Abstract

Keywords: Subjective well-being; happiness; life satisfaction; well-being

It is a pleasure to bring to you the eHandbook of Subjective Well-Being, the science of when and why people experience and evaluate their lives in positive ways, including aspects such as positive feelings, life satisfaction, and optimism. There are chapters in this eHandbook on the philosophy and history of well-being, as well as reviews of empirical research on the ways to assess well-being, the circumstances that predict it, the outcomes that it produces, the societal policies that enhance it, and many other social, biological, and cultural processes that help us understand why some people are happy and satisfied with their lives, while others are not. There are also chapters on theories of well-being, such as the baseline or set-point models.

We believe that Open publication is the wave of the future (Jhangiani & Biswas-Diener, 2017). Therefore, we are presenting the handbook in an electronic format so that it is widely available to everyone around the world. The handbook is entirely open and free – anyone can read and use it without cost. This is important to us as we desire to lower knowledge barriers for individuals and communities, especially because it provides access to students, educators, and scholars who do not have substantial financial resources. We are not certain if this is the first free and open handbook in the behavioral sciences, but hopefully it will not be the last. In the past the prohibitive price of many handbooks have made them available only to scholars or institutions in wealthy nations, and this is unfortunate. We believe scientific scholarship should be available to all.

The field of subjective well-being has grown at rapid pace over the last several decades, and many discoveries have been made. When Ed Diener began his research within the field in 1981 there were about 130 studies published that year on the topic, as shown using a Google Scholar search on "subjective well-being." Eighteen years later when Shigehiro Oishi earned his Ph.D. in 2000 there were 1,640 publications that year on the topic, and when Louis Tay was awarded a Ph.D. in 2011 there were 10,400 publications about subjective well-being. Finally, in 2016 there were 18,300 publications – in that single year alone! In other words, during the time that Diener has been studying the topic, scholarship on subjective well-being has grown over 100-fold!

It is not merely the number of published studies that has grown, but there have been enormous leaps forward in our understanding. In the 1980s, there were questions about the reliability and validity of subjective well-being assessments, and the components that underlie it. One notable advance is our understanding and measurement of well-being. We now know a great deal about the validity of self-report measures, as well as the core evaluative and affective components that make up subjective well-being. Further, scholars have a much greater understanding of the processes by which people report their subjective well-being, and various biases or artifacts that may influence these reports. In 1982 many studies were focused on demographic factors such as income, sex, and age that were correlated with subjective well-being. By 2016 we understood much more about temperament and other internal factors that influence happiness, as well as some of the outcomes in behavior that subjective well-being helps produce (e.g., income, performance, physical health, longevity).

In the 1980s, researchers assumed that people adapt to almost any life event, and that different life events only have a short-term effect on subjective well-being. A number of large-scale longitudinal studies later showed that that is not the case. By now we know what kinds of life events affect our subjective well-being, how much, and for roughly how long. In the 1980s researchers believed that economic growth would not increase the happiness of a given nation. Now we know when economic growth tends to increase the happiness of a given nation. Additionally, we know much more about the biology of subjective well-being, and an enormous amount more about culture and well-being, a field that was almost nonexistent in 1982.

With the advent of positive psychology, we are also beginning to examine practices and

interventions that can raise subjective well-being. Given the broad interest in subjective well-being in multiple fields like psychology, economics, political science, and sociology, there have been important developments made toward understanding how societies differ in well-being. This understanding led to the development of national accounts of well-being – societies using well-being measures to help inform policy deliberations. This advance changes the focus of governments away from a narrow emphasis on economic development to a broader view which sees government policies as designed to raise human well-being.

We were fortunate to have so many leading scholars of subjective well-being and related topics contribute to this volume. We might be slightly biased but most of the chapters in this eHandbook are truly superb. Not only do they provide a broad coverage of a large number of areas, but many of the chapters present new ways of thinking about these areas. Below is a brief overview of each of the sections in this volume:

In Section 1 we begin the volume with chapters on philosophical, historical, and religious thinking on well-being through the ages. Next, we cover the methods and measures used in the scientific study of well-being.

Section 2 is devoted to theories of well-being such as the top-down theory, activity theory, goal theory, self-determination theory, and evolutionary theory.

Section 3 covers the personality, genetics, hormones, and neuroscience of well-being. Then, demographic factors such as age, gender, race, religion, and marital status are discussed.

Section 4 is devoted to how domains of life – such as work, finance, close relationships, and leisure – are related to overall subjective well-being.

Section 5 covers the various outcomes of subjective well-being, ranging from work outcomes, to cognitive outcomes, to health, and finally relationship outcomes.

Section 6 covers interventions to increase subjective well-being.

Finally, Section 7 is devoted to cultural, geographical, and historical variations in subjective well-being. This eHandbook presents the most up-to-date and comprehensive understanding of subjective well-being – and it is freely available to all!

The editors would like to extend their thanks to several individuals who have been critical to the success of the handbook. First, our gratitude is immense toward Chris Wiese, Keya Biswas-Diener, and Danielle Geerling, who organized and kept the entire venture on track. Their hard work and organizational skills were wonderful, and the book would not have been possible without them. Second, we extend our thanks to the Diener Education Fund, a charitable organization devoted to education that in part made this project possible. In particular we express deep gratitude to Mary Alice and Frank Diener. Not only did their help make this eHandbook possible, but their lives stood as shining examples of the way to pursue well-being!

INTRODUCTION, HISTORY, AND MEASUREMENT

From the Paleolithic to the Present: Three Revolutions in the Global History of Happiness

By Darrin M. McMahon, Dartmouth College

Abstract

This article examines three crucial turning points or "revolutions" in the world history of happiness from the Paleolithic to the present, focusing on the impact of the Agricultural Revolution that began c. 10,000 BCE, the "Axial Age" of the first millennium BCE, and the "Revolution in Human Expectations" of the long 18th century. The article contends that each of these revolutions initiated significant changes in humanity's experience and understanding of happiness. And though we are still living in the shadow of the last of these three great revolutions, it may be that humanity stands on the cusp of another.

Keywords: happiness, history, Paleolithic, Axial Age, revolution in human expectations

The tools available to social scientists hoping to measure the happiness of the living are now many and varied. They range from the detailed scales and questionnaires that assess subjective well-being around the globe, to methods of experience sampling, to a variety of physical measures that capture the brain and body's response to stimuli both internal and external. It is true, as Dan Gilbert has remarked, that the nature of subjective experience is such that there will never be a "happyometer," a perfectly reliable instrument that allows us to measure another person's well-being with complete and total certainty. But the alternatives to perfection are still pretty good. Gilbert invokes the wisdom of the builder. "Imperfect tools are a real pain, but they sure beat pounding nails with your teeth" (Gilbert, 2006).

From the perspective of a historian who would hope to measure the happiness of the dead, however, the prospect of broken teeth is real. Try asking a skeleton to meditate in an MRI machine and you will begin to see the problem. The dead, most often, are unresponsive. You can't do experience sampling with a corpse. And though it may be that we are now bequeathing enough survey data to our descendants to enable future historians one day to ask questions of the departed that we currently ask the living—"Did you experience happiness during a lot of the day yesterday?" "On the whole, would you describe yourself as very happy, pretty happy, not so happy?"—for the time being such questions, when posed to people in the past, tend to fall on deaf ears.

Yet if historians' questions, like their instruments, must necessarily differ to some extent from those of their social-scientific colleagues who work with subjects still among us, they needn't throw up their hands in complete despair. A variety of methods and approaches are at their disposal to aid inquiries about happiness in the past. Historians might, for instance, follow the lead of the Marquis de Chastellux, who in the 18th century undertook to write the world's very first history of happiness by means of proxy data. Lower levels of slavery, say, or war, or famine, Chastellux reasoned, ought to correspond to higher levels of what he called "public felicity." By aggregating such data, Chastellux hoped to sketch the broad outlines of the history of social happiness (Chastellux, 1772). And although more recent historians have not, to my knowledge, attempted such an undertaking, they surely can. So too can they undertake conceptual histories of happiness, examining how different cultures have imagined and understood this complex phenomenon at different times (McMahon, 2006). There is a particular need to devote energy to this work in non-western and comparative settings. Finally, historians can draw on the tools developed by their colleagues in the sub-discipline of the history of emotions, who ask how emotions are channeled and expressed under different affective or "emotional regimes" (Reddy, 2001; Stearns, 2012; McMahon, 2013). Although any one of these approaches might be pursued separately, this article draws on elements of each of them in order to sketch, in broad terms, three crucial turning points or "revolutions" in the long history of human happiness. Insight into the different ways that human beings have conceived, experienced, and defined happiness in the past, it is hoped, may be of service to those who think about happiness in the present, and pursue it in the future.

The Deep History of Happiness

How happy were our earliest human ancestors? The question, of course, admits of no easy answer, and yet it is striking how many cultures of the world seem intent on attributing an original happiness to the

very first human beings. Myths of a lost paradise or a vanished golden age are virtually universal in human culture, and their consistent accounts of teeming abundance and ease are striking. At the very least, such accounts can offer clues into how human fortunes have changed over time, to say nothing of men and women's capacity to imagine circumstances better than their own.

For the men and women who first fashioned these myths may have been onto something. Archeologists and anthropologists today emphasize that early human existence was surprisingly prosperous —if not a paradise, then perhaps an "original affluent society," to cite the well-known formulation of the anthropologist Marshall Sahlins (1972). In this view, the hunter-gather bands that roamed the earth for much of the Paleothic era prior to the advent of agriculture roughly 12,000 years ago enjoyed a number of comparative advantages that their later, myth-fashioning descendants did not. For one, what we now style the "paleo" diet—rich in protein and fibers and free of refined carbohydrates—was abundant, varied, and nutritious. Our hunter-gatherer ancestors, it seems, were relatively well-fed. Evidence from fossilized skeletons and dental remains, for example, suggests that early foragers were less likely to experience starvation or malnutrition than their farmer-peasant counterparts of later periods, and that they were, on the whole, of superior stature (Harari, 2015). Average life-expectancy, though brought down by a high incidence of infant-mortality, was, for those who survived the first years after childbirth, surprisingly high, upwards of sixty years, which compares favorably to most human societies up until the time of the industrial revolution. The absence of infectious diseases born of high-density populations and domesticated livestock, moreover, meant that the curse of large-scale epidemics was unknown. With only 5 to 8 million foragers inhabiting the earth on the eve of the Agricultural Revolution there were ample resources and room to move about, which meant that tensions both within and between bands could be diffused by simply moving on. An alternative to war was flight, and a strategy for dealing with excessive coercion was to leave the group and strike out on one's own. As a number of scholars have concluded, this meant that early hunter-gatherers likely enjoyed a significant degree of freedom, and, in the absence of accumulation and private property, equality (Maryanski & Turner, 1992; Sanderson, 1995; Boehm, 2001; Veenhoven, 2005). Certainly their fortunes were superior in these respects to those of the vast majority of men and women born into the highly stratified and coercive societies that followed in the wake of the Agricultural Revolution, in which slavery was common and inequality the norm (Scheidel, 2017). Finally, foraging peoples had the luxury of time. Rough calculations suggest that the average "work week" of hunter-gatherers—measured in the hours necessary to ensure the supply of food and to perform essential tasks—was considerably less than that of modern workers, leaving ample opportunity for leisure, recreation, and social interaction in settings that were favorable to close interpersonal interaction (Sahlins, 1972; Harari, 2015).

Of course, it is important not to substitute our own myths for the myths of old, imagining the hunter-gatherer past as some sort of sylvan idyll before humanity's corruption and fall. Modern observers, it is true, have not always avoided that temptation. But clearly life in the Paleolithic period was never a golden age. Even after our *Homo sapiens* ancestors rose, with the help of fire, tools, and teamwork to the top of the food chain within the last 100,000 years, they still were susceptible to attack by a variety of fierce predators—not least, other members of the genus *Homo*. The evidence of mass grave sites in the Paleolithic period—replete with shattered skulls and severed limbs—belies any easy assumption that our ancestors lived in uninterrupted peace and harmony. And however abundant their streams, forests, and savannahs, eking out an existence—above all in the long winters of the long ice age—was never an easy task. In the end, the life of foraging peoples in the Stone Age was, just as it has been for the great majority of those who came after, a struggle.

Still, when we compare this earlier period with the settled societies that began to spring up in the wake of the Agricultural Revolution, we can understand how later observers might have looked back with a certain elegy. For the broadly egalitarian existence of hunter-gatherers, with their relative freedom and prosperity, gave way to societies of a very different sort, characterized by a far greater degree of hierarchy, inequality, and oppression, as well as the persistent threat of famine, war, and disease. The paths to these destinations, of course, varied considerably, and they frequently doubled-backed. Yet in their circuitous ways, they led across the threshold of what the scholar Walter Scheidel has called "the great disequalization,", the "transition to new modes of subsistence and new forms of social organization that eroded forager egalitarianism and replaced it with durable hierarchies and disparities" of income, wealth, and power (Scheidel, 2017). Agriculture was an important (though not the only) driver in this process, permitting accumulation and surplus, which could then be transmitted to one's offspring, perpetuating status and power. Concentrated state power was another (Scott, 2017). Inequalities followed in turn, and were gradually rendered hereditary, setting humanity on a road to "monarchy, slavery, and empire," and the incessant wars needed to create and defend these institutions (Flannery & Marcus, 2012).

To be sure, there were winners in this process. Those who were able to concentrate the surplus

wealth generated by farming—most often in close concert with emergent states—did far better than their forager ancestors could ever have dreamed—so much so that this early elite has been styled the "original 1%" (Scheidel, 2017). But for the vast majority, lowly peasants and laborers now tied to the land and crowded in settled communities, the tradeoffs were extensive. Although agriculture meant a greater sum total of food (and so expanding populations), the end result was to keep more people alive in worse conditions than they had known before. Diets were increasingly less varied and nutritious, as the shift to agriculture favored carbohydrate-heavy foods such as rice, grains, corn, and potatoes that were high in calories but low in essential nutrients. The labor required to tend to them, moreover, was backbreaking and monotonous, and the reliance on a limited number of staples rendered populations susceptible to crop failure and famine. When combined with the parasites and epidemic diseases spread by domesticated livestock and communicated via concentrated populations, and the war, violence, raiding, and social conflict that attended territorial competition, the picture that emerges is far from pretty. On a range of indices from life-expectancy to stature many human beings around the world would not obtain the levels of their hunter-gather ancestors until after the industrial revolution, if then (Clark, 2007). It may be an exaggeration to say, with Jerrod Diamond, that the transition to agricultural societies was "the worst mistake in the history of the human race" (Diamond, 1987). But the point is well taken. At the very least it reminds us that history is not an inevitable march of progress. Some "advances" actually set us back. The first revolution in the history of human happiness, it seems likely—our exit from our hunter-gatherer past—was an unhappy one.

Why, then, did men and women leave? Hindsight, of course, is 20-20, and the first agriculturalists had no way of foreseeing the human future. Some were coerced, and others tempted into settlement, seeking security in greater numbers. But the broader answer is that evolution is not interested in the fate of individuals, but in the perpetuation of species. Agriculture, for all its drawbacks, enabled *Homo sapiens* to expand exponentially, even when the quality of individual lives suffered (Harari, 2015). From an evolutionary standpoint, greater population was a victory in itself.

It is true that an evolutionary account also suggests that human beings must be happy enough to want to reproduce and carry on. Darwin himself posited an adaptive role for happiness, observing that the "vigorous, the healthy, and the happy survive and multiply," and evolutionary psychologists have further developed that insight (Darwin, 1859; Buss, 2000; Grinde, 2002; Hill, DelPriore, & Major, 2013). If happiness as positive affect is often good for us, they reason, it was also good for our ancestors, who did us the favor of passing on their genes. Good feelings could serve as a carrot to induce adaptive behaviors and a reward for acts that contributed to our fitness, such is social bonding, the search for nourishing food, and sex. Then again, negative affect in the form of jealousy, anxiety, and fear, could serve as a powerful stick, ensuring that we never got too happy for our own good. The picture that emerges from such accounts is one of human beings inclined to adapt quickly to their pleasures, so that they will then set off in search of more. Restless creatures, we are rarely satisfied for long. And it may be that our long evolution in the conditions of the Stone Age has given us a reward system (and anxieties and fears) that are maladapted to the conditions of the modern world.

But if consideration of the early human past can provide material for speculation about our subsequent psychology, it may also help historians understand why so many cultures that developed in the aftermath of the Agricultural Revolution looked with longing to that time long ago, imagining an Arcadian golden age of plenty and ease in contrast to their own experiences of uncertainty and periodic privation. It is altogether telling that the earliest recorded words for "happiness" in virtually every human language are cognate with fortune or luck (McMahon, 2006; Oishi, Graham, Kesebirm, & Galinha, 2013). For cultures regularly subject to upheavals and twists of fate—from the descent of plague to the appearance of a marauding army to the onset of famine or the wrath of one's betters—it was difficult to imagine happiness as something that could endure, still less as something that one could control. Happiness, rather, was in the hands of the gods, meted out by fortune, or forged in the crucible of fate. And though the prosperous might better hedge against uncertainty than the poor, even they were not immune to the upheavals and sudden reversals that inevitably threatened us all. As ancient Chinese sages cautioned, misfortune (*huo*) was fortune's (*fu*) twin. That reflection figures in some of the earliest extant writings of China, and it was repeated down through the ages. As the Daoist philosopher Lao Tsu observed around 500 BCE: "Misfortune *(huo*) is that which beside fortune (*fu*) lies" (Keping, 2001). Artabanus of Persia, as interpreted by the Greek historian Herodotus in the 6th century BCE, echoed this wisdom, but in even darker tones, voicing assumptions that were shared in many cultures.

