ones, by trading them off to obtain an optimal policy mix that maximizes some empirical indicator of subjective well-being. Unemployment may be a case in point. One might propose that to improve the lot of the unemployed, transfers should be increased, and to reduce the economic insecurity of the employed during a crisis, employment protection should be extended. However, such conclusions might be premature. Regarding the first aspect, the personal psychological costs of unemployment due to a strong social work norm might be functionally or even necessary in order to maintain a generous and financially sustainable social benefit system. These costs help to limit moral hazard; namely, that citizens search less intently for re-employment when receiving higher unemployment benefits. With regard to the aggregate level, increased job protection might benefit those who already have a job (see, for example, Clark & Postel-Vinay, 2009). However, it is also likely to make employers more reluctant to hire new workers, which is detrimental for the job prospects for those who are unemployed. Thus stronger labor protection rights might lead to longer individual unemployment spells and to higher general unemployment.

These classic arguments highlight the importance of equilibrium effects and potential (unintended) side effects when thinking about policy interventions. In our opinion, these considerations highlight the limitations of an approach that focuses on an optimal outcome mix. Instead, we recommend an approach that uses a constitutional perspective which derives policy proposals by referring to basic institutions and rules (see also Frey & Stutzer, 2012). This shift in perspective has implications for empirical research on subjective well-being, because the focus is then on the evaluation of institutions. Regarding the important social issue of unemployment, analyses then attempt to evaluate the consequences of labor market institutions and the system of social insurance on the subjective well-being of all the people, irrespective of whether they have the status of employed, unemployed or not in the labor force.

In the following, we try to elucidate these considerations and present examples of how well-being research can be applied to evaluate policy rules and to assess outcomes for policy decisions.

Examples of Policy Evaluation Based on Subjective Well-Being

Labor market regulations. So far, little is known about the institutions that reduce the vulnerability to shocks on the labor market measured by individual well-being. In a longitudinal sample of the European Union, more generous unemployment benefits are found to correlate positively with subjective well-being in the general population (Di Tella, MacCulloch, & Oswald, 2003). Based on the same data from the Eurobarometer, the negative effects of individual and general unemployment on reported life satisfaction are found to be larger in countries with lower job protection (Becchetti, Castriota, & Giuntella, 2010).

In a recent analysis for the United States, Aghion, Akcigit, Deaton, and Roulet (2016) analyze the link between structural change and people's subjective well-being measured based on Cantril's ladder of life. They focus on the moderating effect of a more or less generous unemployment insurance in terms of the maximum weekly benefit amount. Structural change is captured at the level of the metropolitan statistical area in terms of the rate of job creation as well as job destruction. They find that a higher job turnover rate (i.e., the sum of the job creation and the job destruction rate) has a more positive effect on reported well-being in states which have more generous unemployment insurances. This result is due to a much smaller negative effect of job destruction on well-being: They write: "[A] one standard deviation increase in our measure of UI generosity reduces the negative effect of the job destruction rate by 33 percent" (p. 3891).

Based on panel data for Germany from 1992 to 2004, Crost (2016) studies whether workfare programs, as a key part of the active labor market policy in Germany, reduce the negative effect of unemployment on subjective well-being. The analysis indicates that workfare employment offsets part of the negative effect of unemployment on individual life satisfaction, at least in the short run. Based on a day reconstruction survey among 1,080 participants in workfare schemes in Germany, Knabe, Schöb, and Weimann (2017) draw the same conclusion. They find that the life satisfaction of people in workfare employment is between that of employed and unemployed people and that their emotional well-being is even the highest of these three groups. They argue that identity utility might account for part of the effect. In environments with strong social work norms, unemployed people suffer more from their lot (Stutzer & Lalive, 2004). So even workfare employment is able to restore some of the loss in identity from work. Of course, many further applications are possible with regard to different labor market regulations (see, e.g., Alesina, Glaeser, & Sacerdote, 2005, on the regulation of working hours, Dräger, 2015, on employment protection, and Charles, 2004, on the effect of mandatory retirement).

Taxation. Research on subjective well-being has produced different insights which have the potential to inspire our views about taxation (see Weisbach, 2008, for an overview). However, the direct effect of taxation on well-being is difficult to identify, and there are only a small number of studies which consider the well-being consequences of particular tax schemes. One example is the study by Oishi, Schimmack, and

Diener (2012) that finds a positive statistical association between a more progressive taxation regime and subjective well-being in a cross-section of 54 countries, controlling for national income and income inequality. An additional analysis suggests that this effect is mediated by citizens' satisfaction with public goods such as education and public transportation. Alpaslan et al. (2012) exploit exogenous variation in tax rules over time and across demographic groups in Germany and find a positive tax effect on subjective well-being. Importantly, this effect is measured conditional on net income. While they cannot identify the relevant mechanism, they consider a better provision of public goods or more redistribution and insurance through the social security system as potential channels through which higher taxes may promote citizens' satisfaction levels.

Some insights from well-being research have been related to proposals for optimal taxation (see Frank, 2003, Layard, 2006, or Mujcic & Frijters, 2015). These studies refer to the importance of status or relative position as determinants of people's well-being. Individuals do not value simply the absolute level of their income, but compare themselves with people who have higher incomes (see also section 2.2). From this insight, it is inferred that the rise in one person's income or status creates a *positional externality* if it affects the utility of other people. For example, someone owning a fancy sports car imposes a negative external effect on all other people who do not own such a good, but are motivated to strive for it.[6] If people pursue status competition by working and spending more money in order to gain an equal or a higher social position relative to their peers, this strategy leads to a zero-sum or even a negative-sum game. The tax proposal should aim to mitigate this effect by heavily taxing high-income earners (or specifically the consumption of status/luxury goods).

However, the greater the induced distorting effects of taxation are (for example, tax evasion promoted by tolerance towards shadow economies), the less successful taxation interventions are likely to be from a welfare perspective (see also Weisbach, 2008). Even if the taxation of income and consumption were successful in undoing the negative status externalities from income comparisons, status competition might persist via other channels, because people have a natural urge to distinguish themselves from others.[7] The crucial question is whether the positional externalities in these other dimensions are weaker or stronger (see, e.g., Clark, 2016, on social comparisons in different life domains).

While we are beginning to understand positional externalities as a phenomenon, we think that it is premature to draw policy conclusions in terms of optimal income or consumption taxes. Instead, we should engage in the complementary comparative institutional analyses of different governance structures (capturing the revenue-generating side as well as the expenditure side) in terms of their effects on the subjective well-being of different groups in society.

Public or non-tangible goods. In the current politico-economic process, government agencies undertake some of their decisions based on cost benefit analyses (CBAs). CBAs are a corner stone of the welfare economic approach to public policy. However, the benefits from public goods are difficult to measure in monetary terms, as the marginal utility to consumers is not reflected in market exchanges. Inspired by well-being research, a promising method used to quantify the costs and benefits of public goods has been proposed, often called the "*Life Satisfaction Approach*" (see Frey, Luechinger, & Stutzer, 2010). Taking reported subjective well-being as a proxy measure for individual welfare, it is possible to directly evaluate the utility provided by public goods. The marginal utility of public goods (or the disutility of public bads) is captured by correlating the amount of public goods (or public bads) by means of individuals' reported subjective well-being, controlling for many other determinants on happiness. By comparing the marginal utilities of public goods to the marginal utility of income, the trade-off between income and public goods can be calculated.

The Life Satisfaction Approach avoids some major difficulties of both the stated preference and the revealed preference approaches.[8] With the Life Satisfaction Approach, it suffices if respondents indicate their own life satisfaction. As the collection of survey data on subjective well-being is not linked to a specific policy goal, there is little reason to expect strategic answers.[9]

The Life Satisfaction Approach has, among other applications, been used to value airport noise nuisance (van Praag & Baarsma, 2005), air pollution (Welsch, 2006; Luechinger, 2009; Levinson, 2012), crime (Manning, Fleming, & Ambrey, 2016), flood hazards (Luechinger & Raschky, 2009), terrorism (Frey, Luechinger, & Stutzer, 2009), or wind turbines (Krekel & Zerrahn, 2017).

Recent studies have reached a high standard of quality, and the preconditions for its application are continually being refined and formulated. What so far was an academically driven development of a new method may soon become an empirical tool that meets the demands of the political process.

Policy Evaluation in Areas That Might

Involve Suboptimal Behavior

Considering Limited Willpower

From a behavioral economic perspective, policy evaluations need to consider the insight that people are not always able to behave in a manner that serves their own best interests.[10] This questions the standard economic view that people are fully able to behave in a time-consistent manner and to commit to their long-term consumption plans. In contrast to this view, the behavioral economics perspective allows for the possibility that people might consume certain goods in excess of their (long-term) preferences due to limited self-control (see, e.g., O'Donoghue & Rabin, 1999; or Ameriks, Caplin, Leahy, & Tyler, 2007). In cases where suboptimal behavior occurs, the application of a choice-based concept of welfare is insufficient for public policy evaluation, because it assumes that whatever people choose makes them, in their expectation, best off (see, e.g., Bernheim & Rangel, 2007; or Loewenstein & Ubel, 2008). However, the standard economic perspective that focuses on people's behavior as the benchmark for welfare analysis can be complemented with data on subjective well-being. The latter offers an indicator for public policy evaluations, particularly in areas that might involve suboptimal consumption choices resulting from, for example, limited willpower.

With regard to the respective policy consequences, suboptimal consumption patterns due to limited willpower are no cause for immediate government intervention. For instance, people who suffer from limited self-control might search for commitment devices that help them to pursue their optimal consumption path. Policies might then aim to offer individuals who are subject to self-control problems ways of overcoming their weaknesses by proposing self-binding mechanisms (for a broader discussion see, e.g., O'Donoghue & Rabin, 2006a).

A widely discussed policy intervention is the imposition of excise taxes on the consumption of goods that people tend to overconsume. If such taxes support self-control, they might make consumers with limited willpower better off. The regulation of risky health behavior such as smoking offers an excellent example. Analogous to negative externalities, consumers with self-control problems suffer from a negative internality, which could contribute substantially to the welfare costs of addiction (see, e.g., Jürges, 2004).[11] In reference to excise taxes on tobacco products, O'Donoghue and Rabin (2003, 2006b) investigate negative internalities and argue that "sin taxes" can be imposed in cases where people exhibit an over-consumption of unhealthy goods. However, the degree to which such internalities (over and above externalities) serve as a rationale for additional policy interventions is the topic of a lively controversy (see, e.g., Sugden, 2008; Frey & Gallus, 2016; or Schnellenbach & Schubert, 2015).

Evaluation of Tobacco Control Policies as an Example

Tobacco control policies such as cigarette taxes or smoking bans are controversially discussed, as they have a multitude of consequences that affect people's health and welfare in various ways, sometimes with a counteractive effect. In general, tobacco control policies aim at internalizing the social costs of smoking by protecting people from second-hand smoke, as well as at lowering costs for publicly funded health care by making smoking less attractive. A successful tobacco control policy should therefore lead to positive net-welfare effects, overall. Smokers, are nevertheless predicted to be worse off, as the policies restrict their behavior. However, if tobacco consumption involves time-inconsistent behavior, tobacco control policies might also have a positive impact on the individual well-being of smokers, because they can serve as a self-control device. Therefore, different predictions for the welfare consequences of anti-smoking policies emerge, depending on the assumed time consistency in smokers' consumption behavior. However, all the tobacco control policies are expected to make smoking less attractive and to reduce the prevalence of smoking among people who have full self-control and those who have limited self-control. This makes it difficult to assess the various welfare consequences of such policies when the evaluation is based on observed consumption behavior.

To address these challenges, Odermatt and Stutzer (2015a) analyze the welfare consequences of smoking bans and cigarette prices based on data on reported satisfaction with life. They use data from 40 countries and regions between 1990 and 2011 and exploit the staggered introduction of smoking bans and the respective progressively increasing cigarette prices across Europe. They simultaneously analyze the net-welfare effects of smoking bans and cigarette prices and differentiate between the effects not only for likely smokers and non-smokers, but also for smokers who failed to stop smoking. The latter group potentially captures people with limited self-control. Their estimates do not reveal any statistically significant systematic changes in people's life satisfaction levels as a result of implemented smoking bans, on average. For cigarette prices, they show a negative partial correlation with life satisfaction. This latter correlation is driven by a quantitatively relevant negative effect of higher prices on smokers. Furthermore, the results indicate that for likely smokers who failed an attempt to quit smoking, smoking bans are

beneficial in terms of life satisfaction, while higher cigarette prices are not.[12] The results show that the capacity of cigarette taxes to serve as a self-control device might be limited, while the implementation of smoking bans, in contrast, might help smokers to overcome their self-control problems. This is consistent with models that emphasize temptation as being a driver of time-inconsistent behavior. According to these models, cues trigger a temptation to smoke, leading smokers to overconsume the addictive good if they are unable to resist it by exerting their willpower. The insights that some smokers show time-inconsistent behavior and thus benefit from commitment devices that help them to align their actual consumption with their desired long-term consumption-path are of relevance from a welfare perspective and can provide an input for public policy with potential implications for any good that is subject to the risk of overconsumption.

Challenges for Well-Being Evidence-Based Public Policy

Measurement

Many measures of subjective well-being have been analyzed in studies related to public policy. There is no consensus on which measure is best (see Diener, 2006; Helliwell, 2006; Kahneman & Riis, 2005; Dolan & Metcalfe, 2012). This is probably for good reason, as the researcher's choice of the concept to be used should depend on the specific study's objective and research question. We briefly discuss three aspects that might be considered.

First, the well-being approach obviously involves the choice of a concrete evaluation metric that is used to elicit people's judgments. For a measure of reported subjective well-being to serve as a good proxy for individual welfare, one property seems particularly relevant. The evaluation metric should fit people's self-evaluations of their quality of life. Second, in order for changes over time in reported subjective well-being to have an informative value, individuals must be assumed to have stable evaluation standards. If this assumption is violated, any observed changes in reported well-being scores might not be driven by true changes in well-being, but instead potentially result from scale changes.[13] One psychological mechanism is that individuals do not rate their own situation in reference to an absolute standard, but in reference to a relative standard, and that this relative standard might change over time (e.g., Kievit et al., 2010). However, it is still a partly unresolved issue whether the change in the relative standard is associated with a real change in the hedonic experience, i.e., true hedonic adaptation, or only with a change in the description of the same hedonic experience, i.e., scale norming. Third, when using self-reported measures of well-being it is assumed that people's reporting of their well-being does not systematically deviate from their actual assessment. An obvious violation would be if people would have an incentive to systematically lie or to actively manipulate their answers. A more subtle potential violation which is discussed in the literature is distorted response behavior, which is due to context effects such as social desirability, i.e., the tendency of subjects to attribute characteristics to themselves which are socially desirable (Edwards, 1957).[14] It is thus important that researchers are aware of potential design and context effects in their satisfaction data.

Adaptation and Aspirations

A central finding in happiness research is that many changes in life circumstances have only short-lived effects on reported subjective well-being. While it seems self-evident that people's well-being changes in most instances when circumstances change, it is less clear to what extent such changes persist when the new conditions stabilize.[15] Overall, evidence suggests that there is adaptation to changes in circumstances, for example due to major life events. This adaptation, however, differs across events and is far from complete for some of them (for a discussion of the claim that changes in well-being are only temporary, see Powdthavee & Stutzer, 2014, and the other chapters in Sheldon & Lucas, 2014).

The second, closely related phenomenon is the change in people's aspirations due to changes in their life circumstances. One exemplary finding is that people adjust to income increases by increasing their material aspirations in that their new levels of income are considered "necessary" for them to make ends meet (Stutzer, 2004; Di Tella, Haisken-De New, & MacCulloch, 2010). This process has become known as the aspiration treadmill. Hedonic adaptation and the aspiration treadmill have important consequences for the assessment of individual welfare depending on the degree to which they are considered.

One example of their relevance is the case where courts have to decide about compensation for losses suffered in car accidents. For the same physical harm, should they award lower damages to people with a strong capacity to adapt and higher damages to others? Or related to government taxation, should materialists with high income aspirations who suffer a great deal from personal income taxes face lower tax rates than people who can easily adapt to whatever material living standard they are confronted with? Moreover, if people's aspirations or capacities to adapt were taken into account in policy-making, one would have to deal with the incentives that these individualized criteria create; for example, when a person claims to adapt slowly in order to obtain a higher compensation or claims to have high aspirations in order

to be taxed less heavily. People would be induced to "play the system" instead of revealing their true state of subjective well-being. As a consequence, it is difficult, if not impossible, to determine an individually optimized compensation that is considered fair by the persons involved.

An acceptable rule can possibly be found at the constitutional level behind the veil of uncertainty in which nobody knows whether he or she will be the victim of an accident or whether he or she is a quick or slow adaptor. This holds more generally – how adaptation and aspiration effects have to be dealt with in public policy cannot be answered based on some well-being calculus, but requires to be dealt with in a process of collective decision-making.

Utility Misprediction

The conception of individuals who engage optimally in forward-looking utility maximizing behavior is part of the basis of the rational choice approach to human behavior, which is prevalent in economics as well as other social sciences. Studies at the intersection of economics and psychology, however, suggest that people for some circumstances systematically diverge from this view and do not accurately predict the utility they derive from alternative conditions (see e.g., Loewenstein, O'Donoghue, & Rabin, 2003; Kahneman & Thaler, 2006; and Frey & Stutzer, 2014). Odermatt and Stutzer (2015b) show that this also applies after major changes in life circumstances due to widowhood, unemployment, marriage, or disability. People tend to underestimate the degree to which the impact of the event on their life satisfaction declines over time.

The finding that people, on average, do not accurately predict their subjective well-being has profound implications for the modeling of human behavior. While it is in itself questionable whether observed adaptation can be explained from a standard rational choice perspective in which stable preferences are assumed, the finding of a systematic underestimation of adaptation is not compatible with the paradigm of rational expectations, a cornerstone of expected utility theory. From a welfare perspective, mispredicted subjective well-being is relevant for choice formation, where the choice relies on predicted subjective well-being. Mispredicted subjective well-being could result in the misallocation of a person's resources, resulting in a lower level of individual welfare than would be achieved with unbiased decisions.[16]

However, from the results in the literature so far, it is difficult to derive direct policy implications. A better understanding is required on an individual level in order to provide a basis for advancing our understanding of the welfare consequences of misprediction on a societal level. This could, for example, comprise an investigation of the extent to which people's misprediction is carried forward through the political process with potentially biased outcomes on an aggregated level, such as a suboptimal amount of public good provision (see Frey & Stutzer, 2006, for a discussion). Nevertheless, studies based on subjective well-being can provide a source of information for people to improve their choices, both as private individuals and participants in processes of collective decision-making.[17] For example, people equipped with such insights derived from research might decide to overcome behaviors which reduce their well-being by resorting to collective arrangements. They might, for instance, turn to self-binding mechanisms such as government-mandated maximum working hours and weeks of vacation. In this way, well-being research can also contribute to (constitutional) public policy that is aimed at people who are only boundedly rational.

Concluding Remarks

The analysis of people's subjective well-being offers great opportunities for public policy. In this chapter, we have emphasized the evaluation of particular policies as well as the valuation of public goods based on well-being data as promising applications of well-being evidence-based public policy. Based on people's (ex post) judgments of their well-being, it is particularly attractive to evaluate policies in areas of life in which people might be boundedly rational. In these areas, observed behavior is potentially a poor guide to learn about the effects of policies on individuals' welfare.

The "new" approach in the study of public policy should – in our opinion – not be understood as a new paradigm of public policy, though. Insights from this new science are, instead, a complementary – and most valuable – source of evidence for the existing democratic process of political decision-making. While it is tempting to adopt a social welfare maximization approach, this new science does not overcome the criticism against it: It is faulted for disregarding citizens as ultimate decision-makers, and for seeing governments as benevolent maximizers of social welfare, which it captures in terms of measured subjective well-being. It neglects the fact that people differ in their evaluation about what measures they consider to reflect their normative preferences. Moreover, the role that the processes of adaptation and aspiration should play in policy decisions has to be clarified. Finally, the social welfare maximization approach based on subjective well-being neglects the negative incentives for manipulating empirical welfare measures.

Empirical well-being research is, however, well equipped to contribute to a constitutional perspective

of public policy by seeking basic rules that are conducive to the pursuit of individual well-being (Frey & Stutzer, 2012). In this paradigm, the fundamental rules and institutions are set at the constitutional level behind the veil of uncertainty. They determine the decisions taken in the current politico-economic process. The legitimacy of political action finally rests on the voluntary agreements on these fundamental rules by the citizens involved. In particular, the sovereignty of the individual includes the individual's choice on how to best pursue his or her personal well-being. This holds both for the private as well as the collective realm.

Accordingly, the political process should be institutionally structured so that people's interests become the principal controlling force in politics. Fundamental institutions, or rules of the game, have to be established which provide politicians and public bureaucrats with incentives and information to adequately respond to people's preferences. Well-being research provides insights about how and to what extent institutions have systematic effects on indicators of subjective well-being. The focus is on rules and institutions which include written constitutional rules, state laws, social norms, traditions and even self-binding mechanisms (for references to the respective literature see Frey & Stutzer, 2017).

According to this constitutional view, the results gained from well-being research will provide productive inputs for the political decision-making process. These inputs then have to prove themselves in political competition and in public and political debates. An ideal outcome is envisaged, where the integration of this research in the political process will enable people to actively promote and realize their idea of the good life, both individually and collectively.

Footnotes

[1]There is an enormous body of literature that is concerned with understanding subjective well-being. In economics, there are a series of monographs including, e.g., Frey and Stutzer (2002a), Layard (2005), Frey (2008), and Graham (2011), as well as review articles including, e.g., Frey and Stutzer (2002b), Dolan, Peasgood, and White (2008), or Stutzer and Frey (2010). For articles from a psychological perspective, see, e.g., Diener and Biswas-Diener (2008), or the collections in David, Boniwell, and Conley Ayers (2013), or Sheldon and Lucas (2014). Good overviews about cross-country comparisons of well-being are provided in the five World Happiness Reports published so far (Helliwell, Layard, & Sachs, 2017).

[2]Other sources that discuss many issues related to public policy and subjective well-being are Diener, Lucas, Schimmack, and Helliwell (2009), Hämäläinen and Michaelson (2014), or the report of the Legatum Institute (O'Donnell, Deaton, Durand, Halpern, & Layard, 2014). In this chapter, we draw on previous work by Stutzer (2009), and Frey and Stutzer (2010, 2012, 2016, 2017) and develop it further.

[3]Subjective well-being is an umbrella term for different measures proposed in the literature, ranging from affective measures such as experience of fear, happiness, joy, or sorrow to evaluative measures such as life satisfaction or purpose in life. For a definition and description of different indicators, see, e.g., Kahneman and Krueger (2006), Diener, Inglehart, and Tay (2013), Tay, Chan, and Diener (2014). For a recent empirical comparison of different measures see, e.g., Clark (2015).

[4]The discussion and development of aggregate measures of personal well-being has recently been promoted in many countries; for example, by the French Stiglitz-Sen-Fitoussi Commission in 2009, or the Enquete Commissions on Growth, Prosperity and Quality of Life in Germany between 2011 and 2013 (Enquete-Kommission, 2013). Furthermore, new statistics divisions devoted to measuring well-being and progress have been set up by the OECD and many countries, such as the UK, Australia, or Canada, now prepare special reports based on subjective measures of quality of life.

[5]For a review about relative income and subjective well-being, see Clark, Frijters, and Shields (2008).

[6]For recent empirical evidence on position of externalities of consumption, especially of luxury goods, see, for example, Winkelmann (2012) or Perez-Truglia (2013).

[7]Examples of other domains are political power, education, leisure, or status seeking in other activities outside economics and politics, such as sports or the arts (see Frey & Stutzer, 2016, for a discussion).

[8]The contingent valuation method, for example, might overstrain individuals, because the questions asked are hypothetical, and the valuation task is unfamiliar. The respondents tend to be "primed" to the particular issue in question, which might not otherwise concern them at all. Moreover, the respondents may disregard their budget constraints and the substitutes available. The likely result is, thus, a symbolic valuation of people expressing attitudes (Kahneman & Knetsch, 1992). Furthermore, the strategic behavior of respondents may also bias the answers. Revealed preference approaches usually require the observation of undistorted equilibrium prices.

[9]This and further methodological issues are, for example, discussed in Kahneman and Sugden (2005), Welsch and Kühling (2009), and Frey et al. (2010).

[10]A growing body of research has developed in the interdisciplinary field of economics and psychology that investigates systematic deviations from utility maximizing behavior (for reviews, see, e.g., Kahneman, 2003; Camerer, Loewenstein, & Rabin, 2004; Frey & Stutzer, 2007; DellaVigna, 2009; or Rabin, 2013). Thereby, a closer link between the study of suboptimal choices and the research on subjective well-being is, for example, established in (Hsee, Rottenstreich, & Stutzer, 2012).

[11]Allcott and Sunstein (2015) define negative internalities as being the costs individuals impose on themselves by taking actions that are not in their own best interest. Examples are time-inconsistent behavior due to self-control problems or a distorted allocation of resources due to utility misprediction (see Section 5.3).

[12]This finding is contrary to a prominent result published in the study by Gruber and Mullainathan (2005). In two longitudinal analyses for the United States and Canada, they find that tobacco taxes are positively related to smokers' happiness. Similarly, Leicester and Levell (2016) find a positive differential effect of higher cigarette taxes on smokers compared to non-smokers in the United Kingdom. They also study smoking bans. For the identification of their effect, they rely on the different introduction dates across the four regions in the UK. They find no significant effects on mental well-being.