> Short as [the human life] is, there is not a man in the world, either here or elsewhere, who is happy enough not to wish – not once only but again and again – to be dead rather than alive. Troubles come, diseases afflict us, and this makes life, despite its brevity, seem all too long (Herodotus, 2003).

The reckoning was grim, reflecting a view of the world as at once hostile and unpredictable, in which suffering was the norm. It was a world governed by forces beyond our control. And in such a world, happiness must be elusive and fleeting. To conceive of it otherwise—as something that could endure in a world of change—would be to imagine a supreme, even superhuman, achievement, happiness as something divine.

Happiness in the Wisdom Traditions of the Axial Age

In the aftermath of the Second World War, the German philosopher Karl Jaspers published his *Vom Ursprung und Ziel der Geschichte* (1949), "The Origin and Goal of History." An audacious work, the book departed from what Jaspers characterized as an article of faith: that mankind has one single origin and goal. And it advanced the view that world history, as a consequence, possesses a coherent meaning, structure, and end. Few practicing historians are liable to share that view today. And yet scholars, particularly those of world religions, continue to draw on one of Jasper's central themes: the formative influence of what he called the "Axial" age, through which ran the axis of history (Bellah & Joas, 2012). It was this period, Jaspers argued, spanning roughly the first millennium BCE, that witnessed the emergence of the world's great religious and wisdom traditions: from the Confucian and Daoist teachings of China to the doctrines of the Upanishads and the Buddha in India, to the Hebrew prophets in Palestine and the great philosophers of Classical Greece. And though other major traditions were to follow—most notably Christianity and Islam—they built on spiritual foundations already established. The Axial Age, Jaspers contended, bequeathed to humanity a store of spiritual values on which it has continued to draw. "Until today mankind has lived by what … was thought and created in that period" (Jaspers, 2010).

Jaspers himself did not consider the subject of happiness or human flourishing directly. But students of religion who have addressed the impact of the Axial Age have. And in the opinion of one of them, the noted philosopher Charles Taylor, the "most fundamental novelty" of the Axial revolution was precisely its "revisionary stance toward the human good." "More or less radically," Taylor maintains, "all of [the Axial religions] call into question the received, seemingly unquestionable understandings of human flourishing" that had reigned previously (Taylor, 2012). The Axial religions, in short, reconceived and redefined human happiness.

Each did this, of course, in unique ways. But there were, nonetheless, striking commonalities. Most importantly, the wisdom traditions explicitly challenged purely worldly or mundane understandings of happiness as plenty, prosperity, pleasure, or power. Fantasies of freedom and abundance of the type that had likely drawn the imaginations of the poor and powerless since the advent of the Agricultural Revolution (and continued to do so long after) were not always rejected outright: milk and honey might still be seen on the horizon. And it is also true that the various Axial creeds adopted differing perspectives on the instrumental value of material prosperity—with some, Confucians say, or Aristotelians, arguing that a certain degree of wealth was a prerequisite to the pursuit of the higher aspirations of the good life, and others emphasizing the inherently corrupting nature of pleasure and affluence. In most cases, however, moderate worldly prosperity was seen, at best, as a means to higher ends, never as an end in itself. To pursue wealth for wealth's sake, all agreed, was to succumb to one of the many dangerous temptations that common understandings of happiness dangled before us, as if mere riches, power, or sensual satisfaction could fulfill us. Genuine happiness required something more—a connection to the transcendent, to God or the gods, to the Good or the True. It involved, as Taylor asserts, a "going beyond" ordinary human flourishing, however such flourishing might be conceived locally (long life, prosperity, freedom from disease, drought, natural catastrophe, etc. (Taylor, 2012). For the Axial traditions, human happiness must always entail something else.

The Daoist philosopher Zuhang Zi expressed this nicely in the 4 th century BCE with the seemingly paradoxical assertion that "Perfect happiness is without happiness" (*zhi le wu le*), by which he meant that true happiness did not depend on those things that people in the world often considered to be valuable sources of (ordinary) happiness, such as easy living, good food, wealth, longevity, and the like (Keping, 2001). Indeed, those who devoted themselves solely to such worldly goods and pleasures were "upside down people," whose priorities had been inverted (Ivanhoe, 2013). Genuine happiness required devotion to the Dao or Way, the true order and harmony of the universe that transcended the self. Similarly, in this respect, the master Kongzi, known as Confucius in the West, taught that living well went far beyond ordinary pleasures and comforts. Rather, it involved knowing how to find joy in the right things in the right ways. Kongzi emphasized the importance of good conduct to others and the value of family and friends, while praising behaviors, rituals, and rites that took us beyond ourselves, connecting us to the deeper structures and patterns of the universe. It was in this alignment, he believed—between the individual and the transcendent, between right conduct and right order—that true harmony, peace, and joy could be found.

In their common rejection of "ordinary" happiness, conceived largely in hedonic terms, Axial understandings of happiness were thus invariably "eudaimonic," concerned less with good feeling and enjoyment for their own sake, than with living optimally, living well. The very term (eudaimonic), of course, emerged in the context of the Axial wisdom traditions of Classical Greece, employed by Socrates and Plato in explicit contrast both to good fortune (*eutychia)* and to sensual pleasure (Nussbaum, 1986). As described by their acolyte Aristotle, *eudaimonia* was the "highest good," a characterization of a life lived fully in its entirely. Neither a fleeting feeling nor an ephemeral emotion, *eudaimonia* was the product of discipline, dedication, and craft. *Eudaimonia*, in short, required what Aristotle and the Greeks called *arête* (virtue).

Regardless of the word used to describe it, however, the insight that human flourishing demanded the development of human excellence—the cultivation of particular strengths of character and mind—was another common assumption of Axial understanding of happiness. Moses and the Buddha, Aristotle and Confucius, the author of the Upanishads and the Stoics were of one mind on the matter. To learn to live well required preparation, training, and perseverance, a discipline of the body and of the mind. We were not born into the world knowing how to live at the highest level of excellence. This was a skill to be acquired, practiced, and perfected. Living well was a way of life, and it was never easy.

The various traditions took different stances on the role played by the divine in this process. Was revelation necessary for enlightenment? Did human perfection require grace or the direct assistance of the gods? Or did we all, as the Buddhists maintained, have within us the full potential to live happy lives? Regardless of the individual positions taken on these and a range of related questions, none of the Axial traditions denied the importance of the human element in realizing human perfection. Happiness, in other words, did not just happen by chance. It was a product of our characters, of who we were and of who we chose to be. To live well was to make choices about how best to live, and about what kinds of virtues to cultivate in the service of a flourishing life.

Once again, the range of recommendations on these matters put forth by the various wisdom traditions was extensive. And though it may be that there are certain basic character strengths that are lauded universally across cultures, to enumerate them in any detail here would be to go beyond the scope of the present inquiry (Peterson & Seligman, 2004; Haidt, 2006). Still, it is useful to call attention to a number of key virtues and insights extolled by the Axial traditions that have drawn commentary in the more recent scientific literature in relation to human flourishing. Virtually all of the wisdom traditions, for example, reinforce the virtues of gratitude and forgiveness, urging us to express thanks for what we have, and to treat with indulgence those who have done us wrong. Virtually all of the wisdom traditions, likewise, cultivate the virtues of optimism and hope, recommending that we make an effort to see the good in the world, to keep alive its possibility, and to trust that it is there, even (especially) when it is hard to see. Virtually all of the wisdom traditions, furthermore, cultivate the importance of friendship, fellowship, and loving kindness, extolling compassion, love, and human understanding as among the highest expressions of the soul. And so virtually all foster the insight that magnanimity and charity to others are not only good in their own right, but good for oneself, recommending the injunction later voiced by Jesus: Give and you shall receive. Finally, virtually all the wisdom traditions operate on the assumption that there are powerful forces at work in the human mind (and flesh) that militate against the cultivation of every one of these virtues (and others besides), meaning that to craft a flourishing life will inevitably be a challenge—a difficult one—a process of self-mastery that demands continual attention and training.

The upshot of these prescriptions for pursuing a flourishing life is that many—indeed most—will not be up to this challenge. The Buddha, who maintained that all human beings have the capacity for happiness, acknowledged as much when he asserted that all life is suffering, misery, and pain. Most people, that is, live lives of ignorance, illusion, and craving. They could change this by seeking enlightenment, but alas most don't. The other Axial traditions tend to agree: those virtuosi who successfully devote themselves to cultivating genuine human flourishing are necessarily an elite. The happy, as Aristotle says, are the happy few.

Although the great Post-Axial faiths of Christianity and Islam developed their own variations on these themes—while accentuating the importance of the afterlife, where the inevitable sufferings of this world would be overcome—they did not depart essentially from the basic perspectives on human flourishing elaborated here. Many might be called, but few would be chosen. True happiness, whether of this life or the next, remained an extraordinary achievement.

And so humanity plodded on, taking its pleasures where it could, while accepting that happiness—both of the ordinary and extraordinary kind—was more the exception than the rule, the provenance of the lucky, the privileged, and the powerful, on the one hand, and the chosen, the enlightened, and the saved on the other. This is not to say that human beings were less happy (or more) in those times than their later

descendants. In the absence of surveys and direct reports, that question, to repeat, can only be addressed by proxy. Chastellux, for his part, thought that his own age (the 18th century) was the happiest in the history of the world, and there are those among us today who would be inclined to say the same about our own day on the basis of other metrics (average life expectancy for one), building a case for progress over time (Veenhoven, 2005). Then again, we know that human adaptation is a powerful force, and in the absence of direct comparisons, it may be that people of previous times and economic fortunes were just as happy as we are now (Clark, 2007). Historians should devote more attention to the matter.

What we can say here, however, is that regardless of how men and women of the past may have felt, experientially, from day to day, their *expectations* about how they should feel were very different from our own. That was as true in China as it was in Africa or Europe. For until at least the 18th century, men and women across the globe lived in societies that regarded, with good reason, suffering and scarcity as the norm. In societies such as these, happiness might be a hope or a dream, an aspiration or an achievement, or a turn of the wheel of fortune. But it was seldom an expectation, and rarely, even for the most privileged, was it assumed. That would only begin to change—and with powerful consequences—with the dawning of the great revolution in human expectations of the long 18th century.

The Revolution in Human Expectations

It is a striking fact that in 1800 the economic condition of the average human being in the world was no better than it had been in the Stone Age (Clark, 2007). Life expectancy was no better either, and average stature was actually worse. Despite impressive outliers—soaring cathedrals, great pyramids, palaces, and sprawling estates for the landed and wealthy—very little had changed in the economic history of the world.

But change was on the horizon, and indeed had already begun in Western Europe and its North American possessions, preparing the way for the tremendous economic takeoff of the Industrial Revolution and what historians now refer to as the "Great Divergence," the unprecedented economic gap that began to open up between the West and the rest in the late 18th century (Pomeranz, 2000). To look at a graph of average income since 1800 is to watch fortunes soar.

What was the place of happiness in this development? Some economic historians answer that it was considerable (McCloskey, 2016). They point out, for example, that towards the end of the 17th and the beginning of the 18th century, one can detect an important shift in Christian theological reflection, which began to speak less of deferring our happiness until the next life and more of making it here below. De-emphasizing sin and the fires of hell, Christians stressed instead God's benevolence and desire for our well-being during our earthly sojourn. Did not God want us to be happy? By mid-century, an erstwhile Calvinist like Benjamin Franklin was expressing amazement that Christians could reflect any other way. "'Tis surprising to me that men who call themselves Christians," he observed, "should say that a God of infinite perfections would make anything our duty that has not a natural tendency to our happiness" (Franklin, 1960). Increasing numbers of his contemporaries on both sides of the Atlantic were becoming convinced that the Creator would not. As the historian Roy Porter (2000) has aptly observed, the old question "How can I be saved?" was gradually giving way to the new question "How can I be happy here below?"

These changes in religious reflection, which increasingly sanctioned the pursuit of happiness on earth, were accompanied by a new rhetoric and apology for pleasure put forth by thinkers associated with the Enlightenment (McMahon, 2006). Inspired by the thought and example of Isaac Newton, they drew the conclusion that the universe was not random and chaotic, but ordered and predictable, governed by rational principles that could be ascertained through human reason. And if human beings could know and understand the natural world, then they could certainly know and understand the human world, a world of their own making. Setting themselves that task, they labored not only to understand, but to improve. Surely it was no sin to seek greater comfort in life, and to work to better our condition? And why should it be taboo to enjoy our own bodies and the pleasures of the world? Were not human beings constructed so as to pursue pleasure and to flee pain? Pleasure was natural and nature intended us to be pleased. Human beings, in short, were meant to be happy.

Thus, a growing Enlightenment confidence that humans being could control their fate was accompanied by a frank apology for pleasure and happiness. The two, in fact, were increasingly spoken of as one and the same. When the great English utilitarian philosopher Jeremy Bentham recommended that the "greatest happiness of the greatest number" be the standard by which we judge, he understood this to mean the maximization of pleasure and the minimization of pain (Bentham, 1996). Pleasure was good, pain was bad. We should work to spread the one and mitigate the other. That belief, in the 18th century, was widespread (McMahon, 2006).

And so the Enlightenment apology for happiness worked to undermine both the perennial view that saw happiness as a function of fortune—something we cannot ultimately control—and the longstanding assumption common to Christianity and the wisdom traditions that happiness was a product of superior virtue or grace, a rare and special achievement in a world in which suffering was the norm (McMahon, 2004). "Does not everyone have a right to happiness according to his whims?", asked one 18th-century observer in that bible of the Enlightenment, the French *Encyclopédie*. Judged by historical standards, the question was remarkable: a right to happiness?! And yet it was by no means an isolated claim, reflecting a growing belief that justice demanded the happiness of all. Since human beings were meant to be happy, it followed that when they were not, there must be a reason—injustice or false belief, oppression or individual failure. Governments, accordingly, should work to provide the conditions in which human beings could flourish. "The happiness of society is the first law of every government," declared the American founding father James Wilson (2007). The French Jacobin constitution of 1793 imbedded the assumption in its very first article: "The goal of society," it declared, "is common happiness." Here was a creed for a new age.

It was also a creed for a new economy. For regardless of the precise role played by Enlightenment-era discussions of happiness in fostering the economic take off that ensued, clearly an apology for earthly happiness and material improvement was conducive to economic growth. And clearly economic growth—with a new culture of consumption proffering luxury items, comforts, and pleasures to expanding segments of the population—was conducive to the belief that suffering need not be an unfailing law of the universe. As the 18th-century French economist and administrator Anne Robert Turgot observed, in modern commercial society men and women "buy and sell happiness" in the form of discrete packets of pleasure. Modern economies, it seemed, lent themselves perfectly to happiness's pursuit.

Whether they lent themselves to happiness's attainment was another matter. That claim, of course, would be hotly contested in the 19th and 20th centuries, with socialist and Marxist critics of capitalism, among others, charging that it did no such thing. But what united all parties in the dispute was the common assumption that happiness is, and ought to be, the human due. This was the novel consequence of the revolution in human expectations of the long 18th century. The dramatic economic growth that followed, however imperfectly distributed between countries and classes, only fed those expectations, spreading the demand for happiness ever wider. Already, in the middle of the 19 th century, the Scottish critic Thomas Carlyle could draw attention to this remarkable transformation, noting that "Every pitifulest whipster that walks within a skin has had his head filled with the notion that he is, shall be, or by all human and divine laws ought to be, 'happy.'" Carlyle was a skeptic, a dissenter to the new creed of happiness as our "being's end and aim … not yet two centuries old in the world" (Carlyle, 1965). Yet he had put his finger on the way in which that creed had a tendency to crowd out other organizing principles of life, as well as to spread downward and outward to formerly marginalized segments of the population. Notwithstanding two world wars and the incalculable tragedies of the 20th century, it has continued to do so, hastened since the 1960s, as the philosopher Pascal Bruckner has argued, by the expansion of personal credit and an ascendant individualism that has further licensed an ethic of personal fulfillment and non-delayed gratification. Happiness, today, Bruckner (2011) observes, constitutes "the only horizon of our modern democracies." Meanwhile, globalization in the wake of decolonization, notwithstanding its other effects, has begun to narrow the economic gap that opened up with the Great Divergence, exposing hundreds of millions more (above all in China, India, and the emerging Asian economies) to the prospect that happiness on this earth might be more than good fortune or a millenarian dream. The fact that today the United Nations, along with Gallup, the OECD, and other international organizations, collect data on happiness in every country of the world is a sign of this expansion, an indicator of the aspiration that all might be happy one day and that we should work to make it so. The overall significance of this expansion, however, in historical terms, and the "meaning" of the rise of a global conversation about happiness is not yet clear (McMahon, 2010).