[13]These scale changes are discussed in the literature under different terms, such as scale norming (Frederick & Loewenstein, 1999), response shift (Schwartz & Sprangers, 1999), or scale of reference bias (Groot, 2000).

[14]Conti and Pudney (2011) provide an example as evidence of the relevance of social desirability. They find that people report higher values of satisfaction with their job in a face-to-face interview than when self-completing a questionnaire. For a recent review on the determinants of the social desirability bias, see Krumpal (2013).

[15]This question is related to the prominent work by Brickman and Campbell (1971), which proposes the idea of a hedonic set point which is regained after a process of adaptation: People become used to a new situation or repeated stimuli and thereby return to their innate level of experienced well-being. Their conclusions provoked substantial empirical research on adaptation.

[16]A distorted allocation primarily occurs if the bias is not uniform across all goods and activities, because the individual preference ordering of alternatives is altered (see Frey & Stutzer, 2014, for a discussion of the relevance of such an asymmetry for utility misprediction). The presence of an asymmetry is indicated by a well-known claim by Tibor Scitovsky (1976), namely that people tend to overinvest in comfort to which one adapts strongly and to underinvest in creative activities where less adaptation is involved. Along this line of reasoning, Frank (1999) claims that, due to incomplete information about the extent to which we adapt to different goods and experiences, we observe a misallocation towards working and consuming too much.

[17]Ubel, Loewenstein, and Jepson (2005) report findings of experiments which suggest that asking people to reflect on adaptation is sufficient to reduce potential systematic errors in affective forecasts when people predict their quality of life with respect to disability or living in a better climate.

Abstract

Media technology—from mass media to social media and from video gaming to computer-mediated communication—plays an increasingly central role in people's lives. Due to exponential increases in computing power, people now carry incredibly powerful computers—their smartphones—everywhere they go. This ever-greater access to media technology is generating an ever-greater conflict between media activities and the unmediated activities critical for psychological well-being—from our face-to-face conversations and family time to our down time and work lives. What are the costs and benefits of people's modern media technology use for psychological well-being? Using a complementarity-interference (CI) framework, I review research to illuminate key psychological processes (i.e., mediators) and conditions (i.e., moderators) of the relationship between media technology and psychological well-being. Based on the existing evidence, I propose an initial theoretical CI model of the effects of media technology on psychological well-being. I use this CI model to outline important directions for future research, providing guidelines for an integrated, theoretically informed research on media technology.

Keywords: Media, Communication technology, Computer-mediated communication (CMC), Subjective well-being, Human-computer interaction (HCI)

Imagine that you have a time machine that can transport you to the past for a day at a time. You set the year you want to travel to before you go to bed, and you wake up on the same calendar day but as far back in the past as you wanted to travel. You decide to use the machine go back to the time of cavemen. As you wake up in your cave, what options are available to you? You can stay in bed a little longer under the warm animal hide covers, walk around the cave inspecting the carvings, or perhaps take a walk and try to find some food (while presumably avoiding being eaten by a wild animal). Notably, all these options are limited to what's available in your immediate physical environment. Several days later, you decide to take another trip through time back to the time of the Renaissance in the Italy. Now, as you wake up in your bed, you can do much the same things you did on the previous trip—think, eat, look around—but now, you also have additional options. Thanks to developments in media technology, you can now pick up and read a book, transporting yourself in a vivid virtual world that is not constrained by your immediate physical environment. After all this time traveling, you wake up in your own bed in the present time. And you notice that you now have an unlimited number of virtual worlds that you can engage with. You can check your work email or social media feeds on your phone, you can video-call your partner to tell him or her about your time-travel adventures, or you can travel to virtual worlds—past, present, and future—with a few movements of your finger on the TV remote. The focus of this chapter is to explore when, how, and why this vast array of virtual worlds can enhance versus compromise psychological well-being.

Scope and Definitions

Media technology. In this chapter, we will explore psychological well-being in the context of modern media technology. In common parlance, we often think of the word 'media' as referring to mass media, such as news media (e.g., TV, radio), and more recently, to social media (e.g., Facebook, Twitter, Instagram). But media—the plural of medium—broadly refers to any technological tool that serves as a bridge or conduit to stimuli not otherwise available in the immediate physical environment. Thus, *media technology* refers to books and newspapers, radio and television, video and computer games—or to any device or method people use to transcend the constraints of their immediate physical environment: from yesterday's dial-up telephone to the today's smartphone, and from writing a hand-written letter to texting a friend (c.f., Okdie et al., 2014). Related terms also exist in the literature including *information and communication technology*, or ICT, as well as *computer-mediated communication*, or CMC. Most of the findings discussed here apply to—and in fact come from—the literature on ICT and CMC.

While using the broad term, media technology, this chapter will focus primarily on the effects of media technology developed in the past century or so, including television, video games, and, most recently, mobile computers such as smartphones. In other words, we will be focusing on *screen media*

technology. I will use the term *mediated* to refer to the stimuli afforded by the media technology, and the term *unmediated* to refer to behavior that does not involve the use of media (e.g., face-to-face interactions). Even though media technology itself is physical, I will use the term *immediate physical environment* to refer to the environment in which the media technology use occurs.

Well-being. We will explore the effects of media technology on well-being, broadly defined. Because subjective well-being has been defined as a combination of life satisfaction positive affect, and (low) negative affect (e.g., Diener, 1984, 2000; Diener et al., 2017), I will use the term *psychological well-being* to include not only subjective well-being, but also the factors inextricably linked to subjective well-being such as basic human needs (Baumeister & Leary, 1995; Fiske, 2014; Kenrick, Griskevicius, Neuberg, & Schaller, 2010; Ryan & Deci, 2000; Ryff, 1989). We will use the term *emotional well-being* to refer to the affective components of subjective well-being (i.e., positive and negative affect).

Chapter overview. There are many excellent comprehensive reviews of research on specific media technologies, such as television, video gaming, and social media (e.g., Howard-Jones, 2011; Wilson, Gosling, & Graham, 2012). Rather than providing a comprehensive review of existing research, therefore, the goal of this chapter is to provide an integrative, and theoretically-focused overview of the relationship between media technology and psychological well-being, broadly defined. Thus, I will focus on findings that illuminate key psychological processes (i.e., mediators) and conditions (i.e., moderators) of the relationship between media technology and psychological well-being. This focused approach allows the identification of gaps in the literature, thereby providing guidelines for key future directions in this fast-evolving area of research. Because no comprehensive reviews exist on the psychological effects of smartphones—the latest media device to become part of people's lives—I will focus on evidence about smartphones whenever possible, drawing on insights from my own emerging research in that area. First, however, I outline my theoretical approach—the *complementarity-interference framework* (c.f., Kushlev & Heintzelman, in press)—which I then use throughout this chapter to construct an initial *complementarity-interference model* of media technology on well-being (see Figure 1).

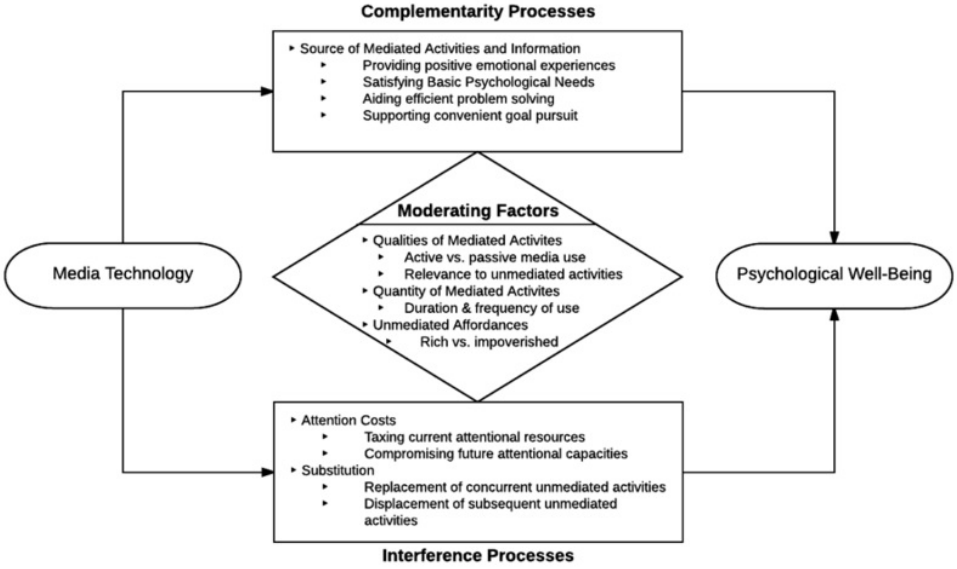

Figure 1. The Complementarity-Interference (CI) Model of the effects of media technology on psychological well-being. Media technology complements the well-being affordances of the unmediated physical environment by providing access to activities and information not otherwise available to users. Media technology can also interfere with the sources of well-being through attention costs and replacement/displacement of unmediated happiness-promoting activities. Moderating factors govern the interplay between these complementarity and interferences processes, including how and how much people use media technology and to what extent the concurrent unmediated physical environment affords engagement in happiness-promoting activities.

A Complementarity-Interference (CI) Framework

The focus of this chapter is to explore how and when modern media technology—and the vast array of virtual worlds it provides—impacts well-being. To answer this question, we need to take into account the context in which such technology use occurs. Indeed, media technology use always occurs in the context of the immediate physical environment—and the affordances of that environment for promoting

well-being. The critical question, then, is when media technology use *complements* versus *interferes* with the sources of well-being available in the immediate environment. Adopting this *complementarity-interference framework*, I explore evidence for both complementarity and interference processes, and then explore the factors that determine when technology enhances versus undermines psychological well-being.

Complementarity Processes

Media technology provides access to a theoretically unlimited number of virtual worlds. In contrast, the activities afforded by the immediate unmediated environment are limited by people's physical locale. Generally speaking, then, the quantity of the digital affordances for increasing well-being is greater than the quantity of the unmediated affordances. By providing more options for engaging in happiness-supporting activities, media technology has the potential to contribute to higher well-being.

Source of positive emotions. Perhaps the clearest empirical demonstration to date of how media technology can complement the unmediated environment comes from a study with patients who were undergoing minor surgery under the waist (Guillory, Hancock, Woodruff, & Keilman, 2015). Each patient was randomly assigned to one of four conditions: (a) a control condition in which patients received standard perioperative management, or three experimental conditions in which patients were asked to engage in one of several activities on their phones during the surgery: (b) text messaging with a companion (e.g., a friend, family member), (c) text messaging with a stranger, or (d) playing an engaging mobile phone game. All participants received an initial dose of analgesic (fentanyl); the researchers then recorded whether patients asked for additional analgesic during the surgery, providing an objective measure of physical pain. Compared to patients undergoing the standard procedure with no technology use, patients who were texting with a friend were approximately 4 times less likely to seek supplemental fentanyl during surgery. Interestingly, patients who were texting with a stranger were almost 7 times less likely to ask for more fentanyl compared to standard treatment. People who played a video game were not significantly less likely to ask for more analgesic compared to those under standard procedure.

The findings of Guillory and colleagues (2015) suggest that, above and beyond mere distraction, mediated social interactions can reduce the intensity of negative experiences—even physical pain. But why did texting with strangers have a more pronounced effect than texting with a companion? Linguistic analyses of the text messages showed that while patients who were texting with a friend talked more about the surgery itself, patients who were texting with a stranger were more likely to express positive emotions in their texts. Thus, by affording mediated social interactions that promote the expression of positive emotions, media technology may directly stimulate subjective well-being.

Source of basic need satisfaction. Another mechanism by which the additional affordances provided by media technology can enhance well-being is by serving as a source of basic psychological need satisfaction. A mother travelling out of town for work might not be able to cultivate a sense of connectedness with her children in person, but she can exchange text messages, call, or even video call her children. And while a skier visiting Los Angeles may not be able to cultivate a sense of competence by skiing on the streets of LA, she could do so by playing a skiing game on her smartphone ("there is an app for that"). Although skiing mediated through a screen might not be quite the same as skiing at Lake Tahoe, research shows that mediated activities can and do satisfy basic psychological needs. Playing video games, for example, has been shown to effectively satisfy people's need for competence (e.g., Przybylski, Weinstein, Murayama, Lynch, & Ryan, 2012; Ryan, Rigby, & Przybylski, 2006). Studies have also provided some initial evidence that computer-mediated communication may stimulate teenagers' sense of social connectedness and subjective well-being (e.g., Desjarlais & Willoughby, 2010; Valkenburg & Peter, 2007).

Efficiency and convenience. One of the key benefits—and in fact, a key purpose—of technology is making our lives easier. With the sources of the Internet at our fingertips, we no longer need to go all the way to the library to find popular literature or scholarly work. And with smartphones in our pockets, we can easily find out how to get to even the most obscure of places. Looking for a nearby café to get some work done? No problem, just ask your phone's personal assistant! Wondering where to find the best Italian restaurant in this neighborhood? The answer is only a tap away through a search engine. Indeed, when people were asked to describe what they like most about their phones, the most commonly used word in their responses was their "convenience" (Smith, 2012).

By providing a convenient portal to information, media technology affords instant access to resources not otherwise available in the unmediated environment. With access to a search engine and a GPS map via the Internet, or to one's family and friends via a quick message, people can more efficiently achieve everyday goals and solve everyday problems. Imagine that your car breaks down on the way to an important meeting. There are no taxis or public transit nearby, and you are going to be late unless you find a solution quickly. Rather than feeling helpless, you can use your phone to call a cab or, perhaps, a friend

who lives nearby. To be sure, more than half of US smartphone users report that they have relied on their phones to get help in emergency situations—with 50% having used their phones specifically to deal with car emergencies on the road (Pew Research Center, 2015).

Beyond emergency situations, media technology can help people solve more common daily problems, such as finding directions on the go—whether it is to a restaurant for lunch, a gas station on the road, or a café for a necessary cup of coffee. And by making problem solving more efficient, recent research suggests that media technology may support psychological well-being. In one experimental study, for example, all participants were asked to locate a building on a university campus, and were then randomly assigned either to have access or no access to their phones during the search for the building (Kushlev, Proulx, & Dunn, 2017). Participants who relied on their phones found the building faster, and, after finding it, felt happier than those who could not rely on mediated information. By complementing the affordances of the unmediated environment, therefore, media technology can increase emotional well-being.

Interference Processes

Media technology can sometimes promote well-being by affording access to positive emotional experiences, psychological need satisfaction, and more efficient ways to solve everyday problems. But these same desirable qualities of media technology could also compromise psychological well-being by leading people to disengage from the affordances of the unmediated environment shown to promote well-being. Put simply, engagement with a mediated environment often entails disengagement from the unmediated environment—and the benefits it affords (e.g., Przybylski & Weinstein, 2013). Yet, the unmediated environment is inextricably linked with human flourishing and well-being (e.g., Cacioppo et al., 2006; Lyubomirsky & Boehm, 2010; Myers & Diener, 1995; Nelson, Kushlev, & Lyubomirsky, 2014; Reis, Sheldon, Gable, Roscoe, & Ryan, 2000). I next explore several key mechanisms of interference.

Concurrent attention costs. People have limited cognitive capacities (Navon & Gopher, 1979), and performing multiple tasks at once can lead to limiting the cognitive resources dedicated to each task. When two tasks require the same cognitive resource, such as attention or working memory, people cannot perform these tasks simultaneously and must instead switch between tasks (Garavan, 1998; Liefooghe, Barrouillet, Vandierendonck, & Camos, 2008; Oberauer, 2003; Pashler, 1998). The very act of switching between tasks also requires deployment of attention and working memory, further taxing people's limited cognitive resources (Liefooghe et al., 2008). Thus, the multitasking afforded by media technology likely reduces attention, working memory, and other cognitive resources people can dedicate to the unmediated environment. At the same time, research shows that distraction is one of the strongest predictors of lower positive affect during positive events—more so than psychological tendencies, such as finding faults with events and even directly suppressing positive emotions (Quoidbach, Berry, Hansenne, & Mikolajczak, 2010).

Although the human cognitive limitations described above apply to any media technology—from books and newspapers to TV's and social media—it is smartphones that have truly extended the realm of technological distraction beyond our homes and into virtually everything else people do. It is hardly surprising, then, that about half of Americans admit that their phones have made it harder to give others their undivided attention (Smith, 2012). Indeed, research confirms that mobile phone use can dramatically reduce people's ability to pay attention to their immediate environment (e.g., Drews, Yazdani, Godfrey, Cooper, & Strayer, 2010; Strayer & Drews, 2007). In a particularly notable study, for example, people who were talking on a cell phone while walking were less likely to see a street entertainer—a unicycling clown—than people not using electronics (Hyman, Boss, Wise, McKenzie, & Caggiano, 2009).

To date, little direct evidence exists on how the documented attention costs of media technology might be impacting psychological well-being. In one of the few existing studies to test the role of attention costs, participants were assigned to spend one week maximizing phone interruptions by keeping notification alerts on and their phones within their reach/sight. During another week, the same participants were assigned to minimize phone interruptions by keeping alerts off and their phones away from easy reach as much as possible. Participants reported higher levels of inattention when alerts were on than when alerts were off. Higher levels of inattention in turn predicted lower psychological well-being (Kushlev, Proulx, & Dunn, 2016).

Delayed attention costs. In addition to compromising attention during other activities, media technology may be changing people's ability to pay and sustain attention at a later time. Children's television viewing habits, for example, have been linked to subsequent attentional problems (e.g., Christakis, Zimmerman, DiGiuseppe, & McCarty, 2004; Johnson, Cohen, Kasen, & Brook, 2007). And playing video games might be an even bigger culprit in causing downstream attentional problems in children. In a US longitudinal study of 6 to 12-year-old children, researchers assessed television viewing and game playing as reported by both the children and their parents (Swing, Gentile, Anderson, & Walsh,

2010). To assess attentional problems, the researchers obtained school teachers' reports of difficulties with paying and maintaining attention, as well as of children's tendency to interrupt others in class. After controlling for existing attentional problems in this longitudinal study, the researchers found that television viewing and playing video games both predicted more attentional problems, but that video games were a stronger predictor.

Media technology use has also been linked to negative academic outcomes in university students with downstream consequences for subjective well-being. In one study, students who used their mobile phone more had lower GPAs, while also experiencing greater anxiety (Lepp, Barkley, & Karpinski, 2014, 2015) —even after controlling for high-school GPA, as well as demographics, addictive behavior, and relevant personality traits. Though phone use was not directly related to life satisfaction, path analyses indicated that phone use is indirectly related to lower satisfaction with life through lower academic performance and higher anxiety directly associated with phone use. Of course, these correlational findings cannot establish causality, underscoring the need for future research using, for example, longitudinal methodology.

One way in which media screen time might be resulting in such downstream attentional and performance issues might be through the effect of screen time on sleep. The light emitted from a screen has been shown to interfere with circadian rhythms and quality of sleep. Researchers have found, for example, that looking at a screen before bed reduces melatonin—a neurotransmitter critical for regulating circadian rhythms (Higuchi, Motohashi, Liu, Ahara, & Kaneko, 2003). Another possible, yet unexplored, mechanism could be found in a more basic characteristic of media: Media experiences are not limited by the same parameters that constrain experiences in the unmediated, physical environment. A scrawny kid might not excel in the school gym, but he can easily become an incredibly strong and agile fighter in the game Street Fighter or become a superhero in the elaborate universe of the World of Warcraft—a massively multiplayer online role-playing game, or MMORPG. But after the rush of playing such video games, this same kid might find it hard to focus on the much less exciting content of his biology textbook.

Clearly, future research is needed to explore these and other possible mechanisms through which media technology consumers develop attentional problems. In addition, future experimental and longitudinal research needs to explore the multiple pathways through which such attentional costs might impact well-being—from directly interfering with engagement in activities associated with greater emotional well-being (e.g., face-to-face social interactions) to having downstream consequences for life satisfaction in the long-term by compromising learning, performance, and achievement.

Substitution. Media technology can tax attention, thus reducing engagement with potential sources of well-being concurrently available in the unmediated environment. But media technology can also completely replace or obviate engagement with the unmediated environment. Thus, people may incur indirect emotional costs of using media technology by foregoing the benefits of happiness-supporting activities available in the unmediated environment. Playing with other children at the playground can be replaced by playing with other gamers while sitting in front of a computer (e.g., Attewell, Suazo-Garcia, & Battle, 2003). Getting a full night's sleep can be replaced by a late television show (Higuchi et al., 2003; Oka, Suzuki, & Inoue, 2008). And getting directions from a friendly local has all but been forgotten since smartphones made it so convenient to get directions on our phones (Kushlev et al., 2017).

Replacing unmediated social activities. Of all the activities that using media technology could replace, the replacement of unmediated social behavior (e.g., social events, face-to-face social interactions) is perhaps the most relevant to well-being. Interestingly, research suggests that media technology is particularly likely to replace interactions with weak social ties (e.g., acquaintances, strangers) rather than interactions with strong social ties (e.g., friends, family). Putnam, for example, famously showed that participation in community bowling leagues decreased as television sets became a staple in Americans' homes in the second half of the 20th century (Putnam, 1995). Importantly, he showed that this effect was specific to participating in bowling leagues, rather than to bowling activity in general. Thus, even as TV watching became more popular, people continued to play bowling with their families and friends, but not with members of the broader community. Putnam thus argued that television might be replacing community involvement, with negative consequences for social capital such as eroding sense of community and trust. Consistent with Putnam's theorizing, recent research shows that portable media technology could also be eroding trust. Specifically, in an American sample from the World Values Survey, people who used their mobile phones more to obtain information were less likely to trust strangers and neighbors (Kushlev & Proulx, 2016).

Due to the advent of mobile computing, people can now take their media-producing screens anywhere they go, thus potentially replacing, and even obviating a much broader array of social behaviors than more stationary media technology, such as TV or computers. Why interact with our classmates or colleagues before class or meeting when we can catch up on our social media feed? And why try to spark a

conversation with a stranger on public transit, when we can safely entertain ourselves on our phones? Yet, social interactions—even those with mere strangers—are an important source of social and emotional well-being. In one study, for example, coffee shop customers were randomly assigned to either have a friendly interaction with the barista while getting their coffee or to have an efficient interaction by minimizing conversation. The friendly customers subsequently felt a greater sense of belonging than the efficient customers. In other words, having a friendly interaction with a stranger helped people to satisfy their basic need for relatedness (Sandstrom & Dunn, 2014).

Emerging evidence suggests that screen time spent on new media might indeed be replacing in-person social interactions, with consequences for psychological well-being. In one experience sampling study, researchers tracked how people felt several times a day for two weeks. They found that the more people used Facebook earlier in the day, the less happy they felt later in the day, even when controlling for earlier affect (Kross et al., 2013). Furthermore, the more people used Facebook, the less they interacted with others in person. Importantly, controlling for the frequency of in-person interactions—which predicted higher well-being—attenuated the negative relationship between Facebook use and emotional well-being. These findings suggest that Facebook use might be linked to lower well-being (for a review, see Wilson et al., 2012) at least in part because social media use replaces face-to-face social interactions.

In addition to providing alternative social activities such as Facebook, smartphones are an incredibly powerful source of information. While undoubtedly convenient, this ease of information access can obviate the need to rely on fellow humans for information, leading people to forgo opportunities to cultivate a sense of community, social connectedness, and trust. In an experimental study I described earlier, people were asked to locate a building, and then randomly assigned either to rely or not to rely on their phones. Participants relying on their phones talked to fewer people to obtain directions and ended up feeling less socially connected than participants who relied on the kindness of others (Kushlev et al., 2017). These findings suggest that portable media technology can reduce sense of community, connectedness, and trust by replacing unmediated, face-to-face social interactions—a key source of social capital.

Displacing sleep time. In addition to replacing activities that satisfy basic psychological needs, media technology might be displacing activities that satisfy basic physiological needs. In a 10-day experience sampling study of working adults, researchers measured late-night technology use (i.e., after 9 pm), including watching TV, and using a computer, a tablet, and a smartphone specifically for work (Lanaj, Johnson, & Barnes, 2014). The researchers found that each type of technology use had independent, within-subjects effects on sleep quantity—even when controlling for the previous night's sleep quantity and quality. Put simply, people slept less on evenings when they used media technology more. Notably, even though people spent ten times fewer minutes using their smartphones than watching TV—4 min versus 40 min—smartphone use explained twice as much of the variance in sleep quantity (4% vs. 2%).

Exploring the link between phone use and sleep further, Lanaj and colleagues (2014) found that by displacing sleep, phones had downstream consequences for how psychologically depleted people felt in the morning: To the extent that phones interfered with sleep, people felt more drained and unable to concentrate in the morning. Morning depletion in turn predicted lower work engagement (e.g., feeling completely absorbed in a work task) as measured by the Utrecht Work Engagement Scale. Though Lanaj and her colleagues did not measure well-being, robust evidence exists that work engagement is associated with psychological need satisfaction (e.g., competence, autonomy) and, consequently, with subjective well-being (e.g., Deci et al., 2001; Harter, Schmidt, & Hayes, 2002). Future research is needed to clearly establish the relationship between media use and well-being as mediated by sleep, depletion, and work engagement.

Interplay Between Complementarity and Interference Processes: The Moderators

I have so far considered some key mechanisms through which media technology might complement or interfere with people's "default" source of psychological well-being: the unmediated physical environment. But, of course, the more interesting theoretical question is under what conditions the benefits of media technology outweigh its costs—and vice versa. Unfortunately, there is little research directly exploring these moderating variables. Yet, given that the literature abounds with both positive and negative findings about the effects of media technology on well-being, understanding the critical moderators between complementarity and interference processes is perhaps the most important avenue for future theoretical and empirical work. Accordingly, using the proposed CI framework, I next explore some of the key possible moderators.