Conclusion

In this brief essay, I have examined three major developments in the history of human happiness, presenting the departure from our hunter-gatherer past at the time of the Agricultural Revolution, the emergence of the wisdom traditions of the "Axial Age" of the first millennium BCE, and the "Revolution in Human Expectations" of the long 18th century as crucial turning points in humanity's experience and understanding of happiness. Judging by a number of indicators, there is reason to conclude that the first revolution was on balance detrimental to the happiness of the many, even as it provided new opportunities to the few. In hostile and unpredictable environments of relative scarcity and insecurity, suffering was regarded as the human norm, while happiness was represented as largely beyond our agency and control, a fortunate condition bestowed by the gods or luck, and seldom lasting or assured.

Yet this prevailing and perennial conception—common to virtually all early societies and kept alive in

the folk cultures of many peoples to this day—was profoundly challenged by the great religious and philosophical traditions of the Axial Age. Taking up the problem of human suffering, they sought means to address it, asserting collectively that human beings do not live by bread alone. True happiness, they agreed, involved a "going beyond" conventional prosperity and the ordinary conditions of life in the pursuit of a higher happiness predicated on the cultivation of human virtue and excellence. Retaining the view that happiness was a rare exception and human suffering the norm, they nonetheless wrested human flourishing away from the clutches of fortune, making it in large measure the product of human will and action aligned with what were deemed the transcendent forces of the universe.

In a very general way, these were the basic orientations on human happiness that held sway in most parts of the world until the 18th century, when a revolution in human expectations began to alter perspectives on the prospects for happiness in this life. Forthrightly hedonic in their equation of happiness and good feeling, these new perspectives presented happiness neither as a matter of chance nor as a reward for superior virtue. Happiness, rather, was treated as a natural endowment, whose pursuit and attainment would follow from the mitigation of pain and the removal of "unnatural" barriers, such as injustice and false belief, that stood in its way. Coinciding with the beginnings of a remarkable economic transformation that continues to this day, this revolution had the effect of gradually eroding the older, eudaimonic perspectives on happiness that had long equated human flourishing with virtue of character.

Needless to say, this revolution occurred only slowly and imperfectly. Yet the dominant ideological systems of the 19th and 20th centuries helped to spread the prospect of happiness to ever wider segments of the world's population, radiating outward from Europe and the New World, so that today more people than ever before are being raised in environments that inspire the pursuit of earthly happiness and encourage expectations that it will be found.

Whether or not such pursuits and expectations correspond to actual increases in levels of happiness is a matter of considerable debate within the contemporary social scientific community, which has pioneered efforts in the last several decades to measure happiness around the world, and to analyze its causes and correlates in relation to economic conditions and other variables. To a significant degree these efforts have drawn on, and contributed to, the new "science of happiness" pioneered by positive psychologists, who have also turned their attention of late to better understanding happiness's foundations. Working together, they hope to help not only individuals, but governments and policymakers, shape better policies and prescriptions for the future.

From the perspective of the student of history, it is noteworthy that there have been significant overlaps between the "modern truths" of the new science of happiness and "ancient wisdom," particularly the eudaimonic insights of the Axial traditions and their post-Axial successors (Haidt, 2006; McMahon, 2016). Research on gratitude, for example, or on charity and loving kindness, meditation and meaning, forgiveness and hope has demonstrated the benefits of these "virtues" in encouraging flourishing lives. Such research would suggest that those who spearheaded the revolution in human expectations initiated in the long 18th century may have been too quick to denigrate and displace the older insights of the Axial traditions. Whether those insights can now be updated with the imprimatur of science and adapted to cultures that have largely accepted the hedonic and democratic consequences of the 18th-century revolution in human expectations remains to be seen. The history of happiness, and in particular the first great revolution examined here, cautions against any facile assumption that "progress" and happiness necessarily go hand and hand. But it also makes room for the possibility that they can advance together. For those hoping to use the knowledge about happiness being generated by researchers today to better guide the policies and prescriptions of tomorrow, aligning the two will be the great challenge, and historians have a role to play in this alignment by further clarifying the relationship between happiness and progress/historical change in the past. Should we succeed in our collective endeavors, we may hope, however modestly, to contribute to the beginnings of a new revolution in the happiness of the world.

Religion and Well-being

By David B. Newman, University of Southern California; Jesse Graham, Eccles School of Business, University of Utah

Abstract

Religion plays an important role in the lives of many people. To understand how religion relates to well-being, it is important to consider the beliefs and practices of the world's main religions. In the first section, we begin by describing how various religions define well-being and how religions envision God. Next, we outline various beliefs about the afterlife and key religious teachings that may affect well-being. In the second section, we describe how religious practices such as prayer, meditation, and fasting could influence one's well-being. We conclude by arguing that it is crucial to consider the specific beliefs and practices of religions to understand more fully how religion relates to well-being.

Keywords: Religion, Well-being, Overview

Religion is a central part of the lives of many people. According to one estimate, 68% of humans claim that religion is an important part of their lives (Diener, Tay, & Myers, 2011). According to a 2016 Gallup poll, roughly 51% of Americans attend church or synagogue once a month or more frequently (Gallup, 2016). Given the paramount role of religion in many people's lives, it is important to understand how religious beliefs and traditions could relate to individuals' well-being.

Research suggests that people who engage in religious activities report higher levels of well-being (Diener et al., 2011; Hackney & Sanders, 2003; Oishi & Diener, 2014). More specifically, religious individuals report higher levels of life satisfaction and positive feelings in the US (Diener et al, 2011) and lower levels of depression in the US and Europe (Smith, McCullough, & Poll, 2003). These effects tend to be small and positive, and the effects also depend on the level of analysis (Tay, Li, Myers, & Diener, 2014). For example, within countries, religion can fulfill needs such as a sense of belonging and community affiliation, which promote well-being. Between countries, religious practices could increase volunteerism and altruistic behaviors. The relationship between religiosity and well-being in non-western nations also appears to be positive but weak (Tay et al., 2014).

In many of these studies, religiosity has typically been measured with a single item, such as "Is religion an important part of your daily life?" or "Thinking about your life these days, how often do you attend religious services, apart from social obligations such as weddings or funerals?" Although such measures could be informative in predicting well-being, specific religious beliefs and practices could relate to well-being in nuanced ways. In order to more fully understand the complex relationship between religion and well-being, researchers should carefully consider what religions *say* about well-being. The goal of this chapter is to provide an overview of these teachings, and of how the beliefs and practices of the major world religions relate to well-being.

To provide an overarching framework to this chapter, we rely on the distinction of *doxis* vs. *praxis* often used to define religions (e.g., Snoek, 1999). *Doxis*, from the Greek word *doxa*, refers to worldviews, beliefs, and thoughts, whereas *praxis* refers to actions, rituals, and practices. Religions are often defined by these two characteristics. Given these two dimensions, we believed it would be helpful to use this distinction in framing our chapter.

To narrow our focus within each of these broad dimensions of religion, we rely on the conceptualizations of religion developed by Ninian Smart (Smart, 1998, 1999). According to Smart, a religious framework is composed of seven dimensions: narrative/mythological, doctrinal, ethical, institutional, material, ritual, and experiential (Smart, 1999). These dimensions capture the broad and encompassing nature of religion. The *narrative dimension* refers to the foundational stories of a religion, passed down through history either orally or written. These stories often concern the religion's founder. The *doctrinal dimension* is related to the narrative dimension as it refers to the philosophical nature of the religion, such as the nature of God. Next, the *ethical dimension* refers to the rules or laws of a religion. The *social or institutional dimension* concerns the organization and gathering of a religious community, for example in a church, mosque, or temple. Religions typically designate a particular day of the week for worship in addition to particular days of celebration or remembrance during the year. Somewhat related, the

material dimension refers to specific places and artifacts that are of particular importance to a religion. The *ritual dimension* concerns the specific practices in which religions express themselves, such as prayer and meditation. Finally, the *experiential dimension* refers to the strong emotional experience connected to the rituals that provide them with meaning.

The advantage of such an organization and framework allows one to categorize and define a religion. Of course, debate continues as to the best way to do this and whether it is even possible (cf., James, 1902). Putting this debate aside, we opted to use a common-sense approach by describing the main world religions. Most individuals are familiar with the names used to define the world's core religions, and some scholars categorize religion using these common labels (e.g., Christianity, Judaism, Hinduism, etc.; Smith, 1991). Similar to Smith's categorization, we believed that fine distinctions between particular religious denominations, such as the difference between Baptists and Presbyterians, would not be fruitful for a concise overview. Therefore, we have opted to rely on Smart's dimensions of religion to guide our discussion of how religion relates to well-being while still referring to core religions. After discussing the main topics and dimensions, we will provide examples from the major world religions, such as Christianity, Judaism, Islam, Hinduism, and Buddhism.

In the first half of the chapter we cover *doxis*, religious beliefs and thoughts. First, we describe how religions conceptualize well-being. Next, we discuss how various religions conceive God (e.g., as a forgiving and loving father, as a harsh and powerful entity) and how these conceptions might relate to well-being. Following this, we depict various beliefs of the afterlife and how these thoughts could influence one's current well-being. Finally, we outline various key rules and guidelines that religions endorse and what role these rules play in influencing one's well-being. Finally, in terms of Smart's dimensions, *doxis* covers the narrative, doctrinal, and ethical dimensions.

The second half of the chapter covers *praxis*, the rituals and practices of religions. We begin with a description of many common rituals such as prayer, meditation, fasting, religious services, pilgrimages, and festivals and holiday celebrations. In each of these sections, we discuss the emotional or experiential aspect that accompanies these rituals. These rituals and practices overlap with Smart's social, material, ritual, and experiential dimensions. The chapter concludes with a section on implications for well-being research.

Doxis

The key beliefs and thoughts discussed in this section cover religious conceptions of well-being, envisagement of God, beliefs about the afterlife, and ethical teachings.

Conceptions of Well-being

Before discussing how religions define well-being, it is important to delineate different types and definitions of well-being used by researchers. One broad and helpful way of classifying well-being is through the hedonic vs. eudaimonic distinction (Ryan & Deci, 2001). Hedonic well-being refers to pleasure and positive feelings. The goal of striving for as much pleasure and hedonic well-being as possible was even endorsed by the philosophers Aristippus, Epicurus, Hobbes, Locke, and Hume (Joshanloo, 2013a). In contrast, eudaimonic well-being refers to a sense of meaning, purpose, and fulfillment in life. Plato, Aristotle, and Fromm endorsed this type of well-being by suggesting that it was more worthwhile to strive after virtue than hedonic happiness (Ryan & Deci, 2001).

Empirically, hedonic well-being typically includes measures of positive emotions, negative emotions, and life satisfaction. Someone experiencing high levels of hedonic well-being is assumed to experience high levels of positive emotions and life satisfaction, and low levels of negative emotions. A common way of categorizing some of these measures is through the term subjective well-being, which consists of positive emotions, negative emotions, and life satisfaction (Diener, 2000). Positive and negative emotions define an affective well-being component, and life satisfaction defines a cognitive well-being component.

Specific definitions and measures of eudaimonic well-being definitions often vary. Measures of eudaimonic well-being include self-acceptance, positive relations with others, autonomy, environmental mastery, purpose in life, personal growth (Ryff, 1989), meaning in life (Steger, Frazier, Oishi, & Kaler, 2006), vitality, and self-actualization (Ryan & Deci, 2001). Despite the many different measures used to capture eudaimonic well-being, researchers tend to believe that eudaimonic well-being is some form of well-being that extends beyond pleasant emotions and feelings.

A useful way of categorizing the well-being types is through the categories of evaluative, experiential, and eudaimonic (Schwarz & Strack, 1999; Steptoe, Deaton, & Stone, 2015). Evaluative refers to judgments of life satisfaction; experiential refers to emotions, often captured in real time through the use of ecological momentary assessment techniques (Shiffman, Stone, & Hufford, 2008); and eudaimonic refers to a sense of meaning and purpose in life. In terms of the broader distinction between hedonic and

eudaimonia, evaluative and experiential would fall under the hedonic category.

With this categorization in mind, it is important to understand what happiness and well-being mean in different religious contexts. Certain differences in relationships between religious practices and well-being could stem from how religions define well-being. In Judeo-Christian traditions, two primary Hebrew words are used to refer to happiness: *ashrey* and *smh* (Charry, 2010). *Ashrey* is often translated as "blessed" or "happy" although it does not refer to a subjective pleasant state or feeling. This word is often found in the Psalms and the book of Proverbs. Typically, this word is used in connection to God and God's teaching. Grammatically, *ashrey* always accompanies another noun to describe the meaning of the word. For example, Psalm 1 begins with the word *ashrey*: "Blessed (*ashrey*) is the man who does not walk in the counsel of the wicked…." One would not use the word *ashrey* as a self-descriptive adjective the way one might use the word happy in contemporary language (e.g., "I am happy").

In Greek, *ashrey* is translated as *macarios*, which could also be defined as happy or blessed. The word *macarios* is the word used often in Jesus' sermon on the mount. Here the word *macarios* is used in a similar way to its use in the Old Testament, in connection to God's commands (e.g., "Blessed (*macarios*) are those who hunger and thirst for righteousness…"; Matthew 5:6).

The word *ashrey* has been defined somewhere in between hedonic and eudaimonic well-being (Charry, 2011). Although it is often translated as happy, its meaning is certainly different from a pleasant emotional state one might experience at a party. Perhaps *ashrey* could be considered closer to eudaimonia as it refers to a sense of "enduring pleasure, contentment, satisfaction…" (Charry, 2011, p. 244), but this must be connected to a life characterized by obedience to God's commands.

The Hebrew word *smh* also means happiness and is found often in the book of Psalms. In contrast to *ashrey*, however, *smh* is more closely related to a positive feeling (Charry, 2010). *Smh* can also be used self-referentially (e.g., "I am happy") and would be categorized as a form of hedonic well-being. Thus, happiness in the Old and New Testaments can refer to both hedonic and eudaimonic well-being.

The concept of happiness or well-being in Islam is also a complex one. It has often been defined in terms of physical, social, mental, and spiritual health (El Azayem & Hedayat-Diba, 1994). Similar to Christianity and Judaism, the concept of happiness is connected to having faith and practicing that faith, i.e., by obeying commands (Joshanloo, 2013a). Furthermore, the Islamic culture views true happiness as inner peace that comes from devotion to God (Joshanloo, 2013a). In terms of the hedonic vs. eudaimonic distinction, the goal of Islam is not to maximize positive emotions or minimize negative emotions (Quran 7:169). Thus, this would seem to favor a eudaimonic goal. However, the Quran also says that Muslims who follow customs, laws, and lifestyles will experience positive emotions, suggesting some hedonic benefits of the devout life as well (Joshanloo, 2013a). Moreover, Islam values low arousal positive emotional states over high arousal positive emotional states, a finding consistent with some cross-cultural research (Tsai, 2007). Thus, the concept of happiness or well-being in Islam consists of both low-arousal hedonic and eudaimonic aspects.

In Buddhism, the concept of well-being is often connected to a practice and cultivation of an equanimity mindset that is achieved through meditation. One must first realize that life is suffering (the first Noble Truth). From this realization, there are multiple steps one should take, outlined in the Eightfold Path, such as practicing mindfulness and compassion. One purpose of these steps is to detach oneself from the desires of the world. In light of these teachings, happiness is sometimes defined as the state beyond bliss that is achieved through right concentration and meditation. Thus, the type of happiness one should strive to achieve does not refer to the hedonic definition of happiness described and sought after in many western cultures.

In Hindu traditions, one of the key objectives is *kama*, which can be defined as pursuit of sensual pleasures, broadly defined. That is, *kama* refers broadly to all senses involved in aesthetic experiences, such as romantic love and the appreciation of beauty in music, art, and food. This concept relates to the notion of hedonic and eudaimonic well-being. Furthermore, this pursuit of sensual pleasures should not be pursued over other primary objectives, such as the pursuits of righteousness (*dharma*), economic prosperity (*artha*), and release from sorrow (*moksa*). Thus, the concept of well-being may not be as highly prioritized as some other values.

Finally, it is important to briefly describe the moral concept of pursuing happiness across religions. In Christianity, for example, Jesus taught people to value the pursuit of a life with God rather than a pursuit of hedonistic pleasures. Jesus once spent 40 days fasting to spend time with God. His teaching to pursue God rather than pleasure evolved somewhat in the Middle Ages such that Christians believed the pursuit of happiness to be morally corrupt. In Islam, the pursuit of hedonism has been discouraged since the original writings of the Quran (Joshanloo, 2013b). Even modern Muslim teachings oppose the pursuit of hedonic well-being, although extreme asceticism and celibacy is also not advocated (Husain, 1998). The Buddha

denounced a life of pleasure after becoming aware of sickness and death; He led a life of asceticism until receiving enlightenment. One of the Buddha's teachings was that desire, including sensual desire, was a cause of suffering. In sum, the main world religions do not teach their followers to pursue happiness as characterized by a hedonistic lifestyle. Rather, they instruct their followers toward a pursuit of deeper meaning, such as connection to God or a state of mindfulness through meditation. In this way the major world religions, by urging against simple pursuit of pleasure but promising deeper meaning and purpose, embody the hedonic/eudaimonic distinction in the modern science of happiness.

Conceptions of God/gods

The way in which one views God or other supernatural powers could potentially influence well-being. For example, viewing God as a harsh, judging figure can lead people to cheat less (Shariff & Norenzayan, 2011). This action may follow from a sense of fear of punishment that could lower one's well-being. The specific views that religions have about God -- from the metaphysical nature of God to what God is like -- can affect people's well-being as well.