At the broadest level, the net effects of media technology on well-being in any given period should depend on: (1) the nature of the media activities, that is what media technology people are using and how they are using it; (2) the quantity of media activities, that is how much people are using media technology; and (3) the well-being affordances within the unmediated environment, that is what opportunity costs people are incurring when using media technology.

Quality: Active versus passive use. Research has suggested that complementarity processes of media technology use are potentiated when people use media actively rather than passively. Direct evidence for the role of active versus passive use as a moderating factor comes from research on social media. Compared to people who use Facebook passively by browsing through others' content, people who use Facebook actively by sharing content with others experience greater social capital and feel less lonely (Burke, Marlow, & Lento, 2010). Active media use thus seems to be a more effective way of satisfying basic psychological needs than passive use.

Quality: Relevance to the unmediated environment. I identified attention costs as one of the key mechanisms through which media behavior interferes with the benefits of unmediated activities. But people frequently use media technology in ways that directly support their unmediated activities. In a representative poll, for example, seven in ten Americans reported having used their phones for purposes directly related to their face-to-face social interactions (Rainie & Zickuhr, 2015).

In situations in which people use media technology to directly support their unmediated activities, the interference process through attentional costs should not apply. Thus, for example, looking at one's phone to find pictures or a video to share with one's dinner companions may result in net benefits to emotional well-being, whereas checking work email might produce net loss for emotional well-being. And while staying at home alone on Sunday to binge watch movies online on Netflix might lead people to forgo the benefits of socializing with friends or family, gathering with friends to socialize and eat Nachos while watching the Super Bowl might lead to greater benefits to well-being than would socializing (and eating Nachos) alone, that is without the stimulating effect of the spectacle.

Only initial evidence exists to show that relevance of media use to concurrent unmediated activities can determine well-being outcomes. In the only such study to-date, parents spending time with their children at a museum were randomly assigned to use their phones a lot or to limit their phone use. Overall, parents assigned to use their phones frequently—compared to those assigned to limit phone use—felt less socially connected while spending time with their children. This overall negative effect on social connectedness was mediated by the negative effect of phone use on attention. Further, the effect of phone use on social connectedness held regardless of whether parents used their phones for social purposes (e.g., text messaging, social media) or work purposes (e.g., email). Thus, any type of phone use that was not directly relevant to parents' experiences with their children at the museum predicted lower social need satisfaction. Notably, however, parents who used their phones specifically to obtain relevant information about the exhibits (e.g., by using the museum's app for information about the exhibits) felt a greater sense of connection (Kushlev, 2015). In other words, relevant phone use predicted higher social need satisfaction. While illuminating, this evidence is correlational and exploratory, underscoring the need for future experimental work to directly manipulate the relevance of media technology use to the unmediated environment.

Quantity. In addition to *how* people use media technology, the effects of media technology on well-being should depend on *how much* people use this technology in any given period of time. Of course, the excessive use of the media technology should be particularly likely to interfere with other behaviors that can satisfy psychological needs. While even 4 minutes of phone use for work before bed predicts less time sleeping at night (Lanaj et al., 2014), excessive phone use has been linked to complete inability to sleep (Tavolacci, Meyrignac, Richard, Dechelotte, & Ladner, 2015). More broadly, spending excessive time online has been linked to dramatic outcomes, such as job loss, marriage breakdown, and academic failure (Whang, Lee, & Chang, 2003). In some cases, the consequences can even be fatal—literally. An 18-year-old Taiwanese teenager died after a 40-hour marathon of playing an online video game. A Korean couple spent so much time raising their virtual daughter in an online game that they neglected their own biological daughter; the daughter (the real one) eventually died (Wallace, 2014). And a British man who regularly played for 12 hours at a time developed a blood clot and died from pulmonary aneurism; he was only 20 years old at the time. On the opposite side of the spectrum, however, some media technology use should theoretically be beneficial to well-being (see Figure 1). Even though excessive video gaming can be detrimental to well-being—and even deadly—some video game playing can also satisfy basic psychological needs (Przybylski et al., 2012; Ryan et al., 2006). This suggests that the relationship between media technology use and psychological well-being may be characterized by a reverse U-shaped function.

Curvilinearity. Researchers have discovered that time spent watching television is curvilinearly related to life satisfaction: Some TV watching predicts greater life satisfaction than both excessive TV watching or no TV watching at all (e.g., Jegen & Frey, 2004). In the domain of video games, a study with 444 Iranian adolescents found that those who spent some time playing video games had better mental health than both non-gamers and excessive gamers (i.e., those who played more than 10 hours a week; Allahverdipour, Bazargan, Farhadinasab, & Moeini, 2010). Similarly, in the realm of social media, studies have suggested that the number of Facebook friends has an inverse U-shaped relationship with subjective

well-being (e.g., Kim & Lee, 2011). And even though multiple studies have found a negative relationship between Facebook use and subjective well-being (Wilson et al., 2012), recent research has suggested that Facebook users are happier and more satisfied with their lives than Facebook nonusers (Brailovskaia, & Margraf, 2016).

Despite this consistent evidence for curvilinearity, future research is needed to provide more nuanced understanding of the curvilinear relationship between media technology use and psychological well-being. In the domain of social media, for example, research could explore whether the documented curvilinear relationship between Facebook use and well-being is driven primarily by passive users, or whether active Facebook users can also get too much. In the context of video games, research is needed to illuminate whether some video games are characterized by stronger curvilinear relationships with well-being than others, as well as whether people are more likely to play some video games more excessively than others. It is possible, for example, that video games with a strong social component—such as MMORPGs, where players can play in online guilds, teaming up with other players in virtual quests—might be particularly beneficial for well-being by satisfying social needs. But such games might also be more likely to result in excessive use, thus compromising well-being.

Research is yet to explore curvilinearity in the relationship between smartphone use and well-being. In examining curvilinearity in the case of smartphones, researchers might be well advised to focus on frequency of use and number of notifications in addition to the total time spent on phones. In one study, for example, phone notifications alone significantly disrupted performance on an attention-demanding task, even though participants did not directly interact with a mobile device during the task (Stothart, Mitchum, & Yehnert, 2015). The magnitude of observed effects on attention was comparable in magnitude to those seen when users actively used a mobile phone (e.g., calling, texting). In other words, even though people spent no time using their phones, they still incurred attention costs simply as a result of receiving notifications.

Affordances of the unmediated environment. According to the CI model, key factors that should determine whether media technology would have a net positive or a net negative effect on psychological well-being should be the quantity and the quality of happiness-promoting activities afforded by the unmediated environment. Indeed, evidence suggests that even though media technology use has opportunity costs for well-being in the context of environments rich in actual and potential social partners (e.g., Przybylski & Weinstein, 2013), media technology can be beneficial to well-being in more impoverished social environments, such as when undergoing minor surgery (Guillory et al., 2015). And, as we saw earlier, smartphone use has been shown to reduce parental well-being *during* a time when parents were spending time with their children at a science museum (Kushlev, 2015). But would phone use have enhanced parental well-being if the study were run not in the stimulating environment of a museum, but rather in an impoverished environment such as while waiting to pick up one's child from school? To date, no research has explored the affordances of the unmediated environment as a moderating factor in the well-being effects of media use, highlighting a fruitful area for future research.

Political, economic, and societal factors. In addition to the affordances of the immediate unmediated environment, the broader context of one's political, economic, and societal milieu is likely both important and understudied moderating factors of media use. I have so far examined a range of psychological mechanisms in depth, largely ignoring the effects of media technology on broader political, economic, and societal factors that also have implications for well-being. Thus, for example, social media and mobile Internet access have allowed an unprecedented ability of groups of people—particularly those in developing or undemocratic countries—to quickly and easily organize and congregate to achieve desired political and social changes. Indeed, three quarters of the people surveyed in India, China, Indonesia, and South Africa agreed that wireless mobile technology has given citizens a greater voice in their country; in the U.S. and the U.K., less than half think so (Qualcomm, 2013). And during the Arab Spring, for example, social media was credited as a critical factor in the successful overthrowing of current regimes in countries like Egypt and Tunisia (Howard et al., 2011). Presumably, the use of media in such critical historical and political contexts fosters social interaction, builds social capital, and could produce happiness boosts that dwarf any costs.

In addition to allowing the organizing of grassroots movements for political change, access to media technology can produce economic benefits for users, particularly in poor and developing countries. For example, small scale framers—who produce up to 80% of the food in developing countries—often sell their produce for much less than market value because they cannot afford to travel by themselves to the city markets. But a mobile phone platform is allowing small-scale farmers in Kenya to easily communicate with each other, organize transportation to the city markets, and thus sell their produce to consumers for up to four times as much profit as before (Al Jazeera, 2014). This economic benefit of technology goes beyond small-scale farming: About three quarters of people in India, China, Indonesia, and South Africa, for

example, agree that wireless mobile technology has been instrumental in finding the highest price for something they want to sell (Qualcomm, 2013).

Finally, the broader societal benefits of having easy access to the Internet through mobile media technology cannot be overstated. Across the developed world, smartphones are being used to provide real-time sharing of information between physicians and patients, thus helping to improve healthcare (World Health Organization, 2011). Like the positive political and economic effects of mobile media technology, however, these effects are more pronounced in developing countries. For example, 9 out of 10 people in China and Indonesia think that mobile technology has made it easier for them to access information to maintain their own and their family's health; in the U.S., only about half think so (Qualcomm, 2013).

In short, the use of media technology in Western, educated, industrialized, rich, and developed—or WEIRD (Henrich, Heine, & Norenzayan, 2010)—countries might have very different effects on well-being from the effects this same technology has in the rest of the world. Just as with most other topics in psychological science, however, research outside WEIRD countries is badly needed.

Future Directions

Theoretical issues. Throughout this chapter, I have been highlighting gaps in the literature, charting important directions for future research. Specifically, guided by CI framework, I have highlighted the lack of evidence for some of the critical mediating and moderating factors in the relationship between media technology and psychological well-being. Mediating factors that need further evidence include, for example, the long-term effects of media technology's attention costs on well-being. Moderating factors that need further research include the relevance of media technology use for unmediated activities, the quality and quantity of the well-being affordances of the unmediated environment, the role of how much and how frequently people are using media technology, and the broader economic and political conditions.

While highlighting these critical areas for future research, it is worth noting that all processes and conditions outlined here can benefit from replication and additional evidence. Indeed, my broader goal in integrating existing evidence in an initial theoretical model has been to stimulate more theoretically-driven future research that could shed light on the critical factors at play. It is worth noting, however, that I view the CI model proposed here only as a blueprint to be improved and refined in the future. Thus, for example, future empirical and theoretical work can reveal other mediating and moderating factors to be added to the model. Future theorizing and research could also increase the complexity of the model by considering how the various processes and conditions interact with each other. Thus, for example, researchers can consider additive and subtractive effects of the various mediating processes, or explore how some of the moderating conditions might interact with one another.

My hope is that by sowing the seeds of a theoretical model, researchers working across disciplines will be able join forces to understand the key factors in the relationship between media technology and well-being. Thus, when new media technologies become an integral part of people's lives in the future—as print media, television, gaming, and mobile computing have done in the past—researchers will be able to launch a focused, theoretically-grounded research program to understand how these new media technologies are similar to—and how they are different from—existing technologies.

Methodological issues. At the methodological level, this review has revealed that even after many decades of research, causal evidence for key factors and outcomes is often lacking. This is no doubt in part due to the challenges of exploring causality when studying the effects of human behavior as it occurs naturally "in the wild". One such challenge is manipulating natural behavior by asking people to use their media technology differently. Such field manipulations can be both practically and ethically problematic. Because media use plays such an integral part in people's daily lives, it could be practically difficult to recruit samples willing to substantially reduce their media use, and even more difficult to make people follow such experimental instructions. On the flip side, asking people to increase their media technology use could be ethically problematic given the existing research on the detrimental—and in some cases fatal—effects of excessive use.

Such legitimate ethical issues can be minimized by reducing the duration of the study—thus minimizing any lasting effects on well-being or health—and by carefully choosing experimental situations in which increased use of media technology is unlikely to produce any serious harm. For example, while it might be ethically and practically unproblematic to study parents as they spend an afternoon with their children in the safe, enclosed environment of a science museum, asking parents to maximize their phone use for an entire week can be ethically problematic (e.g., because it can reduce necessary supervision of children in more hectic and potentially dangerous environments, such as a busy street intersection).

When experimental work is impractical or unethical, researchers should employ alternative methodologies that can give suggestive causal evidence. Some of the research reviewed in this chapter

illustrated the benefits of longitudinal research (e.g., Swing et al., 2010) and experience sampling, or ESM (e.g., Lanaj et al., 2014). These methods can isolate causality by allowing controls for previous media behavior and well-being, while also allowing disambiguation of within and between-subject effects, thus controlling for any individual differences. Of course, only multi-method research program can provide clear evidence for the key factors at play.

Coda

In 1889, the *British Medical Journal* warned readers of "aural overpressure"—a new malady due to "almost constant strain of the auditory apparatus" in people who used telephones for long periods of time. Symptoms of the condition apparently included nervousness, buzzing in the ears, giddiness, and neuralgic pains (Marvin, 1988). More than a century later, and with a lot more phones around us, we seem to be all but free of this supposed malady. This example highlights the fact that new technologies have always generated concerns about the effect they may have on people's subjective well-being (e.g., Turkle, 2011). Far from endorsing unbridled concerns about the perils of media technology on well-being, I have begun to identify the processes and conditions (Figure 1) that determine how and when media technology use could boost or hurt psychological well-being. It is my hope the theoretical model proposed here would stir further theory development and necessary empirical research in order to understand the costs and benefits of the media technology of today and of the future.

Abstract

Diener (2000) proposed that indicators of subjective well-being should complement existing economic and social indicators that reflect the quality of life in nations. In this chapter, we review the reasons for including indicators of subjective well-being in national accounts, describe the policies that subjective well-being measures could influence, and summarize the progress nations have made in implementing national accounts of well-being. We also describe the characteristics of nations that are high in subjective well-being and respond to some common objections towards implementing indicators of subjective well-being in national accounts.

Policy-makers in government and business often guide their decisions by economic and social indicators. These indices are often referred to as national accounts because the indices are often collected using large-scale surveys from nationally representative samples and are thus often considered to accurately represent the nation as a whole (Smith & Mackie, 2015). Nations first started collecting official statistics on their economy, monitoring economic indicators related to the production, income, labor, and market expenditure of the nation. As nations grew wealthier, national accounts also started to include non-economic indicators that monitor physical well-being. Recently, spurred by increasing interest in subjective well-being among researchers, public policy makers, and the general public, national statistical offices have also begun collecting statistics on subjective well-being. Given the increasing prominence of national accounts of well-being, this paper attempts to summarize the types of policies that may be beneficial for subjective well-being, and review the initiatives various countries and organizations implemented to measure the subjective well-being of their constituents.

What is Subjective Well-Being?

Subjective well-being (SWB) is defined as an individual's global evaluation across different aspects of life (Diener, 1984). SWB is often colloquially described as "happiness". However, scientists avoid the term "happiness" in the scientific literature because happiness is a term that encompasses various concepts. Happiness can represent a specific emotion that people feel in response to various life experiences (e.g., I am feeling happy), but happiness can also describe a broad judgment of a person's life (e.g., I have a happy life). Instead, we examine subjective well-being – the extent to which an individual believes that their life is going well.

Subjective well-being consists of two major dimensions – affect and life satisfaction (Diener, 1984). Affect is the term used by psychologists to describe a person's feelings and emotions and comprises of both positive and negative affect. Positive affect includes emotions like happiness, contentment, and joy, while negative affect includes emotions like sadness, anger and fear. Crucially, a person high in SWB often reports experiencing frequent positive affect and less frequent negative affect. On the other hand, life satisfaction involves a person's cognitive appraisal of his or her life. These appraisals could include either be broadly (global life satisfaction measures) or narrowly (satisfaction with specific life domains) defined. However, regardless of the scope of the appraisal, a person high in SWB often reports being satisfied with his or her life.

Reasons for Including Subjective Well-Being in National Accounts

Given that governments and businesses already compile social and economic indicators to track the well-being of their constituents, some critics question the need to include measures of subjective well-being in national accounts. In this section, we briefly review several important reasons for including SWB in national accounts of well-being.

People Believe SWB is Very Important

The strong emphasis on the importance of SWB could be observed throughout history. Aristotle

considered eudaimonia, which was often translated as happiness, as the final and sufficient goal for mankind (Aristotle, 1985), while utilitarians like John Stuart Mill and Jeremy Bentham focused their theories around achieving and maximizing subjective well-being (Mill, 1863).

Besides the deep philosophical roots of subjective well-being, lay persons too place great importance on SWB. For example, we would hardly rate a person who is depressed and dissatisfied with his or her life as a successful person, regardless of the person's economic or social status. The importance we place on SWB could also be inferred from our responses to Mill's classic rhetorical question asking whether it is better to be a dissatisfied human or a satisfied pig. Although the correct choice may not be evident to us, it is clear that most of us would prefer to be a satisfied human rather than an unsatisfied one, and a satisfied pig than an unsatisfied one (Diener, Lucas, Schimmack, & Helliwell, 2009).

The importance lay persons place on SWB was also demonstrated empirically. King and Napa (1998) found that happy people are judged more positively than unhappy people to the extent that happy people are thought to be more likely to ascend to heaven after they die. In addition, college students in 41 nations rated life satisfaction and happiness as extremely important concepts, with an average rating of 6.21 and 6.39 (out of 7) for life satisfaction and happiness respectively (Diener, Sapyta, & Suh, 1998). Crucially, the importance of SWB was reflected not only by Western, industrialized nations but also by less economically developed nations. For example, happiness was rated 6.63 in Indonesia, 6.62 in Brazil, and 6.27 in Ghana. Although subjective well-being may not be the most important value for everyone, it is likely to be a value that almost everyone, lay persons, and philosophers alike, endorses. Since governments in modern democracies are instituted to serve the interests of the populace they govern, governments should thus consider implementing SWB measures in their national accounts.

Current Indicators are Incomplete and Insufficient

Economically developed nations typically monitor quality of life in their societies using both social and economic indicators (Smith & Mackie, 2015). Both measures provide important information about how nations are functioning. However, both types of indicators each have their limitations that can often be addressed by incorporating measures of subjective well-being in national accounts (Diener, Oishi, & Lucas, 2015).

Social indicators often provide relevant information for policy making. These indicators evaluate diverse areas ranging from health outcomes (e.g., obesity rates), education outcomes (e.g., percentage of college graduates), to environmental outcomes (e.g., PM2.5 levels). Governments track social indicators because these indicators were presumed to reflect characteristics of a good society. By tracking these indicators, nations and organizations should then be able to monitor these attributes and enact policies to address insufficiencies in certain areas.

Unfortunately, there is no obvious method to identify characteristics of a good society (Diener et al., 2009). Governments and organizations thus often rely on experts to identify these characteristics, which represent the first limitation of social indicators – that there is often no consensus, even among experts, on the indicators to be included (or excluded). For example, number of hobbies is included in the Living Conditions Index of the Netherlands (Boelhouwer & Stoop, 1999), but is its inclusion justified? What about people who do not have hobbies? Is it justifiable to infer that people without hobbies are not satisfied with their lives? What if people do not have hobbies because they are spending their time on other meaningful activities (e.g., taking care of their children, volunteering with charities)? Although there are certain items that almost everyone would agree should be included as social indicators of well-being, the number of such items is relatively small compared to the number of possible items that could be used as social indicators of well-being. If experts cannot agree on the indicators to be included, then it is highly likely that the social indicators selected to predict the well-being of a society are incomplete.

Even if we manage to accurately identify the characteristics of a good society, the use of social indicators as predictors of well-being still face another limitation: How do we integrate the information obtained? Few would argue that every indicator is equally important. For example, Maslow (1954) would argue that the indicators relating to our physical needs (need for food and water) are more important than the indicators relating to our need for safety (need for safe shelter) and thus should be weighed heavier. However, beyond this basic rule, coming to an agreement on the importance of other indicators will be difficult. As the list of indicators increases, the difficulty of weighing the indicators will also increase exponentially, making an already difficult task almost impossible (Diener et al., 2009). For example, Becker, Denby, McGill, and Wilks (1987) examined the quality of life in 329 metropolitan areas and found that 59 of the 329 regions could be ranked anywhere from first to last depending on how the indicators that make up the overall quality of life index are weighed. Thus, a metropolitan area's quality of life rating could differ drastically depending on a person's weighting of the indicators. Similarly, a nation's index of well-being could also differ drastically, depending on the weights we assign to each indicator. If so, then

how can we be certain that the index of well-being is accurate and complete?

There is no doubt that social indicators provide useful information, but they also have limitations (see Diener et al., 2009 for a review). Social indicators reflect the values of the people compiling the list. In addition, it is often difficult to integrate and weigh the indicators objectively. Due to these limitations, indicators of subjective well-being such as life satisfaction are needed to complement social indicators to provide a more complete understanding of quality of life. Since subjective well-being indicators are often broad assessments of a person well-being, these indicators do not rely on the identification of a list of characteristics. In addition, subjective well-being indicators could provide a common metric that can be used to compare outcomes across domains. For example, a government might face trades-off when deciding whether to boost healthcare spending or to devote more resources to improve the environment. Although subjective well-being indicators cannot provide absolute answers, they can provide information about the relative effect of improvements in each domain, allowing the government to compare the two policy decisions.

Besides social indicators, nations also invest considerable resources to generate and monitor economic indicators. These indicators often measure a nation's labor and trade productivity with the assumption that a nation with strong economic performance is also a nation that is flourishing. Some common economic indicators include the Gross Domestic Product (GDP), inflation rates, unemployment rate, and tax rates.

Needless to say, economic indicators are important to societies. Since industrialization, governments have relied and continue to rely primarily on the information derived from economic indicators to inform their policies. However, economic indicators also suffer from a number of important limitations. Similar to social indicators, there is a concern about what economic indicators are to be included, and how to integrate the information derived from economic indicators. Furthermore, governments and organizations should recognize that economic indicators often have large blind spots, often omitting other aspects of life that are important to well-being (Diener & Seligman, 2004). For example, GDP is used as a measure of material well-being of a society because it is supposed to reflect the total goods and services produced and consumed in a society. However, GDP often underestimates the levels of well-being in a society because there often are other activities that may have economic value, but are still not included in GDP. Work (e.g., laundry, cooking), as well as child care that occurs in the home, are not included in GDP although such work contributes significantly to GDP when they are purchased as part of a service outside the home (Diener et al., 2009; Diener & Seligman, 2004).

Other than blind spots, economic indicators often inform policy makers that something is wrong, but they often do not reveal what is driving the problem (Diener, Kesebir, & Lucas, 2008). For example, economic indicators could inform policy makers on the number of lost workdays, or the productivity of the economy. However, economic indicators alone will not explain why workers are taking more days off. Workers may be taking more days off due to mental illnesses, physical illnesses, or even because they are working in a miserable environment. Without additional information, it will be tough for policy makers to identify and remedy the root cause.

Economic indicators are useful but do not provide governments and organizations with complete information. Economic indicators often do not value non-market goods and services, and often do not reveal the true cause of a problem. As a result, indicators of subjective well-being could complement economic indicators by addressing the insufficiencies of economic indicators. For example, subjective well-being measures could be used to help policy makers value the externalities incurred by economic activity (Diener et al., 2009). Negative externalities like air pollution could be measured by the decrease in SWB of the citizens within the area affected by air pollution, which in turn can help inform cost-benefit analyses involving the activity that led to the air pollution. Obviously, much more work is needed to evaluate the validity and effectiveness of such a method. Nonetheless, the example demonstrates how policy makers could derive concrete values using indicators of SWB.

Subjective Well-being is Beneficial

Besides being a very important value to most people, research conducted in the past decade demonstrates that subjective well-being is also associated with several positive outcomes at both the individual and societal level (Diener & Chan, 2011). People high in SWB are often healthier, more successful, and have better social relationships (De Neve, Diener, Tay, & Xuereb, 2013; Lyubomirsky, King, & Diener, 2005).

Pressman and Cohen (2005) wrote a comprehensive review of the beneficial effects of positive affect on health. In addition, several longitudinal and experimental studies demonstrated the beneficial effects of SWB on health. For example, Danner, Snowdon, and Friesen (2001) examined the diary entries of Catholic sisters written at age 22 and found that sisters who used more positive emotional words in their

entries were more likely to live longer six decades later. A study examining a representative sample of older people living in England also found that people who report enjoying life more frequent lived longer, even after controlling for several health-related factors (Zaninotto, Wardle, & Steptoe, 2016). In addition, participants who were experimentally infected with the cold virus, and who reported experiencing high levels of positive affect were less likely to fall sick and even recovered faster compared to people who reported experiencing low levels of positive affect (Cohen, Doyle, Turner, Alper, & Skoner, 2003). A separate study also found that inducing a positive mood after a stressful experience led to a faster recovery of the cardiovascular system (Fredrickson & Levenson, 1998).

People high in SWB also tend to be more successful than their peers. Dotson and Allenby (2010) found that bank employees with higher job satisfaction produced more revenue on average, while customer service representatives in a bad mood completed fewer calls per hour (Rothbard & Wilk, 2011). Individuals higher in SWB were more likely to be re-employed after unemployment (Krause, 2013), and positive moods were also associated with better performance for both sales managers and subordinates in customer service (George, 1995). In addition, people high in SWB are more likely to earn higher incomes, more likely to secure a job, and report higher job satisfaction (Diener, Nickerson, Lucas, & Sandvik, 2002). People high in SWB are also beneficial to organizations, although the benefits of SWB on organizational performances are often small (Tenney, Poole, & Diener, 2016). Companies with higher employee satisfaction had higher rises in share prices (Edmans, 2011) while manufacturing plants with higher employee job satisfaction were more also productive (Böckerman & Ilmakunnas, 2012).