In Christian and Judeo traditions, the nature of God is quite complex. On the one hand, God is viewed as a powerful, judging God. For example, when God sends a flood to destroy mankind with the exception of Noah and his family, God clearly shows power. He is also viewed as a judging God who does not tolerate sin. Such patterns are seen in the Old Testament in various instances, such as the flood during the time of Noah. On the other hand, the God of the Bible is also viewed as a loving father who cares for His children and who forgives those who repent. This view is exemplified in particular in the New Testament, as Jesus welcomes children to come to Him, places them in His arms, and blesses them (Mark 10: 13-16). In numerous occasions, Jesus also forgave those who had sinned (e.g., a paralyzed man, Matthew 9; those who crucified Him, Luke 23).

These particular views of God can lead to different well-being outcomes. Imagining God as a punishing God could lead to a sense of fear which could lower one's well-being, particularly if one believes the sins committed are not forgivable. In contrast, imagining a loving God who desires a personal relationship with people could provide one with a greater sense of hedonic and eudaimonic well-being. The mechanisms explaining how social relationships could increase well-being could be similar to the mechanisms explaining how a relationship with a kind and loving God could increase well-being. This likely improves both hedonic and eudaimonic aspects of well-being.

In Islam, God is viewed as a powerful creator who can judge and also as a merciful and compassionate God. In a similar manner to the Christian view of God, this juxtaposition could have diverse effects on well-being. In contrast to the Christian view of the Trinity (i.e., God as three persons in one), Muslims believe in a monotheistic God, i.e., God as a single entity. They also believe that God cannot be fully comprehended, but they believe it is possible to have a personal relationship with God. That is, no intermediary is necessary to communicate with God.

The view of God in Hinduism and Buddhism is a bit less straightforward. There are various different views in Hinduism about the nature of god, whether one even exists, whether multiple gods exist, etc. Some Buddhists, such as those part of the Theravada school, follow the teachings of Buddha, but they would not consider Buddha God in the same way that Christians refer to Jesus as God or the way Muslims refers to Allah as God. Buddhists who are part of the Mahayana school, in contrast, consider Buddha as a god. Among the various schools of Buddhism, a main focus seems to center on the practice of teachings rather than on the nature of God. We will return to the effect of these teachings on well-being in a later section.

Beliefs about the Afterlife

Another aspect of Smart's doctrinal dimension concerns beliefs, specifically regarding views of the afterlife. Similar to common values, these beliefs can have important and somewhat complex associations with well-being.

A common belief among some of the main world religions is the belief that the afterlife consists of some form of heaven and hell. In the US, for example, 85% of Christians and 89% of Muslims reported believing in heaven; 70% and 76% of Christians and Muslims, respectively, believe hell exists (Pew Research Center, 2014a). Islam describes heaven as a place filled with joy and happiness, also referred to as paradise (*Jannah*). Christianity describes heaven as the dwelling place of God (Psalm 33), paradise (Luke 23), and where the streets are paved in gold (Revelation 21). Hell, in contrast, is described in Islam as a place of blazing fire. In Christianity, hell is often depicted as a place of weeping and gnashing of teeth.

According to Christian and Islamic traditions, people will face a day of judgment and their fate will be determined, often by what they have believed or done while on earth. A common belief seems to follow the saying that one will reap what one has sown. Good deeds and actions will be rewarded, whereas bad

deeds will be punished.

This view of the afterlife and judgment can certainly influence well-being. One psychological theory that pertains to these beliefs is systems justification theory (Jost, Banaji, & Nosek, 2004), which states that individuals want to hold a favorable view of themselves and a positive attitude about the system and how it is organized. Although the system often refers to current political and economic situations, it can be applied to beliefs about the afterlife. Some empirical work suggests that the belief in a just world in which one can rationalize inequality relates positively to life satisfaction (Napier & Jost, 2008).

Although Christianity and Islam believe in some sort of reward and punishment system, it is important to make a distinction between different views about how one can enter heaven. According to some denominations of Christianity, one enters heaven by committing good deeds or actions (e.g., going to church/mass, giving money to the poor, etc.). When asked about whether one will go to heaven, this view may cause some uncertainty, stress, and worry (e.g., "have the good deeds I have done outweighed the bad ones?"), which could lower one's well-being. In other Christian denominations, salvation is not earned by deeds committed by the individual, but rather it is granted by grace, a sacrifice made by Jesus on behalf of those who believe in God. This view of salvation by grace likely promotes a sense of calm, relief, and joy which could increase well-being. This distinction between belief in salvation by grace vs. works -- and its relationship to well-being -- remains a fruitful avenue for future research.

According to Islamic traditions of the afterlife, both notions of grace and works are important. On the one hand, Muslims are instructed to pray daily, give to the poor, and fast; they are rewarded based on these actions. On the other hand, entering Paradise is ultimately based on God's grace. According to one hadith by the Prophet Muhammed, "No one of you will enter Paradise by his deeds alone." They asked, "Not even you, O Messenger of Allah?" He said, "Not even me, unless Allah covers me with His Grace and Mercy." Some scholars believe that entering Paradise depends on God's grace, and the level in Paradise depends on one's actions. Clearly, grace and action play important roles in understanding the afterlife in Islam.

Related to the notion of the afterlife is the belief in *karma*, common in Buddhism and Hinduism. According to these religious traditions, karma represents a cycle of suffering and rebirth. Actions and events that occur in one's life could be the result of the actions of one's life, either in one's own past or from a past life. The general belief is that actions may have consequences in the future. The good deeds could be rewarded by a higher being. In terms of one's well-being, this belief could lead to exaggerated reactions to positive and negative events. For example, when a negative event occurs, one might believe that God is punishing them even though they did nothing wrong at the present time. Alternatively, when positive events occur, one might receive a boost in momentary happiness if one believes that this positive event is a reward for a previous action.

Ethical Teachings

There are certain teachings that are common across many or all of the main religions of the world. These teachings express moral values, rules of conduct, and ethical principles. Here we describe a few of these common rules and teachings and explain their relationship to well-being.

The first is the "golden rule," which states that you should do to others as you would have others do to you. Practicing this principle should increase one's well-being in multiple ways. It could increase one's eudaimonic well-being by providing one with a closer sense of connection to another. It could also provide a reciprocal effect in which the recipient of the kind act could become happier which could reflect positively on the benefactor. Empirically, some research suggests that people tend to report greater well-being on days when they engage in eudaimonic behaviors, such as volunteering, in comparison to days when they engage in hedonistic activities, such as attending a party or getting drunk (Steger, Kashdan, & Oishi, 2008). However, doing unto others as one would do unto oneself could also result in lower well-being if these actions require one to sacrifice certain needs that would otherwise increase well-being, such as autonomy. In fact, when Mother Theresa was engaged in helping the poor, she often felt sad, unhappy, and lonely (Ward & King, 2016; Zaleski, 2003).

Related to golden rule, according to many religions, it is considered better to give than to receive. In Islam, for instance, individuals are told that true enrichment comes primarily from the soul. Secondary importance is placed on material wealth. In Christianity, money is listed as the root of all evil. Pursuing money can be considered an idol and can lead to greed. Instead, individuals are told to give away a portion of money back to God as a tithe. It is often said that it is better to give than to receive. In contrast, according to the Hindu principle of *Artha*, one should actually pursue wealth or material well-being. Buddhists believe that money is not intrinsically evil or wrong, but it could be used for the wrong reasons.

Research has shown that there is a positive relationship between income and well-being, but the

positive effects tend to slope off around yearly salaries of $75,000, depending on the specific well-being indicator (Kahneman & Deaton, 2010). The way one spends money, however, can influence one's well-being (Dunn, Gilbert, & Wilson, 2011). Spending money on others, for example, can actually increase momentary well-being (Dunn, Aknin, & Norton, 2008). Presumably, the act of prosocial spending fosters social relationships and can make one feel good about oneself.

Many of the world religions encourage its followers to express gratitude. Christians are called to give thanks in all circumstances (1 Thessalonians 5:18) and express gratitude to God (Psalm 118). The Quran mentions that the soul will profit by being grateful (Quran 31:12). The Buddha taught his followers to express gratitude as well. Empirical research suggests that expressing and feeling grateful can increase one's well-being (e.g., Emmons & McCullough, 2003; Nezlek, Newman, & Thrash, 2017; Seligman, Steen, Park, & Peterson, 2005). Relatedly, it is commonly taught that one should not worry. For example, Christians are commanded to not be anxious about anything (Philippians 4:6). Removing worry can alleviate stress and improve well-being.

Similarly, many of the world religions encourage or teach their followers to forgive one another of their wrongdoings. The act of simply belonging to a religious group could even increase the likelihood that one would forgive others (Wuthnow, 2000). Individuals who tend to forgive others report higher self-esteem and lower anxiety and depression (Hebl & Enright, 1993). The process or act of forgiving someone could increase one's well-being by lowering grief, anger and anxiety (Coyle & Enright, 1997). In one study examining forgiveness behaviors over time, benevolence toward an aggressor was positively related to satisfaction with life, positive mood and was negatively related to negative affect (Bono, McCullough, & Root, 2008). Thus, the teaching to forgive another of their wrong could help improve one's well-being.

Moreover, one should not compare oneself with others, but rather should be content with what one has. The Bible often warns people to not compare them with others, but to think about how God views them. In Islam, individuals are actually encouraged to look at those below them, i.e., those less fortunate, and not to look above them. Research suggests that comparisons can alter the standard to which one makes a judgment (e.g., Bless & Schwarz, 2010).

In addition to these relatively straightforward ways of attaining happiness, some religious teachings concerning well-being are actually counterintuitive. For example, one of the Beatitudes from Jesus' Sermon on the Mount says, "Blessed are those who mourn, for they will be comforted." As described previously in this chapter, the word for blessed here is the Greek word *macarios* which is roughly equivalent to the Hebrew word *ashrey*, meaning happy or blessed, but typically in reference to obedience of God's commands. Another counterintuitive Beatitude says, "Blessed are the meek, for they will inherit the earth." The second half of each of these verses provides some insight into how those who mourn and those who are meek will be happy. Nevertheless, these teachings do not converge with commonsense views of how to become happy. Finally, at the end of the Beatitudes, people are told to rejoice and be glad when others insult and persecute them because of God. They are told that their reward in Heaven will be great.

These teachings actually overlap to some extent with the teachings concerning how one should handle negative experiences. According to the Hindu principle of *moksa*, one can find liberation from sorrow. The goal is to achieve a level of bliss or happiness by understanding one's soul. This should help one in the midst of life's setbacks. That is, one can actually experience happiness in the face of tragedies. Buddhist wisdom says that the mind should be balanced and that mental training can help one maintain a level of happiness in the face of life's difficulties. As discussed previously, Christians can expect to suffer and those individuals should be considered blessed and happy if the suffering comes because of their faith. In a similar manner, Islam preaches that God tests people through hardships. This knowledge can actually help one cope with suffering and could increase one's well-being in the long term.

Praxis

The second section of the chapter concerns religious practices and behaviors and how they relate to well-being. The description of these practices and behaviors conceptually overlap with various dimensions outlined by Smart, such as ritual, ethical, and institutional. We begin with a section on religious rituals. The goal of this section is to provide a broad overview of some of the main rituals common across the main world religions. It is beyond the scope of this chapter to cover every ritual, so we will focus on acts of prayer, meditation, fasting, worship services, pilgrimages, and holiday festivals and celebrations.

Prayer

According to a Pew Research Center poll, 55% of Americans pray on a regular basis (Pew Research Center, 2014b). Some form of prayer or communication with a higher being is described in many religions, although the exact form of prayer may vary from religion to religion. In Islam, for example, prayer is a mandated part of their religion as one of the five pillars of Islam. Muslims are required to pray five times a

day; parts of these prayers involve reciting sections of the Quran in Arabic. In addition to these obligatory prayers, Muslims may pray voluntarily, and additional congregational prayers occur as well. Obligatory or congressional prayers are also often performed in various Catholic and Anglican denominations. Many Christian traditions have prayers that are recited from passages in the Bible, but there is also great emphasis on voluntary prayers. These prayers occur at various times during the day. In fact, Christians are called to pray without ceasing (Thessalonians 5:17). Prayers are often regarded as conversations with God. Specific categories of topics such as adoration, confession, thanksgiving, and supplication are often taught as a guideline for how one should pray. Prayers among Hindus and Buddhists are also important aspects of their worship. Sometimes prayers occur in private in the face of a deity (e.g., an image or statue) or in larger congregations.

Given the nuances and different types of prayer, the relationship to well-being could be complex. Prayers should help one feel connected or closer to God, and this could influence well-being depending on how one views God (e.g., as a loving father or as a judgmental ruler). The effects of obligatory prayer on well-being may dissipate with time given the habitual nature. Voluntary prayers may have a stronger influence on well-being or could be the result of some event which could have a strong influence on well-being (e.g., a negative event occurs which causes one to feel sad and to pray). The content of the prayer could influence well-being in different ways. Some research suggests that individuals who engage in prayers of thanksgiving and adoration tend to be happier that those who do not, whereas those who engage in obligatory prayers, and prayers of confession and supplication tend to report lower levels of well-being (Whittington & Scher, 2010). Of course, further research is needed to understand the effect of these processes on well-being. Additional research is required to understand the effect of prayer location (e.g., whether one is in isolation or with others) on well-being.

Meditation

Related to prayer, meditation and mindfulness techniques involve some type of quiet reflection, an emptying of one's thoughts, and a time in which one is not disturbed or distracted by external stimuli or environmental factors. In Buddhist traditions, meditation involves a focus on a narrow or specific object, such as one's breath. Next, the goal is to be mindful of one's environment and surroundings while still remaining calm and focused on the narrow object. In Hindu traditions, the goal of meditation is to become one with God. Although people commonly associate meditation and mindfulness to Buddhism, meditation and mindfulness techniques are also practiced in Christian traditions. Christians are often called to meditate on God's Word (i.e., the Bible) by considering the commands and reflecting on them.

Research suggests that mindfulness can lower one's stress and increase well-being (e.g., Brown & Ryan, 2003). The exact mechanisms explaining how and why mindfulness techniques improve well-being is an active area of research (e.g., Gu, Strauss, Bond, & Cavanagh, 2015). Future studies can examine whether these processes exist within religious contexts as well.

Fasting

Another common ritual in many religions is fasting. Similar to meditation, the goal of fasting is to become less focused on a particular external distraction. In Islam, fasting is one of the five pillars. Muslims are called to fast from dawn to sunset each day during Ramadan. The goal is to feel more closely connected to God, and this could increase a feeling of attachment to God. Because all Muslims are called to fast during the same time, it could also promote a sense of belonging and connection to others which could increase well-being. Hindus will often fast on particular days of the month or even specific days of the week. It can also occur during religious festivals and holidays. Buddhists will often fast during spiritual retreats and it accompanies meditation. In many Christian denominations, fasting involves not only abstinence from food, but emphasis is placed on devoting oneself to God and Biblical commands. This emphasis on a connection to God, similar to the other religions during fasting, likely increases one's well-being.

Of course, fasting could occur with more negative thoughts and feelings. In Judaism, for example, fasting often occurs with sorrow. The two most common days of fasting are on Yom Kippur and Tisha B'Av. Yom Kippur is known as the day of repentance or atonement. This is typically a sorrowful day as one reflects on and repents for one's sins. Tisha B'Av is a day meant for remembering tragedies that have happened to the Jewish people. Thus, the act of fasting on these days likely occurs with lower levels of well-being. Thus, the act of fasting may lead to increases or decreases in well-being depending on the specific contexts.

Worship Services

Religious services and community worship are important ritualistic experiences that have important implications for well-being. In Christian and Jewish traditions, fellow believers gather together at a church,

cathedral, or synagogue for worship. At worship services, people hear the word of God, often through the preaching of a pastor, priest, rabbi, or spiritual leader. Songs are often sung and passages of the Old Testament or Scripture are read aloud. In some denominations, attendance is considered obligatory, whereas attendance is voluntary in others. Muslims also gather together for worship, but the emphasis of meeting at a mosque is typically for prayer and a reminder. An imam will deliver a homily or short speech on Fridays, but the meeting or gathering follows a different format from Christian or Jewish worship services. Hindus and Buddhists often meet together for temple worship even though emphasis is also placed on private worship. Buddhist monks will often live together in intentional and/or monastic communities.

Being together in community can fulfill needs for affiliation and belonging, which can increase eudaimonic well-being. Community can also provide encouragement, laughter, and joy, which could increase hedonic well-being. A gathering together for the purpose of worship provides individuals with a sense of unity and it binds people together (Graham & Haidt, 2010). These gatherings also provide individuals with a social support system that could increase well-being (Salsman, Brown, Brechting, & Carlson, 2005).

Pilgrimages

An example of another community activity is a pilgrimage, a form of which is present in most of the main world religions. In Islam, Muslims are obligated to take a pilgrimage to Mecca at some point in their life as this is one of the five pillars of Islam. The pilgrimage involves sleeping in various desert plains, walking around the Kaaba in Mecca, and walking between Mount Safa and Mount Marwah.