People high in SWB are not only more likely to be more successful than their peers; they are also more likely to have better social relationships than people low in SWB. A longitudinal study found that children who report low life satisfaction were more likely to be victimized later in life, and were less likely to be prosocial (Martin, Huebner, & Valois, 2008), while adolescents who reported high positive affect had fewer relationship conflicts ten years later (Kansky, Allen, & Diener, 2016). People high in SWB were also more likely to get married, remain married, and to report high marital satisfaction (Harker & Keltner, 2001; Lucas, Clark, Georgellis, & Diener, 2004). In addition, Cunningham (1988) found that inducing a positive mood led participants to become more talkative and more self-disclosing, while children induced with positive moods also displayed better social skills and higher self-confidence (Kazdin, Esveldt-Dawson, & Matson, 1982).

The bulk of the research has demonstrated that individuals high in SWB function better in various domains from health, to social relationships. Given the benefits of SWB on individuals and societies, subjective well-being is therefore not only a private affair involving the individual but should also be a public affair because it is in the best interests of governments and organizations to ensure that their constituents are doing well.

Indicators of Subjective Well-being are Easy and Inexpensive to Implement

National statistics are often computed by government statistical agencies. As a result, national statistics often contain higher quality information since only governments and big organizations like Gallup could devote the resources needed to ensure large and representative sample sizes, high response rates, and the ability to collect the data over a long period of time. For example, in 2012, the Gallup opinion surveys cost the company $10 million a year and generates little to no revenue (Boudway, 2012). At the national level, the 2010 Census in the United States cost taxpayers $13 billion (The Economist, 2011), while the 2011 Census in Australia cost the nation $440 million (Australian Bureau of Statistics, 2011). Obviously, a lot of resources has been and continues to be devoted to collecting national statistics. In addition, the cost of conducting the US Census has been increasing exponentially over the years, from $12 million for the 1900 US Census to $4.5 billion for the 2000 US Census (Gauthier, 2002). With the burgeoning cost of collecting national statistics, critics may be concerned that incorporating indicators of SWB into national statistics will incur further cost that outweighs the benefits of including these indicators.

While it is not yet possible to evaluate the cost and benefits of including indicators of SWB into national statistics, it seems unlikely that it would be exorbitantly expensive for governments and organizations to include indicators of SWB in their survey. Indicators of SWB are often self-report measures where we ask participants to report their satisfaction using a one to seven scale (Diener et al., 2009; Smith & Mackie, 2015). Such measures are often easily administered verbally or on pen and paper, and can often be completed within a short period of time. Therefore, governments and organizations that opt to include such measures into their surveys should not experience much difficulty incorporating the measures into the survey and neither should they report a significant increase in time taken to administer the survey. Given the relatively low cost in collating indicators of SWB and the potentially valuable information that governments and organizations could derive, governments and organizations should thus consider implementing indicators of SWB in their surveys.

Summary

There are multiple reasons for incorporating indicators of SWB into national accounts. First, people believe that SWB is important, and strongly value SWB (Diener et al., 1998). Second, current social and economic indicators omit important characteristics that are important to quality of life (Diener & Seligman, 2004). Third, SWB has beneficial outcomes for both individuals and societies (Diener et al., 2015). Fourth, it is easy to implement indicators of SWB in national outcomes with little cost (Diener et al., 2009).

Although we have highlighted the limitations of social and economic indicators, we do not believe that these indicators are problematic, or should be ignored. Neither are we suggesting that indicators of SWB are better than social and economic indicators. Social and economic indicators obviously provide governments and organizations with useful and important information about their constituents, and we do not believe that indicators of SWB are in competition with social and economic indicators. Instead, social, economic, and SWB indicators should be seen as complementary measures that work in tandem to provide us with a better understanding of a nation's well-being. When considered together, these indicators allow us to better predict a nation's well-being and enable policy makers to enact more effective policies that work for the better of society.

What Types of Policies Could Subjective Well-being Measures Influence?

Indicators of SWB provide us with a broad understanding of the factors contributing to a person's or a society's well-being. However, national accounts are produced not only for descriptive purposes but more importantly, are used to meet the needs of policy makers in planning and assessing the impact of policy decisions. In this section, we review the type of policies that might be beneficial for well-being, and how indicators of SWB could assist policy makers with policy decisions. In many of these areas we review, there is only preliminary evidence, thus we are not suggesting that that policy makers should base their policy decisions on the research we present. Instead, these are just some of the policy recommendations that we could envision, and further research will be required to provide evidence for the effectiveness and validity of these policy alternatives.

Economic

Researchers have found a robust, albeit complicated, relationship between income and SWB. There is consistent evidence that rising income is often accompanied by rising SWB (Diener, Tay, & Oishi, 2013; Gardner & Oswald, 2007). However, researchers have also observed satiation points and a declining marginal utility of income on SWB, indicating that money is not everything (Diener, Sandvik, Seidlitz, & Diener, 1993; Jebb, Tay, Diener, & Oishi, 2016). These findings present alternative methods for measuring cost of living indexes and are useful for policy makers in policy areas relating to wage distributions. For example, when deciding upon an appropriate minimum wage, policy makers often rely solely on economic measures that take into account the cost of housing, transportation, and other services essential to survival. Instead of relying exclusively on economic measures, however, policy makers can also take into account the income satiation points of SWB – levels of income where SWB does not increase further and determine an appropriate minimum wage. Doing so will ensure that characteristics not captured by economic measures (e.g., child care, housework), will be taken into account, and given an appropriate weightage.

Unemployment is another area where SWB measures could influence policy. Lucas et al. (2004) found that unemployment is detrimental to SWB such that life satisfaction does not fully return to pre-unemployment levels even after people were re-employed (Clark, Georgellis, & Sanfey, 2001). Furthermore, a longitudinal study examining a nationally representative sample in the United States between 2008 to 2011 found that unemployment rate was significantly associated with job dissatisfaction over time (Tay & Harter, 2013). Even though unemployment is detrimental to SWB, there is evidence that the negative effects of unemployment could be alleviated by welfare policies such as income security, employment programs, and regulations that protect workers (Easterlin & Switek, 2014; Radcliff, 2013). Besides providing policy makers with such information on which to base policies upon, policy makers could also derive value estimates using SWB measures, and weigh the trade-offs between two competing policies alternatives.

Besides governments, organizations and businesses could also use subjective well-being findings to design policies for workplaces. Research examining well-being in the workplace has found several features that are conducive to employee's well-being. For example, a workplace that has strong social support among employees is strongly associated with higher employee well-being (Humphrey, Nahrgang, & Morgeson, 2007), while having a supervisor who is friendly and communicates clearly is also associated with higher workplace well-being (Colquitt, Conlon, Wesson, Porter, & Ng, 2001). These results suggest

that organizations and businesses could have a direct influence on their employee's well-being. For example, by being more mindful in their hiring processes, organizations could foster a work environment that is conducive to employee's well-being, which in turn spurs job productivity and increases profits.

Interestingly, some corporations already seem to understand that insuring employee's well-being is the key to increased productivity and profit. In companies like Google, Facebook, and Airbnb, it is common to find workplaces equipped with gyms, a cafeteria with restaurant quality dishes, and amenities like a nap room, massage therapists, and even a playground equipped with slides and swings. Although it is commendable that companies are placing so much effort in insuring employee's well-being, we question if such initiatives are actually improving employee's well-being since there have been no studies examining the effectiveness of such initiatives. Companies looking to evaluate the effectiveness of their initiatives could consider incorporating indicators of SWB into employee's evaluations, allowing companies to determine the effectiveness of such initiatives.

Environmental

People living in a clean and green environment often report higher SWB (Bird, 2007). For example, a survey involving 10,000 individuals found that individuals living in urban areas with more green space reported higher well-being and lower mental distress (White, Alcock, Wheeler, & Depledge, 2013). In another study, participants who were instructed to take a walk along a nature reserve experienced an increased in positive affect compared to participants who walked along an urban path (Hartig, Evans, Jamner, Davis, & Gärling, 2003), a finding that was replicated by MacKerron and Mourato (2013), who tracked participants using GPS locations to determine whether participants were in an and urban area, or in an area surrounded by nature. These studies have implications for a wide variety of public policies. For example, policy makers may want to consider providing more parks and green spaces within urban environments or even attempt to increase the amount of greenery found along streets. Wider implications include revising zoning laws and zoning areas to account for the benefits of green spaces.

Indicators of SWB could also be used to evaluate the negative effects of air pollution. When trying to evaluate the cost of air pollution on society, we currently depend almost exclusively on economic indicators, measuring the cost of medical care incurred as well as the cost to repair the damage that has been done. Alternatively, we could consider using indicators of SWB and quantify the extent of the damage done by referencing the drop in SWB reported by regions affected by the pollution. For example, Luechinger (2009) examined, over a period of time, people living upwind or downwind from power plants which were scheduled to have scrubbers (which removes a majority of the pollutants from the effluent) installed. He found that people living downwind from the power plants report higher life satisfaction after the installation of the scrubbers, whereas people living upwind from the power plants did not report a change in life satisfaction, demonstrating that efforts to remedy pollution can be effective in improving SWB. Indeed, we still cannot accurately quantify levels of SWB in monetary terms, however as indicators of SWB becomes widespread, improved methodologies will also develop in tandem such that such conversions may be possible.

An increase in urbanization around the world is associated with an increase in transportation and commuting concerns as more people flock towards the suburbs and must commute to work. A large amount of evidence now shows that long commutes tend to be detrimental to people's SWB. For example, Stutzer and Frey (2008) found that people with long commutes reported lower life satisfaction than people with short commutes. Schwarz, Kahneman, and Xu (2008) also found that among a variety of different activities, people reported lowest affect balance scores during commutes. Furthermore, the negative effects of commuting do not appear to be limited to people who commute using private transport. Evans and Wener (2006) demonstrated that New York rail commuters who had long commutes also reported higher stress and had higher levels of cortisol on commuting days. Given that commuting is detrimental to well-being, policy makers may need to re-evaluate the premise of working in a physical office, and consider alternative work arrangements such as telecommuting, or flexible working hours such that employees could avoid long commutes. Policy makers may also need to consider policies that could reduce the length of commutes, or improve the experiences of commuting. Regardless of the policies being debated, indicators of SWB will be able to assist policy makers in making informed decisions.

Health

As people live healthier and longer, health organizations have also shifted their focus away from prolonging life and towards improving quality of life (Kurth, 2005). Diseases and illnesses inflict misery and ill-being onto the patient. Therefore, modern nations often spend vast amounts of money on disease treatment and prevention, in hope that proper treatment could alleviate patients' ill-being. Unfortunately, nations rarely have enough resources to meet the demand for healthcare. Thus, nations often need to ration healthcare spending through various means (Dolan, 2007). For example, governments will need to decide

which diseases and illnesses they should focus their attention on, which will inform their decision for the allocation of funds. Currently, policy makers often based their decisions on two criteria – the seriousness of the disease or the likelihood that treatment of the disease could ease suffering. However, policy makers could also use indicators of SWB as part of the evaluative process. For example, Dolan (2008) suggested examining the SWB of patients who are suffering the disease and use their reports to calculate Happiness Adjusted Life Years (HALY), a measure that is similar to the Quality Adjusted Life Years. Policy makers can then use this information to make an informed decision. As a further advantage, because measures like HALY are calculated independent of the disease symptoms that vary across illnesses, these measures could be used as a common metric, allowing policy makers to make comparisons across illnesses.

Besides physical health, indicators of SWB could also be used to monitor the mental health of societies, and in particular, of youth and children. Monitoring the mental health of the young is important because mental health problems have direct consequences for the well-being of children. Not only is suicide the third leading cause of death among youth in the United States (Spencer, 2006), anxiety disorders also predict dropping out of school (Kessler, Foster, Saunders, & Stang, 1995), while depression predicted a decrease in educational achievements like school performance (Asarnow et al., 2005). The goal of monitoring the mental health of young and old alike is to identify people who are suffering from ill-being and in need of professional help. If such programs were linked to treatments, then it is easy to imagine that such initiatives could prevent behavioral and psychological problems in the long run. To monitor the health of children, policy makers could, for example, evaluate the mental health and well-being of students as part of their health assessment in schools. Besides evaluating students' mental health, these reports of well-being could also be used as indicators of educational performance. Many governments spend large amounts of money assessing the academic progress of children through standardized testing. However, governments seldom assess whether students enjoy school, or whether they are actively engaged with the material. Indicators of SWB could fulfill this role. By asking students about their well-being in school, policy makers will be able to evaluate the effectiveness of the educational system and identify areas that need improvement.

Social

Social capital, as a resource, is often defined as the quality of social networks within a community. Societies with strong social capital are characterized by high levels of civic participant, high levels of trust, and with strong norms for reciprocity (Putnam, 1993). Social capital is positively associated with SWB at both the individual and societal levels (Putnam, 2001). Individuals reported higher SWB not only when their own levels of social capital were higher, but also when the level of social capital of the community they were residing within was higher. The positive relationship between social capital and SWB was also replicated in a cross-national sample (Helliwell, 2006). Given the time end effort required to build social bonds, changes in social capital often do not occur immediately. Thus, policy makers interested in evaluating the short-term effectiveness of policies intended to increase social capital could use indicators of SWB as effective proxies. For example, social capital could be increased by initiatives to increase social interaction. Policy makers build communal areas (e.g., resident centers, parks) within neighborhoods; encourage residential architectural designs that allow greater neighbor interaction, or even organize frequent town meetings or events that bring residents together. In the long run, these initiatives could result in an increase in social capital, but indicators of SWB could be used in the interim to evaluate the effectiveness of such initiatives.

As the urban population continues to grow, indicators of SWB could also be used to assist city planners in evaluating the aspects of a city that contributes to well-being. For example, Kansas City, Missouri, conducted a survey of its citizens in 2006, examining their well-being and satisfaction with city facilities and services. Results indicated that the residents of Kansas City did not report high levels of well-being and were not satisfied with the facilities and services provided by the city. More importantly, administrators in Kansas City were also able to determine which facilities or services Kansas City residents were most dissatisfied with, and could then take steps to improve the situation. While administrators would be able to infer that residents were generally not satisfied with the facilities and services provided by the city using economic or social indicators, they would have a harder time pinpointing the specific areas for improvement using economic or social indicators.

Characteristics of Nations High in Subjective Well-Being

Nations high in subjective well-being often demonstrate several characteristics (see Oishi, 2012 for a review). First, nations high in SWB are often developed nations with relatively high wealth and national income (Diener, Kahneman, Tov, & Arora, 2010). Second, nations high in SWB are often low in corruption (Tay, Herian, & Diener, 2014), and have efficient, effective governments (Helliwell, Huang, Grover, & Wang, 2014) that emphasizes a strong rule of law (Diener, Diener, & Diener, 1995), a strong emphasis on

protecting human rights, and are often low in corruption. Third, nations high in SWB have progressive tax structures (Oishi, Schimmack, & Diener, 2012) as well as income and employment security programs that protect the less privileged (Di Tella, MacCulloch, & Oswald, 2003; Easterlin & Switek, 2014; Radcliff, 2013). Initial evidence also suggest that places high in SWB are also healthier (Lawless & Lucas, 2011), have better healthcare coverage (Boarini, Comola, de Keulenaer, Manchin, & Smith, 2013), and are often greener (White et al., 2013), although further research is required to determine if the relationship holds at the national level.

A nation that exemplifies almost all of the characteristics of a society high in SWB is Denmark. Not only are Danes frequently ranked among the happiest people in the world (Helliwell & Sachs, 2017), Danes enjoy a high standard of living, and Denmark often rank among the highest in cross-national rankings of performances. For example, Denmark is ranked fifth in the Human Development Index, which takes into account indicators such as life expectancy, education attainment, and GDP per capita (United Nations Development Programme, 2016). Denmark also rank among the highest in the Democracy Index (Economist Intelligence Unit, 2016), an index that measures the state of democracy in a country by taking into account various important indicators of democracy such as the protection of civil liberties, whether the nation has democratic electoral processes, and the extent of political participation in a nation. Among the nations surveyed, Denmark also has one of the highest per capita income (World Bank, 2016a); the highest social mobility (Causa & Johansson, 2010), a high level of income equality (World Bank, 2016b), the lowest perceived levels of corruption (Transparency International, 2016), and one of the highest personal income tax rates (KPMG, 2016).

Denmark also ranks highest in the world for workers' rights and strong employment security programs (International Trade Union Confederation, 2014). Denmark also has a universal healthcare system, ensuring that almost all health care provision is free for Danes. In addition, Denmark is a very environmentally conscious nation, relying on wind power to provide 42% of the nation's electricity. Unsurprisingly, Denmark also ranks among the highest in the Environmental Performance Index, which measures how well individual countries implement the United Nations' Sustainable Development Goals (Yale University, 2016).

Costa Rica is another nation that reports high SWB despite its' poor GDP per capita earnings. Costa Ricans are also frequently ranked among the happiest people in the world (Helliwell & Sachs, 2017), despite being a developing country, with a 2015 GDP per capita of only US$10,630 (World Bank, 2016a). In contrast, Denmark had a GDP per capital of US$52,000 in 2015. In the 2017 World Happiness Report, Costa Rica was ranked 12th among the nations surveyed, the highest among the nations surveyed in the Americas (Helliwell & Sachs, 2017). The country has consistently performed well in the Human Development Index, ranking 66th among the nations surveyed in the 2016 Human Development Index, the highest among the Latin American nations (United Nations Development Programme, 2016). The United Nations Development Programme (UNDP) also found that Costa Rica attained higher human development standards compared to other countries at the same income levels (United Nations Development Programme, 2016).

Similar to Denmark, Costa Rica also employs a universal healthcare system and is also an environmentally progressive nation. In 2015, it is the only country to meet all criteria established by the UNDP to measure environmental sustainability (United Nations Development Programme, 2015). It was also ranked 42nd in the 2016 Environmental Performance Index, only outranked by the USA and Canada among the Americas nations surveyed (Yale University, 2016). Despite a lagging economy, Costa Rica has a literacy rate of 96.3%, one of the highest in Latin America, and a high-quality education system, ranking 52^{ng} in the 2016 Global Competitiveness Report, 3 rd among the Latin American Countries (World Economic Forum, 2016).

Besides differences of SWB between nations, there are also significant differences in SWB within nation. The United States overall reports pretty high SWB. However, using data the Gallup-Healthways Daily Well-being Index, we also found significant differences in SWB between zip codes. For example, residents living in Delaplane, Virginia are mostly white, middle-aged, report a median household income of US$124,141, and do not attend church regularly. They report experiencing high SWB. In contrast, residents living in Port Murray, New Jersey report similar demographic indicators, but often report experiencing low SWB. Meanwhile, residents living in Denmark, South Carolina are majority black, young adults earning a median household income of US$21,026 who attend church regularly, yet they report experiencing high SWB. This example illustrates that although cross-national indicators are useful, we should also not assume that national accounts of well-being are adequate in describing the well-being of everyone living in the nation. Instead, the well-being of citizens living in different regions of a nation could differ drastically, and indicators of SWB should be used to identify within nations differences too.

Progress on National Accounts of SWB

Diener (2000) first proposed that nations should adopt national accounts of well-being to complement economic and social indicators. Since then, there has been significant discussion and refinement of the idea among academics and scientists. For example, Diener and Seligman (2004) published the influential article "Beyond Money: Towards an Economy of Well-being", also arguing that economic indicators are insufficient to reflect the quality of life in societies. Then, Diener (2005) published a set of broad guidelines for measuring and implementing national accounts of well-being. From 2005 to 2007, Diener coordinated a program at the University of Pennsylvania to discuss and further refine the ideas of national accounts of well-being with psychologists, philosophers, economists, and policymakers. Subsequently, Diener et al. (2009) authored a volume presenting the reasons for national accounts of well-being, and provided examples of policies that SWB measures could influence. Diener et al. (2015) then published a follow-up to Diener (2000), reviewing the significant progress that has occurred within the last fifteen years regarding the acceptance and implementation of national accounts of SWB by policymakers. Smith and Mackie (2015) also outlined how national statistical offices could measure SWB measures, and how SWB measures could guide policy.

As Diener et al. (2015) reviewed, there has been significant acceptance of the idea that national accounts of SWB are beneficial to nations and organizations. For example, Diener presented findings on SWB to the World Bank in 2003, to the United Nations Development Program in 2008, and again to the World Government Summit in 2016, a meeting that was attended by government representatives from 130 nations. In addition, the 2009 report of the Commission of the Measurement of Economic Performance and Social Progress (Stiglitz, Sen, & Fitoussi, 2009) recommended that government population surveys should measure people's well-being.

In 2012, the UN General Assembly adopted resolution 65/309, affirming that economic measures alone do not adequately reflect the well-being of people, and broader measures of well-being should be considered. In 2013, the National Academy of Sciences of the USA issued a positive review of well-being measures. In the same year, the Organization for Economic Cooperation and Development (OECD), which assist in the coordination and collection of statistics across nations, also published a positive discussion of SWB measures and their uses in policymaking.

Not only has there been significant acceptance of the idea that national accounts of well-being are beneficial, there has also been significant implementation of national accounts of well-being across different nations. For example, in 2010, the prime minister of the United Kingdom announced that the UK would measure SWB to assist policy decisions. In addition, Bhutan also conducted the first measurement of the Gross National Happiness Index (GNH) the same year. The GNH is an index used to measure the collective happiness of a nation. Furthermore, the United Nations Development Program also published a report of SWB in nations around the world in 2010. To date, over forty nations have assessed SWB in surveys conducted by the government or international organizations. Australia, Germany, Switzerland, and the UK also have large ongoing longitudinal panel studies that examine well-being (Diener et al., 2009). International organizations like Gallup also assess well-being through the Gallup World Poll as well as the Gallup-Healthways Index of Well-being.

Besides implementing national accounts of well-being, several nations have also appointed government officials to monitor and enhance the well-being of their citizens. For example, the United Arab Emirates (UAE) has a Minister of State for Happiness, whose main role is to institute programs that enhance the well-being of people living in the UAE. Ecuador also has a Minister of Good Living, who occupies a post similar to that of UAE's Minister of Happiness. As part of her goal to enhance the well-being of people living in the UAE, Her Excellency Ohood Al Roumi has recently implemented a 100-day program of positivity in schools, where children learn about and practice positive interactions with others. In addition, the UAE also collaborated with the University of Pennsylvania's Positive Psychology Center to create the Happiness & Positivity Program for the Private Sector, which aims to equip UAE private sector employees with intuitive and practical skills to become the drivers of happiness and positivity in their respective organizations.

Some Objections Answered

Some skeptics have argued that well-being is an individual's affair, and governments should not interfere with such a personal issue by telling people how they should live. This objection disregards the fact that governments already intervene in numerous aspects of their citizens' lives through taxes, laws and other policies. Furthermore, there are legitimate consequences of well-being beyond the individual level that allow us to question whether well-being is only an individual concern. Besides the societal benefits of well-being that we reviewed earlier, there is also evidence that an individual's well-being (or ill-being) can influence the well-being of people around them. For example, caregivers who were caring for family

members suffering from medical illnesses often report low levels of well-being and are often found to have a higher risk for depression (Hooley, Butler, & Howlett, 2005; Visser-Meily et al., 2005). Moreover, what has been perceived as private and beyond the interference of governments has varied over the years. For example, the choice to smoke was once thought to be an individuals' affair as well. However, as increasing evidence suggests that smoking is detrimental not only to the individual, but to society as well, the perception that smoking is an individual choice also begun to fade, and governments now often institute policies to discourage smoking.

Another common objection raised against accounts of well-being has been that well-being is nothing more than hedonism, the pursuit of pleasure and self-indulgence. Thus, striving for high well-being is a luxury and not a basic need. This criticism is a misconception because a plethora of research has demonstrated that high SWB is associated with positive outcomes. For example, SWB is substantially increased when basic needs of citizens are met (Tay & Diener, 2011) and when gains in economic resources are allocated to meeting the basic needs of people (Diener et al., 2013). Other than the outcomes observed for health, social relationships, and other achievement-related outcomes that we previously reviewed, high SWB is also beneficial for being prosocial, organizational citizenship, work performance and business productivity (Tenney et al., 2016). For example, higher SWB is associated with volunteering more (Oishi, Diener, & Lucas, 2007), more frequent blood donations (Priller & Schupp, 2011). People high in positive affect also reported being more creative (Johnson, Waugh, & Fredrickson, 2010), and lower job turnover (Griffeth, Hom, & Gaertner, 2000).

Conclusions

Economic and social indicators have long dominated national accounts. However, these indicators have limitations and large blind spots, often omitting important characteristics that contribute to quality of life. Therefore, indicators of SWB should be incorporated into national accounts, not to replace existing economic and social indicators, but to complement them. By including indicators of SWB into national accounts, we broaden the information available to policy makers and enable them to design more effective policies that improve the lives of their constituents.

Since Diener (2000) first proposed the use of national accounts of SWB, there has been significant acceptance and implementation of the idea by governments, organizations, and behavioral scientists alike. Several nations now have parliamentary members overseeing initiatives to ensure the well-being of their citizens. Over forty nations have assessed SWB in the surveys they conduct, and behavioral scientists have also begun to analyze these data to determine the policy implications of specific research findings. Going forward, we hope to convince more nations of the benefits in measuring SWB in national statistics and for more collaboration between policy makers and scientists to examine the implications of research findings on public policy. In particular, more evidence is required to confirm the hypothesis that adoption of national accounts of SWB is beneficial for citizens' well-being both in the short and long term.