In other religions, pilgrimages are not required but are often undertaken by a substantial portion of followers. In Hindu traditions, for example, various cities in India are visited which are considered to be holy. Some Christians will take trips to the Middle East to visit important sites described in the Old and New Testament. An important pilgrimage among Catholics is the Camino de Santiago (aka Way of St. James), a route that culminates in a visit of the Cathedral of Santiago de Compostela in Spain. The culminating purpose of this pilgrimage is to visit the remains of Saint James, who is believed to be buried in Santiago de Compostela.

Pilgrimages, when done with other fellow believers, can have similar positive effects on one's well-being as worship services. These acts likely bind people closer together, providing them with a sense of closeness and bonding. These pilgrimages can also instill experiences of awe and wonder, experiences that often covary with well-being (e.g., Rudd, Vohs, & Aaker, 2012).

Celebrations of Holidays and Festivals

Festivals and holidays can be times of great celebrations and exuberance, times of somber reflection, or some mix of the two. In Christian traditions, the celebrations of Christmas and Easter are oriented around the birth and resurrection of Jesus. These days of celebration are joyous occasions accompanied by food, presents, and friends and family. The Jewish New Year celebration of Rosh Hashanah is also a festive and joyous occasion. Buddhist festivals are typically joyous occasions as well that involve food and some sort of ceremony.

More somber holidays include Good Friday and Yom Kippur, days of remembering the death of Jesus and the atonement of one's sins, respectively. The two major holidays in Islam, Eid al-Fitr and Eid al-Adha begin with the word *Eid* which translates to solemn festival. Eid al-Fitr occurs just as Ramadan ends and means the "festival of breaking of the fast." It is obligatory to give money to the poor, pray, and display signs of happiness. Eid al-Adha is celebrated in remembrance of Abraham who was saved from having to sacrifice his son Ishmael after being presented with a ram as a substitute. This festival is sometimes referred to as the festival of the sacrifice.

In Hindu traditions, the word for festival comes from the Sanskrit word "utsava" which means removal of worldly sorrow. Hindu religious festivals are typically joyous occasions (e.g., *Pongal*) but they can also include time for fasting and serious reflections (e.g., *Maha Shivaratri*). The festival celebrations can sometimes last for several days and often involve feasting with friends and family. This would certainly seem to increase hedonic and eudaimonic aspects of well-being.

Clearly, festivals can have mixed effects on well-being. Most celebrations likely increase hedonic and eudaimonic well-being as they involve a gathering of people with food and merriment. Somber holidays and festivals likely do not increase hedonic forms of well-being at the moment, but they could increase a sense of meaning and purpose in life by solidifying one's belief or by enabling one to remember a somber past.

Conclusions

In this chapter, we have outlined various beliefs and practices of the main religions of the world. These beliefs and practices could have important implications for well-being researchers and could highlight avenues for future research. Although it has been shown that religious individuals report greater well-being, the exact mechanisms are less well understood. Specific religious practices could potentially mediate the relationship between religiosity and well-being. Moreover, certain religious beliefs may moderate relationships between religiosity and well-being. For example, the belief about how one is accepted into heaven (e.g., grace vs. works) could moderate the relationship between a specific act (e.g., committing a transgression) and well-being. Among those who believe they will earn salvation through their actions, a transgression could cause one to worry about how that could potentially affect their eternal destination, whereas those who believe in salvation by grace may not be as influenced by a transgression in terms of the well-being. Furthermore, a greater understanding of the process from religiosity to well-being could be achieved by building models that integrate beliefs and practices as moderators and mediators, respectively. For example, social support found in community worship may mediate the relationship between religiosity and well-being more strongly among Christians than other religious groups. The key mediator among Hindus, on the other hand, may be related to a sense of peace or tranquility that occurs through individual prayer. That is, a specific religious belief may moderate the mediation or indirect effect from religiosity to well-being.

To examine such models and test these kinds of theories, it is critical to move past single item measures of religiosity. One possible solution would be to ask participants to report their specific religious belief. To make such statistical comparisons, it would require large and diverse samples. Of course, there is often great heterogeneity of specific religious beliefs and practices within a particular religion, denomination, or sect. For example, two individuals might report being Buddhist, but yet their beliefs and practices may vary substantially. It would be important to ask participants to describe their actual beliefs and to record their religious practices in real time.

Future research could utilize text analysis techniques to capture individual differences in religious beliefs. Another avenue to address religious practices would be to utilize ecological momentary assessment techniques by having participants record their religious experiences and well-being in the moment.

One limitation of this review is that we have not addressed all religious beliefs and practices. Within each major religious group there are many specific denominations and sects, and these differences should be considered when researchers examine the link from religiosity to well-being. There are also individuals who identify as atheist or agnostic who nevertheless have spiritual beliefs and/or engage in certain religious practices, such as meditation (e.g., Harris, 2014). Future research should try to disentangle these individual differences. Our goal was to provide a useful overview of what the main world religions say about well-being through their beliefs and practices. We hope that well-being researchers can use this chapter as a guiding framework to address research questions concerning religion and well-being.

Acknowledgements

We would like to thank Ed Diener, Jamaal Diwan, Randy Newman, Shige Oishi, Varun Soni, and Louis Tay for their helpful comments on an earlier draft of this chapter.

Well-Being Concepts and Components

By William Tov, Singapore Management University

Abstract

Well-being is a broad, multifaceted construct. This chapter reviews different ways of defining and measuring well-being and the implications this has for understanding the correlates and causes of well-being. Hedonic well-being (HWB), eudaimonic well-being (EWB), and other conceptions of well-being are discussed. Specific components and aspects of HWB are elaborated on. These include the distinction between affective and cognitive well-being. Major aspects of affective well-being include valence, frequency versus intensity, arousal, and interpersonal engagement. Major aspects of cognitive well-being include life satisfaction, life evaluation, and domain satisfaction. Processes underlying the structure of cognitive well-being are discussed including top-down versus bottom-up models, and the tendency to use heuristics versus stable sources of information to evaluate one's life. Trait versus state conceptions of well-being are introduced. Different well-being assessment methods (online, recall, global) can be located on a state-trait continuum. The distinction between state and trait measures of well-being has implications for understanding the structure of affect, the relation between well-being and health, and cultural variation in well-being. Future research is needed to clarify the distinct correlates of affective versus cognitive well-being, as well as how positive and negative emotions are operationalized. In addition, a better understanding of the components of EWB and how they are related to HWB and affective dimensions beyond valence will shed light on the validity of the EWB construct. Finally, greater sensitivity to the state-trait distinction will deepen our knowledge of the processes that shape both HWB and EWB.

Keywords: hedonic well-being, cognitive well-being, affective well-being, state versus trait, emotion, satisfaction

The term *well-being* encompasses all the ways in which people experience and evaluate their lives positively. What exactly it means to experience life positively can be understood in myriad ways. Some equate well-being with *happiness*, but this can sometimes conjure up images of an immensely joyful, cheerful person that many do not identify with. As a result, some prefer to view well-being as a prolonged state of *contentment*. For others still, well-being is simply about *wellness*--as in having good physical and mental health. None of these views is incorrect; but each perspective is incomplete in itself. A great challenge for the science of well-being has been to define and measure this broad, encompassing construct. An important development in this field over the past few decades is the recognition and growing acceptance that well-being consists of many aspects--that it cannot be fully represented by any one measure. A person who is depressed cannot be said to be well; however, to equate well-being with an *absence* of depression misses much of what people strive for when they seek to enhance and preserve their well-being. In other words, well-being includes the lack of suffering, but it is more than this (Diener, 1984; Seligman & Csikszentmihalyi, 2000).

This chapter reviews various conceptions of well-being and how different components of well-being have been measured and studied in the psychological literature. The variety of ways in which well-being has been defined could be said to dilute the construct or render it meaningless. However, the causes, consequences, and correlates of well-being may depend on how it is defined and measured. A single intervention might improve some aspects of well-being but not others. Such an understanding is critical for the design of policies aimed at improving well-being.

Conceptions of Well-Being

What does it mean to "be well"? Numerous scholars have answered this question in different ways, resulting in a variety of well-being concepts. There are two major approaches to conceptualizing well-being (Ryan & Deci, 2001). The first approach emphasizes a person's evaluation of their own life--both emotionally and cognitively. It has been referred to as *hedonic well-being* (HWB) and consists of (i) frequent pleasant feelings, (ii) infrequent unpleasant feelings, and (iii) an overall judgment that life is satisfying. This tripartite model is also referred to as *subjective* well-being (Diener, 1984) because it prioritizes a person's own assessment of how well their life is going and whether they are getting the things they want in life--without specific concern for what these "things" actually are.

The second approach includes several concepts that together have been referred to as *eudaimonic well-being* (EWB). This approach takes as its starting point that there are certain needs or qualities that are essential for one's psychological growth and development; the fulfillment of these needs enables a person to reach their full potential (Ryan & Deci, 2001). The concept of *psychological* well-being (Ryff, 1989) is an example of the EWB tradition. Drawing on the theories of Erikson, Jung, Maslow, and Rogers (among others), Ryff posited six key features of people who are functioning well in life. Such people should have the maturity to be guided by internal standards (autonomy), be capable of trusting and loving others (positive relations), be able to manage external stressors and leverage on opportunities (environmental mastery), have a positive attitude toward themselves (self-acceptance), have important aims and goals (purpose in life), and accept new challenges in life as furthering their development (personal growth). Other EWB approaches emphasize living up to one's *personal* potential--in line with Aristotle's view of eudaimonia as living in accord with one's true nature (or *daimon*). From this perspective, EWB is rooted in the pursuit of goals and activities that are consistent with one's values and identity (McGregor & Little, 1998; Waterman, 1993).

Measures of HWB and EWB are highly correlated suggesting that positive feelings and positive functioning tend to go hand in hand. Nevertheless, a number of studies suggest that the two sets of measures are distinguishable from one another (Compton, Smith, Cornish, & Qualls, 1996; Keyes, Shmotkin, & Ryff, 2002; Linley, Maltby, Wood, Osborne, & Hurling, 2009). Specifically, HWB measures (e.g., pleasant feelings, unpleasant feelings, life satisfaction) often correlate with each other more strongly than they do with EWB measures (e.g., meaning, growth, autonomy), and vice versa. Some studies have found distinct correlates of HWB and EWB measures. For example, HWB is associated with the pursuit of projects that are fun and likely to be successful; EWB is associated with projects that are closely aligned with one's values and identity (McGregor & Little, 1998). Challenging activities are associated with a greater sense of EWB (personal expressiveness; Waterman, 1993) but can sometimes be associated with less HWB (positive emotion; Moneta & Csikszentmihalyi, 1996). Enacting moral behavior toward others is associated with EWB; *receiving* the same from others is associated with HWB (Hofmann, Wisneski, Brandt, & Skitka, 2014). The amount of time spent imagining the future was associated with greater EWB (meaning) but less HWB (happiness); in contrast, the amount of time spent thinking about the present was associated with greater HWB but was unrelated to EWB (Baumeister, Vohs, Aaker, & Garbinsky, 2013).

Additional well-being concepts have been proposed that are not consistently included in either hedonic or eudaimonic conceptions of well-being. Csikszentmihalyi (1990) described the state of flow, in which a person is optimally engaged with what they are doing. Flow states require a delicate balance between the challenges of a task and the person's skill at meeting these challenges. Ideally an activity should not be too easy or too difficult but challenge the person at a level slightly above their current skills. This creates an opportunity for the expansion of one's skill level if the challenge is met. Research suggests that flow states involve higher levels of engagement and concentration than nonflow states, but are not always accompanied by higher levels of pleasant feelings (Csikszentmihalyi & LeFevre, 1989; Moneta & Csikszentmihalyi, 1996). Thus, flow states may be more closely related to EWB (growth and mastery) than HWB.

Some accounts of well-being (Boehm, Peterson, Kivimaki, & Kubzansky, 2011; Diener, Wirtz et al., 2010; Su, Tay, & Diener, 2014) include optimism--the general expectation that one wil experience more positive than negative outcomes in life (Carver & Scheier, 2003). The disposition to be optimistic is associated with greater satisfaction and happiness and lower levels of depression and stress (Scheier & Carver, 1992), lower risk of health problems and faster recovery from illness (Boehm & Kubzansky, 2012; Scheier & Carver, 1992; Seligman, 2013). Several of these studies show that optimism prospectively predicts better health outcomes even after controlling for a range of demographic and personality variables. These findings led Taylor and Brown (1988) to suggest that highly positive beliefs about one's future, oneself, and one's ability to control outcomes, might be important hallmarks of mental health. In particular, such "positive illusions" may be especially functional when facing adversity. Optimistic beliefs tend to correlate strongly with measures of EWB (Diener, Wirtz et al., 2010; Su et al., 2014) and HWB (Lucas, Diener, & Suh, 1996), but are not completely synonymous with either conception of well-being.

Other conceptualizations have been proposed that include mixtures of HWB and EWB. Keyes (2002) offered the term *flourishing* to describe a condition characterized by high levels of both HWB and EWB. Seligman (2013) presented a similar model of flourishing called PERMA: positive emotion, engagement (flow), (positive) relationships, meaning, and achievement. According to Seligman, these five elements of well-being are pursued for their own sake and not necessarily to increase other well-being elements. Diener and colleagues (Diener, Wirtz et al., 2010; Su et al., 2014) also offered a conception of flourishing, viewing well-being as *social-psychological prosperity* or *capital*. This might be thought of as a set of beliefs or resources that not only enhance well-being but also strengthen mental and physical

resilience in times of adversity. Such resources include those in the PERMA model, as well as optimism, given its power to predict health behavior and recovery.

Kashdan, Biswas-Diener, and King (2008) raised a number of issues with the concept of EWB. They noted that whereas HWB is consistently defined as the experience of pleasant affect, unpleasant affect, and life satisfaction, EWB consists of a range of constructs that vary across researchers. As a result, there is no unified operational definition of EWB, although certain components (e.g., growth, meaning, authenticity, and mastery) appear in most conceptions of EWB (Huta & Waterman, 2014). The challenge hinges on what theorists consider to be an optimally functioning person. Some components emphasize the integrity of the person (e.g., authenticity, autonomy), others emphasize social functioning (positive relationships), still others emphasize engagement with life and its challenges (growth, meaning, mastery, striving for excellence). More work is needed to understand how and why specific components of EWB are interrelated--with each other and with external outcomes.

Another theoretical issue concerns the very notion of EWB concepts as indicators of well-being (Kashdan et al., 2008; Ryan & Deci, 2001). For example, Ryff (1989) views autonomy, mastery, and positive relationships as defining elements of psychological well-being. A monk who lives alone in the mountains and is happy and satisfied with his life would be well in terms of HWB, but might not be functioning optimally in terms of EWB. In contrast, Ryan and Deci's (2000) self-determination theory posits autonomy, competence, and relatedness as universal needs that, if unfulfilled, may decrease HWB. Thus, the elements of EWB are thought of as *antecedents* to well-being rather than as *defining* well-being. A similar issue might apply to concepts such as flow and optimism. Are these defining elements of well-being or should they be considered antecedents of well-being? An answer to this issue is not easily resolved empirically, particularly when no single criterion of well-being exists. It also quite plausible that bidirectional influences exist among components of HWB, EWB, and other related concepts. Ultimately, the resolution of what constitutes well-being may depend on the theoretical perspective one chooses to adopt. Readers interested in a deeper discussion of these issues, should refer to the excellent volume on EWB edited by Vittersø (2016).

For remainder of this chapter, we elaborate on the components of HWB. The reason for this is that there is a larger body of research in this area, as well as a fairly consistent operational definition of its components (pleasant affect, unpleasant affect, and life satisfaction).

Affective Versus Cognitive Well-Being

HWB (subjective well-being; Diener, 1984) consists of an affective component and a cognitive component. Affective well-being (AWB) refers to the experience of pleasant and unpleasant feelings. A person with high AWB generally experiences a preponderance of pleasant over unpleasant feelings. Thus AWB is typically assessed by asking respondents how often they have experienced specific emotions (e.g., happiness, joy, contentment, sadness, anger, worry, etc.). Cognitive well-being (CWB) is based on an evaluation of how well one's life is going relative to an ideal state of affairs. A person with high CWB should judge that their goals, desires, and standards are largely met by the current conditions of their life. CWB is most commonly assessed by measures of life satisfaction (Diener, Emmons, Larsen, & Griffin, 1985), but also includes satisfaction with specific areas of life such as health, work, and family (i.e., domain satisfactions; Diener, Suh, Lucas, & Smith, 1999). AWB and CWB are strongly correlated. To a certain extent, these interrelationships are expected. The fulfillment of valued goals and standards is often accompanied by pleasant affect whereas the lack of fulfillment may result in unpleasant affect. Thus, emotional experiences provide some information about how well one's life is going and thus may factor into one's judgment of life satisfaction (Schwarz & Clore, 1983; but see Yap et al., in press). Nevertheless, correlations between AWB and CWB are not so strong that they could be considered redundant. For example, Lucas et al. (1996) observed concurrent correlations as low as -.30 between life satisfaction and negative affect, and as high as .65 between life satisfaction and positive affect, on various self-report measures of well-being.

Different processes are involved in the experience of AWB and CWB. Emotions are often experienced in reaction to specific events. In contrast, satisfaction judgments may involve a range of factors. This can include the specific standards one uses to judge whether life is going well, and how satisfied one is with specific areas of life (e.g. work, relationships, health; Kim-Prieto, Diener, Tamir, Scollon, & Diener, 2005). Compared with AWB, CWB tends to be based more on stable sources of information such as global assessments about one's life circumstances and domains of life, rather than specific events or activities (Luhmann, Hawkley, Eid, & Cacioppo, 2012; see also Schimmack & Oishi, 2005). Thus, if one's social relationships are generally supportive and enjoyable, a recent argument with a friend is unlikely to reduce CWB as much as AWB. The implication of this finding is that CWB should be more stable across time, whereas AWB should be more variable as it fluctuates with recent events.

Analyses by Eid and Diener (2004) support this hypothesis.

If CWB tends to be based on information that is more stable (relative to AWB), then it should be more strongly associated with factors that stabilize or destabilize the general conditions of one's life. Indeed, income and unemployment correlate more strongly with CWB than with AWB (Diener, Ng, Harter, & Arora, 2010; Howell & Howell, 2008; Luhmann, Hofmann, Eid, & Lucas, 2012; Schimmack, Schupp, & Wagner, 2008; Tay & Diener, 2011). These factors are often related to the conditions of one's society more generally, and may explain why national differences tend to be larger in terms of CWB (Tay, Chan, & Diener, 2014). Major life events such as bereavement and childbirth also seem to have greater impact on CWB than AWB (Luhmann, Hofmann et al., 2012). Interestingly, whereas CWB decreased in the months following childbirth, AWB increased. Perhaps the birth of a child creates opportunities for pleasant social interactions, but the time spent caring for the baby and resulting lack of sleep negatively affect other areas of life (and hence CWB). Positive social relationships correlate more strongly with AWB than CWB. For example, social support is a strong predictor of positive emotions, and feeling respected is one of the strongest predictors of both positive and negative emotions (Tay & Diener, 2011).

One caveat to the notion that CWB is based more on stable information relative to AWB is that personality traits such as extraversion and neuroticism correlate more strongly with AWB (Schimmack et al., 2008). Although AWB may respond more to recent events, there are stable individual differences in mean levels of affect (see Trait versus State Well-Being). Covariation with personality traits may suggest that AWB is partly influenced by heritable predispositions to experience certain kinds of emotion. Extraverts may attend to positive stimuli more than introverts (Derryberry & Reed, 1994), and this tendency may increase the likelihood that they experience pleasant emotions. Extraverts may also actively seek pleasant social situations (Emmons & Diener, 1986). However, personality traits do correlate with CWB. A meta-analysis by DeNeve and Cooper (1998) examined a range of traits and did not find consistent differences in their association with CWB (life satisfaction) versus AWB. A key difference may be that Schimmack et al. controlled for the effect of general evaluative biases (i.e, a tendency to rate oneself positively on a range of traits) when comparing the effect of personality traits on AWB and CWB. Additional studies suggest that although CWB is associated with extraversion and neuroticism, this relationship is mediated by AWB (Schimmack, Diener, & Oishi, 2002; Schimmack, Radhakrishnan, Oishi, Dzokoto, & Ahadi, 2002). That is, these traits are associated with CWB largely because they influence levels of pleasant and unpleasant affect, which in turn influence how well people evaluate their lives.

Thus far, AWB and CWB have been discussed in a somewhat monolithic fashion to highlight the differences between them. That said, each construct in itself can be understood in terms of more specific components and processes that are important for understanding the causes and consequences of well-being.

Major Aspects of AWB

Valence. A basic feature of affective experience is the degree to which it is pleasant or unpleasant. This quality is fundamental to the notion of AWB as the preponderance of pleasant over unpleasant feelings. The distinguishability of pleasant (positive) affect versus unpleasant (negative) affect has been debated and studied from many perspectives. The degree to which they are correlated with each other depends on how they are measured--a point that will be revisited in this chapter. For now, it is generally understood that positive (PA) and negative affect (NA) are separable though not completely independent. In this section, the emphasis is on their distinct correlates and causes. The validity of the tripartite model of subjective well-being (PA, NA, and life satisfaction) depends partly on the identification of factors that are uniquely related to PA and NA (Busseri & Sadava, 2011). For example, the fulfillment of basic needs is a strong predictor of NA but not of PA (Tay & Diener, 2011). Struggling to find food and shelter may induce unpleasant emotions; however, having food and shelter in and of itself may not produce many pleasant emotions.

A number of studies suggest that PA and NA are associated with distinct personality traits. Extraversion is more strongly associated with PA, whereas neuroticism is more strongly associated with NA (DeNeve & Cooper, 1998). These differences could be due to overlapping item content in that some extraversion scales include subscales directly measuring positive emotion (e.g., the NEO-PI-R; Costa & McCrae, 1992), and neuroticism by definition involves the tendency to experience negative emotion. However, specific behaviors associated with extraversion (e.g., social activities) are also associated with higher levels of PA but are not consistently related to NA (Clark & Watson, 1988). Moreover, *acting* extraverted is associated with increases in momentary PA for both introverts and extraverts (Fleeson, Malanos, & Achille, 2002). In contrast, neuroticism and dispositional negativity are associated with greater sensitivity in regions of the brain that are associated with threat perception (e.g., the amygdala; Everaerd, Klumpers, van Wingen, Tendolkar, & Fernandez, 2015; Shackman et al., 2016). This suggests that the correlation between self-reported neuroticism and NA is not simply due to a tendency to endorse negative

items.

Both PA and NA predict health outcomes. Many studies have established that chronic levels of negative emotion are associated with increased risk of health problems such as coronary heart disease (Frasure-Smith, Lesperance, & Talajic, 1995; Russek, King, Russek, & Russek, 1990; Smith, 1992). Negative emotions such as anger and anxiety activate the body's stress response, which can impair immune system functioning if such activation is chronic (O'Leary, 1990). Independently of NA, several studies have found that PA predicts mortality and disease in the direction of lower risk (Diener & Chan, 2011; Pressman & Cohen, 2005). In a classic study, Cohen, Doyle, Turner, Alper, and Skoner (2003) exposed participants to the cold virus. Those who tended to experience PA were less likely to develop a cold than those less inclined to experience PA; the tendency to experience NA was not associated with cold susceptibility. In a world sample, Pressman, Gallagher, and Lopez (2013) found that both PA and NA were uniquely associated with self-reported health. The size of these relationships were similar on average, although the positive correlation between PA and health was larger in less wealthy countries. The processes by which PA reduces the risk of illness require further study. Effects of PA on health may be related to stronger immune system functioning, healthier behavior, or stronger social support (Pressman & Cohen, 2005). There is also some evidence that positive emotions quicken the recovery of cardiovascular activation triggered by negative emotions (Fredrickson & Levenson, 1998), potentially offsetting the stress response.

Frequency versus intensity. The frequency of an emotion (how often it occurs) can be distinguished from its intensity (how strongly it is felt). According to Schimmack and Diener (1997), mean levels of affect reflect a combination of frequency and intensity. Suppose that each day for one week, participants rated how happy they feel on a scale from 0 (*not at all*) to 10 (*extremely*). Their mean level of happiness across the week could be computed by averaging the seven ratings they made daily. Joe only experienced happiness on two days, but both days were fairly intense (7). In contrast, Ted experienced happiness every day of the week, but at a lower intensity (2). Both Joe (7 x 2 / 7 = 2) and Ted (2 x 7 / 7 = 2) would end up with the same mean level of happiness. However, both men clearly experience happiness differently. Joe is happy less often, but when happy, he feels it intensely. Ted is happy often but at a mild intensity. These differences can only be captured if we separate intensity from frequency. Specifically, the average intensity is best understood as the magnitude or strength of an emotion *when* it is felt (Schimmack & Diener, 1997). By this definition, the average intensity of Joe's happiness is 7, whereas Ted's is 2. Frequency might be measured as the number of times happiness was experienced at all (i.e., a non-zero rating was given). In that case, Joe's frequency is 2, and Ted's is 7. Thus, by one measure (intensity), Joe is happier; but by another measure (frequency), Ted is happier. Are both statements correct? One way to answer this question is to ask Joe and Ted to evaluate their lives more generally: how happy are they overall? Diener, Sandvik, and Pavot (1991) found that measures of long-term, global well-being were better predicted by the frequency of happiness rather than its intensity. (Diener et al. actually measured frequency in terms of the proportion of time participants felt more positively than negatively).

Intense positive emotions may be less predictive of overall well-being because such experiences tend to be uncommon (Diener et al., 1991). Their rarity implies that the occurrence of such intense emotions may not adequately represent a person's normal life circumstances. Furthermore, it appears that people who experience intense PA are also likely to experience intense NA (Schimmack & Diener, 1997; Diener, Larsen, Levine, & Emmons, 1985), which would seem to counteract the effects intense PA. Several processes may contribute to the tendency to experience both intense PA and NA (Diener, Colvin, Pavot, & Allman, 1991). One such process is highly valuing and investing in certain goals and events (Diener et al., 1991; Pomerantz, Saxon, & Oishi, 2000; Schimmack & Diener, 1997). The goals that are extremely valued will produce more intense PA if they are attained (e.g., winning a championship) but more intense NA if are not.

The distinction between frequency and intensity may affect the interrelation between PA and NA. Diener, Larsen et al. (1985) showed that over an extended period of time, mean levels of PA and NA are only weakly correlated--suggesting that they are independent. However, mean levels of affect confound frequency and intensity. When intensity is partialed out, PA and NA are negatively correlated. This is because the remaining variation in mean level affect reflects the frequency of emotional experiences, which tend to be inversely related. This finding is qualified by the definition of frequency that is used. When frequency is defined as a proportion of time spent feeling positively versus negatively, a negative relation is observed because time is inherently limited. More time spent feeling sad means less time to spend feeling happy. However, if frequency is defined in more absolute terms--a simple count of how many times one felt PA or NA--then frequencies are positively correlated (Schimmack & Diener, 1997; Schimmack, Oishi, Diener, & Suh, 2000). This is consistent with the observation that people who experience many positive events also tend to experience negative events (Magnus, Diener, Fujita, & Pavot, 1993).

Other dimensions of affect. In addition to their valence, frequency, and intensity, emotions may

also be characterized by their level of arousal (Barrett & Russell, 1998; Larsen & Diener, 1992). Pleasant emotions may be low (e.g., calm) or high (e.g., enthusiasm) on arousal. Similarly, unpleasant emotions may be low (e.g., boredom) or high (e.g., anxiety) on arousal. Arousal represents a dimension of affective experience that is empirically distinguishable from intensity (Kuppens, Tuerlinckx, Russell, & Barrett, 2013; Schimmack & Diener, 1997). A person who is extremely calm may not be any more aroused than one who is only somewhat calm. Although AWB primarily emphasizes the valence of affective experience, the relation between emotions and other variables may also depend on arousal. In their review of the literature, Pressman and Cohen (2005) observed that mild levels of PA tend to be associated with better immune functioning; in contrast, highly arousing PA can be detrimental in a manner that is similar to highly arousing NA. People with asthma may have more difficulty breathing when they experience extreme NA or PA (Ritz & Steptoe, 2000), although it is unclear from this study whether arousal or intensity is the key factor given that a mixture of high arousal and low arousal affects were combined in the NA and PA scores. Given that depression and anxiety are often correlated, some researchers have suggested that a general negative disposition may underlie the detrimental effects of high arousal (anger and anxiety) and low arousal (depression) NA on health (Suls & Bunde, 2005).

The cultural value of certain emotions may depend on their level of arousal and not just their valence. Although people generally want to feel more pleasant than unpleasant emotions, the specific types of emotions they want to feel varies across culture. For instance, European Americans tend to value high-arousal PA (e.g., excitement) more than Hong Kong Chinese; the latter value low-arousal PA (e.g., calmness) more than the former (Tsai, Knutson, & Fung, 2006). Because East Asian cultures emphasize attention and accommodation to the social environment, low-arousal PA may be especially functional in this cultural context; in contrast, U.S. cultural norms tend to emphasize the agency of the individual and high-arousal PA may facilitate the assertion of such agency. Tsai et al. found that European Americans tended to be more depressed when they did not experience *high-arousal* PA as often as they desired; in contrast, Hong Kong Chinese were more depressed when they did not experience *low-arousal* PA as often as they desired.

Another dimension that may be culturally variable is the degree to which emotions are interpersonally engaging (e.g., feeling close to someone) or disengaging (e.g., feeling proud or superior to others). The frequency of *disengaging* emotions was a stronger predictor of general "good feelings" among U.S. participants; in contrast, the frequency of *engaging* emotions predicted good feelings among Japanese participants (Kitayama, Markus, & Kurokawa, 2000; Kitayama, Mesquita, & Karasawa, 2006). The findings of Tsai et al. and Kitayama et al. are consistent with the general tendency for East Asians to value collectivism and Westerners to value individualism (for a review, see Tov & Nai, *in press*).

Major Aspects of CWB

CWB judgments involve an evaluative assessment of one's life as a whole (global measures) as well as specific aspects of life (domain specific measures). Some researchers describe CWB as an attitude (or evaluative belief) about one's life (Schimmack, 2008). Most CWB concepts assume that a comparison is made between one's current state and a desirable state of affairs (Campbell, 1976; Diener et al., 1985). Positive CWB (e.g., satisfaction) arises when the current state or circumstances meet or exceed what is desired; otherwise, negative CWB (e.g., dissatisfaction) may arise. Measures of global CWB include life satisfaction (Diener, Emmons et al., 1985) and Cantril's (1965) self-anchoring striving scale, which is also referred to as *life evaluation* (Kahneman & Deaton, 2010; Tay & Diener, 2011). Life satisfaction (LS) can be assessed directly by asking respondents how satisfied they are with life, as well as additional questions about whether they are getting the important things they want in life. The life evaluation measure asks people to think about the best possible and worst possible life they could live, and to locate their current life somewhere in between these two anchors. The two measures correlate strongly with each other (r = .57 and .82 at the individual and nation levels, respectively; Diener, Kahneman, Tov, & Arora, 2010). People may also have evaluative beliefs about specific areas of life (e.g., work, family, health, and leisure). These more specific *domain satisfaction* (DS) judgments may be based on more specific standards (e.g., whether pay is commensurate with job skills and hours). A key point is that the individual decides for himself or herself the standards by which they judge their life and its domains.

Top-down versus bottom-up models. How does a person evaluate his or her life *as a whole*? The target of judgment is extremely broad. One hypothesis is that people evaluate specific domains (DS) first. Satisfaction across domains is then aggregated to arrive at satisfaction with life as a whole (LS; Campbell, Converse, & Rodgers, 1976). This bottom-up model assumes that LS is derived from satisfaction with important areas of life. Thus, conditions at work, the quality of relationships, health, and other relevant domains each contribute to LS. One problem with this model is that LS judgments tend to be higher than what would be predicted from a set of DS judgments (Diener, Napa Scollon, Oishi, Dzokoto, & Suh, 2000). Moreover, this positivity bias is systematically related to cultural ideals regarding LS. That is, people who

live in cultures that strive for higher levels of LS tend to exhibit larger biases (i.e., larger LS given their DS scores). This finding supports the plausibility of top-down models, in which the direction of causality runs from LS to specific DS judgments. In these models, one is satisfied with life not so much because of satisfaction with work and relationships; instead, satisfaction with these domains is the product of a general tendency to be satisfied with life as a whole. A more extreme top-down model views personality traits such as extraversion and neuroticism as causing both LS and DS. This model implies that correlations between LS and DS are fully accounted for by personality traits. Heller, Watson, and Ilies (2004) found no support for such a model. Although personality traits do correlate with LS and DS, the latter two remain strongly correlated with each other even after accounting for personality. Instead, support was found for both top-down and bottom-up processes. Personality traits can be viewed as influencing LS, which in turn influences specific DS judgments (top-down process). Alternatively, traits can be viewed as causing both LS and DS (top-down), with additional effects of DS on LS (bottom-up). It is likely that both processes operate together (Schimmack, 2008). One way the relation between LS and DS could simultaneously reflect top-down and bottom-up processes is in the weight that individuals place on specific domains. For example, happy people place more weight on the domain they are most satisfied with when judging LS; in contrast, unhappy people place more weight on the domain they are *least* satisfied with (Diener, Lucas, Oishi, & Suh, 2002). Thus, the top-down process is reflected in how a person weights each domain, and the bottom-up process is reflected in the effect of that domain on LS.

Effects of heuristics versus stable sources of information. Schwarz and Strack (1999) noted that the task of evaluating one's life as a whole is actually quite difficult. There are a potentially large number of important life domains so that a truly comprehensive assessment of one's life should take hours. Yet, people seem to answer LS questions fairly quickly. To account for this phenomenon, Schwarz and Strack proposed a judgment model of well-being. They suggested that CWB judgments are largely constructed on-the-spot from whatever information is currently on the person's mind and deemed relevant. When the target is broad (e.g., life as a whole), many kinds of information are deemed relevant. This includes current mood as well as social comparison. The narrower the target is (e.g., as in DS judgments), the more selective the use of information. The number of dates a person had in the past month could be relevant for judging LS but not satisfaction with health. The judgment model implies that LS judgments are highly unstable--susceptible as they are to momentary influences. However, Schimmack and Oishi (2005) showed that the effects of momentary factors such as mood and priming are generally small (see also Yap et al., in press). Instead, LS judgments are largely based on chronically accessible information--specifically, on how well one is generally doing in important areas of life.

State versus Trait Conceptions of Well-Being

The scientific study of well-being (and happiness in particular) was once questioned on the grounds that it referred to phenomena that were momentary and fleeting. The judgment model of well-being (Schwarz & Strack, 1999), for example, assumes that people do not actually have enduring representations of how happy and satisfied they are with life. However, Headey and Wearing (1989) provided evidence that PA, NA, and LS were fairly stable across a six-year period (*r*'s were between .35 to .52; see also Lucas & Donnellan, 2012; Schimmack & Oishi, 2005). These correlations suggest that HWB components contain some stability, but not so much stability that they remain unchanged in response to life events (Lucas, 2007; Luhmann, Hofmann et al., 2012). It is now recognized that well-being consists of both state-like variation and trait-like stability (Eid & Diener, 2004). Trait levels of well-being refer to how a person feels or how satisfied they are in general or on average (across time and situations). State levels of well-being refer to feelings and satisfaction at a particular moment in time or within a restricted period of time (e.g., the past week). Trait measures of well-being tend to be influenced by personality traits, cultural values, memory biases, and general beliefs about the self (Robinson & Clore, 2002b). State measures of well-being may reflect unstable factors such as the day of the week, temperature, or the nuances of a recent event or activity. Thus, state and trait measures of well-being involve different processes; they are influenced by different factors and are associated with distinct outcomes.

Measures of well-being can be placed on a continuum ranging from state-like to trait-like. It is helpful to distinguish between online, retrospective/recall, and global measures of well-being (Kim-Prieto et al., 2005; Scollon, Diener, Oishi, & Biswas-Diener, 2004). *Online* measures ask respondents to report how they are feeling "right now". Because respondents are often randomly alerted to complete a survey (e.g., through smartphone), online measures may instruct participants to report how they were feeling just before they were alerted to avoid effects of the alarm itself on their mood. *Recall* or retrospective measures ask respondents to report how they felt over a specified period of time. The time frame can range from the past hour to the past year. Finally, *global* measures typically ask respondents to report their well-being in general. Whereas online measures capture well-being states and global measures capture well-being traits, recall measures reflect a mixture of states and traits. Robinson and Clore (2002a) showed that people spend

increasingly more time assessing their emotion as the target period increases from the past hour to the past few weeks. This is consistent with the idea that people are recalling the specific events that they experienced: the longer the target period, the more events there are to recall. However, when the target period concerned the past few months or longer, no further increase in time was observed. People spent nearly as much time recalling their emotion over the past few years as they did over the past few weeks. This suggests that at some point, people stop recalling specific events and rely on more general beliefs about themselves. Such beliefs are more likely to reflect the influence of personality traits and cultural values. Distinctions between online, recall, and global measures produce important insights about affective structure, health, and cultural variation in well-being.

Structure of Well-Being

Diener and Emmons (1984) showed that state PA and NA tend to be inversely correlated at a single moment in time. People rarely report feeling pleasant and unpleasant at the same time. However, when reporting how they felt over the past year, levels of PA and NA were weakly correlated. Additional work by Diener and Iran-Nejad (1986) clarified that state PA and NA tend not to co-occur at high levels of intensity; however at lower levels of intensity, people can experience PA and NA in different combinations (see also Tay & Kuykendall, 2017). The co-occurrence of low intensity state PA and NA, combined with the inverse relation observed at high intensities may contribute to their reduced correlation at broader time frames. Thus, PA and NA may diverge more from each other at trait levels than at state levels. Watson, Clark, and Tellegen (1988) did not observe consistent effects of time frame on the correlation between PA and NA--which were largely independent in their studies. However, their measures consisted of predominantly high-arousal PA and NA terms (e.g., excited, distressed). Thus the typically inverse relation between valenced states may have been offset by positive covariation due to high arousal levels (Barrett & Russell, 1998).

Far less work has examined momentary measures of CWB and how these relate to AWB. Tov and Lee (2016) examined daily satisfaction (a state-like measure of CWB) and its covariation with daily affect. Daily satisfaction was more strongly correlated with daily PA than daily NA. The effect replicated when participants reported their well-being over the past few days. A similar pattern has also been observed with a time frame of the past two months (Luhmann, Hawkley et al., 2012) as well as among global, trait measures of HWB (Lucas et al., 1996; Robinson, 2000). Thus, the relation between CWB and PA appears to be similar at both state and trait levels--although more research is needed.

Relations Between AWB and Health

Most research findings that suggest a protective effect of PA and detrimental effects of NA on health are based on trait measures of affect (Boehm & Kubzansky, 2012; Diener & Chan, 2011; Suls & Bunde, 2005; Pressman & Cohen, 2005). These measures tend to reflect the frequency rather than intensity of emotional experience (Schimmack & Diener, 1997). Thus, it is chronically experiencing these emotions that appears to affect health outcomes. Such effects could reflect other personality traits or individual differences that predispose people toward healthy or unhealthy behaviors. For example, conscientiousness is associated with a variety of health protective behaviors (Bogg & Roberts, 2004) and is also correlated with trait measures of well-being (DeNeve & Cooper, 1998). Interestingly, however, these effects often hold when controlling for demographic factors such as age and income.

The relation between emotion and health is more complex when considering state PA and NA. As noted earlier, state PA--particularly high arousal PA--can sometimes affect cardiovascular and pulmonary functioning in a way that is detrimental for those already predisposed to suffer from asthma or heart attacks (Pressman & Cohen, 2005). In contrast, although trait NA is associated with negative health outcomes, there may be circumstances in which state NA is beneficial. Advertising campaigns that use fear to promote healthy behavior (e.g., anti-smoking, vaccination) appear be more effective at inducing changes in attitudes and behavior that non-fear appeals (Tannenbaum et al., 2015). Some studies also suggest that state anxiety and guilt may motivate patients to better adhere to treatment protocols than those who do not experience these emotions (Mayne, 1999).

Retrospective Well-Being

A concern with recalled or retrospective judgments of well-being is their susceptibility to memory biases (Schwarz & Strack, 1999). They may also be vulnerable to heuristic biases such as peak-and-end effects (Fredrickson, 2000)--the tendency to evaluate a past episode by its most intense experience as well as its ending, with less weight placed on the overall duration of the episode. If recalled experiences are inaccurate, what utility could they have for understanding a person's well-being? Although retrospective well-being assessments are far from a perfect recollection of past experiences, they do reflect actual experiences (Scollon et al., 2004; Tov, 2012). Moreover, peak-and-end effects are not consistently observed when emotions are recalled for time frames that involve several episodes (Miron-Shatz, 2009;

Parkinson, Briner, Reynolds, & Totterdell, 1995). Instead, the average level of affect experienced during the period is a stronger predictor of retrospective well-being than either peak or end experiences. Finally, retrospective well-being judgments mediate the effect of daily events on global well-being measures, even after controlling for trait happiness and neuroticism (Tov, 2012). Thus, how we remember our well-being over the recent past forms a bridge from momentary well-being to more stable forms of well-being.

Retrospective judgments have important implications for decision-making. For example, the decision or desire to repeat a vacation was predicted by retrospective but not online measures of emotion (Wirtz, Kruger, Scollon, & Diener, 2003). Cultural differences in well-being may also manifest in retrospective measures more strongly than online measures. Oishi (2002) found that participants of Asian descent tended to report lower retrospective well-being over the past week than European Americans. However, the two groups tended not to differ on measures of online well-being during the same week. This suggests that retrospective well-being may be influenced by cultural norms and values and is consistent with Robinson and Clore's (2002b) model of emotional self-report. More specifically, culture may shape people's beliefs about which emotions are desirable to experience (Tsai et al., 2006), and such beliefs may influence how people remember and reconstruct their past emotional experiences (Scollon, Howell, Caldwell, & Ito, 2009). On the other hand, cultural differences in online emotional experience have been reported in other studies (e.g., Scollon et al., 2004; Kitayama et al., 2006). Such differences appear to be larger for disengaged emotions (e.g., pride and anger) than for other emotions—with Asians tending to report lower levels than European Americans. Thus, the extent to which culture influences retrospective versus online affect may also depend on the particular emotional state examined.

On the whole, the above findings offer some insight into how global well-being can be stable in the face of most events but still be responsive to change during major life events. Cultural values, personality traits, and other individual differences may influence how we remember our recent past, and these influences may act on global well-being in a similar manner. However, these factors may only shape memory to a certain point. Actual experiences impose a reality constraint on recall biases. A person who is injured in a car accident may not be able to recall the experience as a positive one no matter how inclined they are toward positivity.

Future Directions

A great deal of research has examined the structure and correlates of PA, NA, and LS. This work has advanced the field but there remains much to learn about well-being. First, many studies separately examine AWB and CWB. Researchers have only recently begun to understand the processes that are unique to these components. For example, Luhmann, Hofmann et al. (2012) find some evidence that adaptation to life events occurs more quickly for AWB than CWB--but the findings depend on the particular event (e.g., bereavement versus unemployment). Few studies have compared the unique effects of PA, NA, and LS on health. Wiest, Schüz, Webster and Wurm (2011) observed that both PA and LS (but not NA) independently predicted mortality. Additional research on the unique or divergent correlates of HWB components provides important insights into how interventions can best enhance well-being, or why some interventions and policies fail to obtain their desired effects. In addition to measuring AWB and CWB, researchers should also attend more to how PA and NA are operationalized. Certain measures of affect (e.g., Watson et al., 1988) measure high-arousal states, other measures are more valenced-based (e.g., SPANE; Diener, Wirtz et al., 2010).

More theoretical and empirical work is needed to understand how EWB should be conceptualized, as well as the processes that contribute to convergence and divergence between HWB and EWB. Following the recommendation of Kashdan et al. (2008), it will be extremely informative to study specific components of EWB and how they relate to components of HWB. For example, although meaning and satisfaction are highly correlated, they diverge more in response to negative experiences than positive experiences (Tov & Lee, 2016). Although positive experiences are generally associated with greater meaning and satisfaction, negative experiences (e.g., a romantic break-up) can be meaningful but *dis*satisfying. In addition, the implications of an event for one's future appears to be a predictor of meaning but not satisfaction (see also Baumeister et al., 2013 for a related analysis).

Efforts to identify the unique correlates and processes underlying AWB, CWB, HWB and EWB are likely to require large sample sizes to detect such differences. This is because these constructs tend to be strongly correlated with each other so that the amount of unique variance (e.g., in EWB after controlling for HWB) will tend to be small. For example, Tov and Lee's (2016) observation that certain negative experiences are negatively correlated with satisfaction but positively correlated with meaning is based on thousands of events reported by over 2000 participants. These correlational differences amounted to a Cohen's Q of .05, which is a small effect. Realistically, many differences among well-being components will be in the small to moderate range. Nevertheless, small effects can be theoretically and practically

important—particularly when they represent phenomena (e.g., daily experiences) that may cumulate over time (Abelson, 1985). Well-being researchers who seek to uncover such effects will need to sample many people and experiences to ensure that differences in well-being components are not simply due to noise or random error. Large sample sizes also allow researchers to use more sophisticated statistical methods (e.g., structural equation modeling) to control for measurement error when they examine how different aspects of well-being are related to other outcomes.

Occasionally, the contrast between HWB and EWB is described as "feeling good" versus "doing good." This contributes to the view that EWB is less affectively tinged than HWB. Indeed, certain elements of EWB (e.g., mastery, growth, flow) are enhanced by activities that challenge the person. Such activities may not be pleasant but contribute to a person's development. However, other dimensions of affective experience may be more relevant for EWB. For example, inherent in the experience of flow (Csikszentmihalyi, 1990) is the notion of an optimal level of arousal. A task that is too easy (skills exceed the level of challenge) induces boredom; a task that is too difficult (challenges exceed skills) induces anxiety. Thus the balance between challenge and skills maintains a level of arousal that facilitates concentration, interest, and engagement. Ryan and Frederick (1997) describe subjective vitality as a feeling of positive energy that arises from the pursuit of activities that are personally expressive or self-actualizing-- a feeling of being alive. Subjective vitality correlated only modestly with high-arousal PA suggesting that it reflects a distinct aspect of experience. Thus, similar to HWB, it may be possible to conceptualize EWB as consisting of distinct affective and cognitive elements. This expanded view of EWB offers more avenues to explore processes that link these two well-being conceptions.

A final related point is that divergences and similarities between state and trait measures of well-being deserve more attention. Divergences are important to identify and understand because they prevent inferential fallacies. For example, although chronic or trait NA is deleterious to health, it would be erroneous to conclude from this that state NA is equally deleterious. Momentary anxiety could lead one to take one's symptoms seriously and seek early care, and thus be beneficial. Similarities are equally valuable to identify. If trait-level relations are also mirrored at the state-level, this can guide intervention efforts toward specific behaviors and experiences that enhance well-being. For example, if extraverted *behavior* induces PA (mirroring the relation between extraversion and PA at the trait level), then well-being interventions might teach skills to enact these types of behaviors with the idea that such tendencies over time may contribute to higher but stable levels of PA. The state-trait distinction could also further the understanding of EWB components--which have tended to be measured as traits rather than states (Waterman, 2008).

Abstract

Subjective well-being, by definition, is a construct that relies on people's *subjective* evaluation of their lives as a whole. The subjective nature of the construct makes self-report a natural method for assessing SWB. However, the psychometric properties of these measures still must be questioned and assessed, both using traditional techniques for evaluating reliability and validity, and using more targeted approaches for understanding the processes by which respondents make these judgments. This chapter reviews the evidence about the nature and psychometric properties of self-report measures of SWB, including traditional global measures of life satisfaction and positive and negative affect, and more recently developed experiential measures including experience sampling and the day reconstruction method. Although specific questions remain about the processes underlying SWB judgments and certain limitations exist, research shows that the psychometric properties of these measures are generally quite good.

Keywords: Subjective Well-Being, Self-Report, Measurement

There are many reasons why applied and theoretical researchers seek simple, well-validated measures of the quality of a person's life as a whole. Such measures can help clarify which life circumstances or individual-level characteristics are critical ingredients of "the good life," and these findings can in turn reveal fundamental features of human nature. For instance, external circumstances that are reliably associated with differences in well-being could provide information about *basic needs* that must be satisfied for humans to flourish (Baumeister & Leary, 1995; Wilson, 1967). Similarly, individual-level characteristics or personality traits that reliably predict well-being may point towards critical skills or approaches to life that foster high levels of well-being. Such findings could be used by applied researchers at the individual level to guide personal life decisions and at the societal level to guide public policy (Diener, Lucas, Schimmack, & Helliwell, 2009).

A minimal amount of introspection reveals, however, that different life circumstances are likely to affect different people in different ways. Although strong social relationships and a meaningful career may both, on average, contribute to a good life, it also seems likely that the value that people place on these two characteristics will vary across individuals; some people may be willing to sacrifice some degree of relationship quality to obtain a successful career, whereas others may make the opposite choice. Thus, to capture one's overall quality of life, some amount of subjectivity must be incorporated into this evaluation.

Subjective well-being (SWB) is a construct that focuses explicitly on these subjective evaluations. Indeed, one simple, over-arching definition of SWB is that it represents "a person's subjective evaluation of the quality of life as a whole." This definition acknowledges that the subject's own evaluation is prioritized, which means that different people can evaluate the same objective life circumstance in different ways and can weight different life domains differently. In addition, the focus on "life as a whole" means that the totality of one's experiences and circumstances add up to an overall sense of quality of life, and that different life circumstances may balance each other out in their impact on the overall evaluation. SWB can be contrasted with *objective list* definitions of well-being, which typically identify a limited set of measurable dimensions that must be considered, without input from the subject himself or herself, to obtain an overall evaluation of the quality of life (see Diener et al., 2009, for a discussion). SWB researchers typically object to such objective list approaches by pointing out both that it is difficult, if not impossible, to develop uncontroversial lists of important domains, and that empirical evidence suggests that people do weight domains differently.

One implication of this focus on subjective evaluations is that the study of SWB appears, necessarily, to require the use of self-report measures. If researchers wish to capture a person's own evaluation of his or her life, then it is difficult to think of alternatives to self-report measures. Unfortunately, self-reports have known limitations (Lucas & Baird, 2006; Paulhus & Vazire, 2007), which can lead to concerns about the psychometric properties of existing self-report well-being measures. Thus, it is especially important to consider the evidence that exists for the reliability and validity of subjective well-being measures. Because

there is no gold-standard measures against which self-reports can be compared (as there might be for other constructs that can be assessed by self-reports, like height or one's grade point average), the process of validating measures of SWB can be challenging. In general, the process proceeds by considering evidence for reliability and construct validity, and also by addressing specific theoretical questions about how SWB evaluations are made. In this chapter, I review the evidence for the reliability and validity of SWB measures, along with the critiques of these measures and the alternatives that have been proposed.

Self-Report Approaches to Measuring Subjective Well-Being

Many different approaches to evaluating SWB have been developed, with the simplest consisting of brief, self-reported evaluations of the quality of one's life as a whole. For instance, single-item life satisfaction measures that ask "All things considered, how satisfied are you with your life as a whole" are often included in large-scale panel studies and national surveys. Multiple-item versions of these measures have also been developed, typically with similarly worded questions that tap into this overall sense that one's life is going well (e.g., Diener, Emmons, Larsen, & Griffin, 1985; Lyubomirsky & Lepper, 1999).

Diener (1984) noted that these judgments of life satisfaction form a class of measures that he referred to as being "cognitive" in nature. This term reflects the fact that answering such questions requires respondents to reflect on their lives and consciously select a response that best reflects their overall evaluation. Diener noted that such cognitive judgments could be contrasted with a separate class of evaluations that are based in respondent's typical affective experiences (e.g., Watson, Clark, & Tellegen, 1988). The reasoning behind the use of such measures is that those whose lives are going well should typically experience high and frequent levels of positive affect, along with low and less frequent experiences of negative affect. Thus, an overall evaluation of life could be obtained by capturing a person's typical levels of affect. Diener noted that these different components of SWB may ultimately result from different causes, and thus, should be assessed separately to obtain a more complete evaluation of one's life as a whole (though Busseri & Sadava, 2011, noted that there is some amount of conceptual ambiguity in this tripartite model of SWB that could be clarified with additional theoretical precision; also see Schimmack, 2008).

Traditionally, both the cognitive and affective components of SWB were assessed using global, retrospective (or "evaluative") measures that required respondents to think back on their lives and the characteristics of those lives to come up with judgments of life satisfactions or ratings of the frequency or intensity of affective experiences over some extended period (Watson et al., 1988). However, there is reason to believe that such retrospective evaluations of affective experience may not accurately capture the actual experiences that people have in their daily lives. For instance, Robinson and Clore (2002) noted that different processes are likely used to make judgments about one's current affective experience, one's very recent affective experiences, and one's affective experience from far in the past. Specifically, they argued that people can typically report with some degree of ease about their current affective experiences simply through careful introspection, but that past experiences are rated by accessing episodic and semantic knowledge. The more recent the experience, the more likely respondents are to rely on episodic memories of the actual experience; the more distant, the more likely respondents are to rely on semantic knowledge or stereotypes about how one *typically* feels in similar situations. Thus, they argued, different time lags lead to differential accuracy, if the criterion is the actual emotional experiences that would have been reported in the moment. In addition, some research suggests that when asked to aggregate over extended periods of time, certain biases affect this aggregation process, leading to global evaluations that do not match with the actual experiences as it occurred (Kahneman, Fredrickson, Schreiber, & Redelmeier, 1993; Redelmeier & Kahneman, 1996).

Because of the potential for inaccurate reconstructions of one's affective experience at some earlier point in time, some researchers have suggested that we should distinguish between measures that focus on retrospective evaluations and those that capture people's emotional reactions to life as it is lived (Kahneman & Riis, 2005). For instance, it is possible to use *experience sampling methods*, where respondents are signaled multiple times per day (typically, using mobile phones) and asked to complete surveys about what they were doing, who they were with, and how they were feeling (Mehl & Conner, 2013). Kahneman (1999) argued that the benefits of these momentary---or *experiential*---reports (namely the fact that they avoid problems with inaccurate memories and aggregation biases) makes them closer to a measure of *objective happiness* than more evaluative, retrospective measures. Of course, this is an argument that must be evaluated with empirical data, as this approach may introduce new methodological problems that do not exist with more traditional retrospective methods (a concern I address below).

Finally, because methods like the experience sampling are extremely time- and resource-intensive, both for the researcher and the participant, new methodologies that combine the strengths of these experiential measures with the efficiency of more traditional questionnaire measures have been developed.

For instance, Kahneman, Krueger, Schkade, Schwarz, and Stone (2004) proposed a new technique, one based in existing approaches to assessing time use, to assess affective experiences throughout the day. Their *Day Reconstruction Method* involves respondents breaking their day down into distinct episodes that represent coherent blocks of time that share some respondent-defined characteristic (e.g., "eating breakfast," "walking the dog," or "cleaning the house"). Participants are asked to list all episodes they engaged in throughout the day, to describe the features of these episodes (e.g., what the participants were doing, who they were with, where they were), and to report the affect that they experienced during each episode. The idea is that these day reconstructions, if completed relatively close in time to the actual experience, will capture relatively accurate episodic memories of the recent events. Thus, they would have many of the advantages of the experience sampling method, while only requiring a single, constrained assessment occasion. Again, as with the experience sampling method, these reasonable assumptions can be validated with empirical evidence.

The Reliability and Validity of Subjective Well-Being Measures

As I noted above, unlike certain self-report measures (such as those for height, weight, grade point average, or even for some ratings of physical health), there is no gold standard against which self-report measures of SWB can be compared. By definition, the evaluation is a subjective one, and thus, it captures internal thoughts and feelings that are not visible to outside observers. This fact, however, does not mean that self-reports themselves are unimpeachable sources of information about people's SWB. People may misremember their affective experiences, may disproportionately weight certain irrelevant sources of information when deriving a cognitive judgment of life satisfaction, may be unable to translate an internal feeling to a meaningful response on an experimenter-provided scale, or may be unwilling to provide an honest response when questioned about their well-being (see Schwarz, 1999, for a general discussion of many of these issues). Thus, it cannot be taken for granted that any measures of SWB---self-report or otherwise---reliably and validly captures the evaluation of interest.

In general, the quality of SWB measures has been assessed using traditional approaches to understanding psychometric properties. For instance, indexes of reliability can be used to assess the extent to which measures are free from measurement error. For multiple-item measures, this is typically assessed using internal consistency coefficients, and for most measures, these coefficients tend to be high, reflecting the fact that items that are typically included in well-being measures tend to be moderately to strongly correlated (see, e.g., Diener et al., 1985). The reliability of single-item measures is slightly trickier to assess, because internal consistency coefficients cannot be used to assess reliability. The reliability of these measures is especially important, however, as single-item scales are often included in large-scale surveys. Fortunately, because the conditions of people's lives tend to be relatively stable, at least over short periods of times (e.g., most people's income, employment status, marital status, and health are stable in the short term), one would expect measures that are based, at least in part, on these circumstances, to be relatively stable, too. With this assumption in mind, short-term stability coefficients, or even longer-term stability coefficients with varying intervals can be used to assess the reliability of the measures.

For example, Lucas, Freedman, and Cornman (in press) assessed the stability over the course of a one-hour interview in a group of participants who had also been assessed numerous times over the previous six years. This research design allowed the authors to estimate stability over a very short interval, to assess the extent to which the two measures of life satisfaction were related to measures of life satisfaction assessed in prior years, and to test whether survey content administered between the two measures influenced the ratings that respondents provided. Together, these analyses provide information about the reliability of single-item measures and the extent to which any instability is due to systematic effects. Their results showed that although stability over the hour-long interview was only .62, the measure assessed at the beginning of the survey correlated just as strongly with prior years' assessments as did the measure assessed at the end of the survey (with correlations in the range of .40-.50). Moreover, the intervening survey content appeared not to have a major impact on the final life satisfaction rating.

Other research has used multi-wave data to estimate the reliability of these single-item measures of life satisfaction (see Alwin, 2007; Kenny & Zautra, 1995 for general approaches to accomplish this goal). For instance, Lucas and Donnellan (2007) used two long-running panel studies to separate stable trait variance, reliable but slowly changing autoregressive variance, from unstable state variance in life satisfaction (which can serve as an estimate of measurement error). They estimated the reliability of life satisfaction to be approximately .67. Similarly, Lucas and Donnellan (2012) extended these analyses to four panel studies and used measures of domain satisfaction to separate reliable state variance from measurement error, and they found reliability estimates closer to .75. These estimates are also reasonably consistent with meta-analytic analyses conducted by Anusic and Schimmack (2016) and Schimmack and Oishi (2005). Together, these results suggest that single-item measures have a reasonable degree of reliability (for a more detailed review of the evidence for the reliability of single- and multiple-item measures of SWB, see

Chapter 5 of Diener et al., 2009).

Assessing reliability is relatively straightforward, as this psychometric property can be described using quantitative indexes. Validity, however, is more complex and more difficult to establish in any sort of definitive way. Although validity is often simply defined as whether a test measures what it is supposed to measure, providing evidence for validity has proven to be controversial (see Borsboom, Mellenbergh, & van Heerdan, 2004, for a review and discussion). For instance, in contrast to the simple definition provided above, Messick (1995) suggested that validity could be defined as "an overall evaluative judgment of the degree to which empirical evidence and theoretical rationales support the adequacy and appropriateness of interpretations and actions on the basis of test scores or other models of assessment" (p. 741). This definition emphasizes that validity reflects a judgment that is based on theories of the underlying construct that one hopes to assess.

Diener et al. (2009) reviewed evidence for four types of validity that could be considered when evaluating self-report SWB measures. The weakest form is *face* validity, which simply refers to whether the measure appears to measure what it is supposed to measure. Most SWB measures have high levels of face validity, though it is possible to come up with reasons why face valid measures may not be desirable or reasons why measures that lack face validity can serve as useful tools for assessing the construct. Thus, researchers tend to focus on the other three forms of validity.

Content validity refers to the extent to which the measure in question captures the breadth of the construct of interest, without including content that should theoretically be excluded. Diener et al. (2009) noted that there are two types of measures where content validity is typically a concern. First, for multifaceted measures of well-being, such as the Oxford Happiness Scale (Hills & Argyle, 2002), one could raise concerns about the inclusion of irrelevant content. For example, this scale includes the item "I think I look extremely attractive" which is not a face valid indicator of SWB. It is possible that happy people are more likely to endorse this item, regardless of their objective appearance, in which case content validity may not be affected by the item's inclusion. However, if the item truly taps the respondent's objective appearance, then the item could shift the focus of the total scale score away from its desired target.

The second type of scale for which content validity is typically a concern is for measures of the affective components of SWB. For many years, debates have taken place about the number and nature of affective dimensions that exist, and these debates shape the measures that are used to assess affective well-being. For instance, the widely used Positive and Negative Affect Schedule (PANAS; Watson et al., 1988) does not include items assessing face valid indicators of affective well-being such as *happy* or *sad*. This is because the measure was designed to assess particular forms of positive and negative affect that are based on underlying theories about the nature of affective experiences. Researchers who use affective well-being scales should consider these existing theories and choose measures that best tap the content that they believe is theoretically most relevant (for instance, alternatives to the PANAS like the Scale of Positive and Negative Experiences [SPANE; Diener, Wirtz, Kim-Prieto, Choi, Oishi, & Biswas-Diener, 2009] may provide a better match with some measurement goals).

Convergent and *discriminant* validity are complementary forms of validity that reflect the extent to which a measure correlates strongly with other related measures (convergent validity) and correlates weakly or not at all with measures to which it should be unrelated (discriminant validity). In terms of convergent validity, it is especially important to show that different measures of the same construct cohere even when assessed using different methods of assessment. This is because correlations between measures can be inflated by shared method variance that may be independent of construct variance. Numerous studies show that standard, widely used measures of SWB tend to show reasonable levels of convergent and discriminant validity, even when different methods of assessment are used (Lucas, Diener, & Suh, 1996). For instance, Schneider and Schimmack (2009) reported a meta-analytic average correlation of .42 between self- and informant reports of well-being.

The final form of validity, and the most complicated to assess, concerns *construct* validity (Cronbach & Meehl, 1955). This form of validity reflects the extent to which a measure behaves as it would be expected to behave, given theories about the construct itself. Thus, to test construct validity, one must have some idea about how a measure should relate to additional constructs. Diener et al. (2009) reviewed a broad range of correlates of SWB, including income, social relationships, and relevant behaviors. They conclude that widely used measures of SWB show relatively strong evidence for construct validity. For instance, there is strong reason to expect that income would be related to well-being, given that money can purchase many of the things that might be expected to cause high well-being; and indeed, income is consistently related to measures of SWB (Lucas & Schimmack, 2009). Similarly, if low levels of life satisfaction reflect a genuine evaluation of one's life as being of poor quality, one might expect scores on

life satisfaction measures to predict suicidal behaviors, which appears to be the case (Koivumaa-Honkanen et al., 2001). Other studies show that domain-specific well-being measures predict relevant behaviors within those domains (e.g., job satisfaction predicts turnover; Tett & Meyer, 1993). Although this is just a brief overview of the type of evidence that can be used to assess validity, prior in depth reviews suggest that established SWB measures show an impressive degree of validity (Diener et al., 2009).

Although reliability is often a concern with single-item measures, there can also be reasons to be skeptical about the validity of such short measures. This is because psychological constructs are often complex, and it may be difficult to capture this complexity in a single item. For instance, personality traits like extraversion are often difficult to capture with a single-item because the construct itself is multifaceted. SWB constructs like life satisfaction, however, are often much simpler. It may be more reasonable to assess one's overall satisfaction with life with a single-item than it is to assess broad personality traits or attitudes. Indeed, multiple-item measures of life satisfaction often have items that are very close in meaning to one another, and those items that deviate often perform worse than the more straightforward items (Oishi, 2006). In any case, evidence suggests that when single- and multiple-item measures are compared, they tend to perform similarly. For instance, Cheung and Lucas (2014) used data from large, representative samples to compare the associations between various criterion variables and both single- and multiple-item measures, and they found that correlations tended to be very similar in size. They concluded that there was not a loss of validity when single-item measures were used.

The Judgment Model of Subjective Well-Being

One of the biggest challenges to the validity of SWB measures comes from the judgment model of SWB (Schwarz & Strack, 1999). This model starts with the reasonable assumption that when asked about their well-being, respondents do not have a response stored in memory that can simply be accessed and reported. Instead, respondents must construct a response at the time of judgment. Researchers who work from this judgment-model tradition consider the various steps that take place when such a judgment is formed, and they investigate various sources of validity and invalidity that affect each step of the process.

For instance, because respondents may not have the ability or motivation to consider all relevant domains of their lives when making a life satisfaction judgment, it is possible that they rely on various heuristics to quickly derive an appropriate response to an experimenter's question. Most famously, Schwarz and Clore (1983) suggested that respondents may rely on their current mood at the time of the judgments as a proxy for how they feel about their life overall. To provide evidence for this possibility, Schwarz and Clore (1983) manipulated mood (in one study, by having respondents write about positive or negative life events, and in a second by contacting participants on days that varied in the pleasantness of the weather) and then asked participants to report on their satisfaction with life (the experimenters made sure to present the life satisfaction question as if it were part of an unrelated task so that participants would not make a connection between the mood induction task and the well-being question). In accordance with their predictions, Schwarz and Clore (1983) found that those who were exposed to the positive mood induction procedures reported much higher life satisfaction than did those exposed to the negative mood induction procedures.

Importantly, the authors included additional conditions in their design to provide support for the idea that respondents heuristically rely on mood as a proxy for a broader life satisfaction judgment. Specifically, in additional conditions, the authors drew respondents' attention to the fact that the mood they were currently experiencing may have resulted from the prior induction. By making the cause of the mood salient, the authors argued, respondents would be less likely to rely on this mood when making the life satisfaction judgment. Again, results supported this hypothesis: the previously described mood effects on life satisfaction judgments were eliminated when the cause of the mood was made salient. Subsequent studies replicated these results with additional mood inductions, including having one's favorite soccer team win or tie an important game or having participants complete the well-being questionnaire in a pleasant or unpleasant room (Schwarz, Strack, Kommer, & Wagner, 1987).

In a related series of studies, Schwarz, Strack, and colleagues suggested that the specific sources of information that are used when evaluating SWB can be influenced by contextual factors. Specifically, people base their judgments about the quality of their lives on different life domains, depending on which of these domains are salient at the time of the judgment. For instance, Strack, Martin, and Schwarz (1988) asked respondents about their satisfaction with life and their satisfaction with dating in one of two conditions: either with the dating question asked immediately prior to the global life satisfaction question or immediately following the question. The idea was that if satisfaction with dating was made salient, then respondents would be more likely to incorporate this specific life domain into their overall evaluation of life than if the domain had not been made accessible. Again, the results supported this prediction, with much stronger correlations between the two questions when the domain satisfaction rating was presented

prior to the life satisfaction question. Schwarz and Strack (1999) review additional studies that further clarify how this information is used in global well-being judgments, along with other contextual factors (such as information about social comparison or subtle features of questionnaire design) that can impact global well-being judgments in ways that potentially affect the validity of the measures. This programmatic line of research has had an important impact on perceptions of the validity of global self-reports of SWB (e.g., Kahneman & Krueger, 2006).

Concerns About the Judgment Model

In recent years, broad concerns have been raised about standard research practices in the field, especially within (though certainly not limited to) specific domains in social psychology (Bakker, van Dijk, & Wicherts, 2012; Open Science Collaboration, 2015; Simmons, Nelson, & Simonsohn, 2011). These new methodological critiques suggest that certain "standard operating procedures" within the field can lead to high rates of false positive findings. These methodological practices include the reliance on very small samples, which can increase the rates of false positives that make it in to the published literature (Bakker et al., 2012); an aversion to publishing replication studies (Makel, Plucker, & Hegarty, 2012) and null results (Ferguson & Heene, 2012); and flexibility in analyses, which, when combined with natural tendencies to fall prey to confirmation bias, allow for capitalization on chance in support of a prediction (Gelman & Loken, 2013; Simmons et al., 2011). Because most of the published findings that support the judgment model were published at a time when these problematic methodological practices were the norm, it is worth revisiting the findings to determine whether the evidence is as strong as its advocates claim.

Indeed, a close look at the studies that are typically cited in support of the judgment model suggest that there is cause for concern. First, sample sizes from these studies are almost always extremely small (though for an exception, see Deaton, 2012). For instance, Yap et al. (in press) reviewed as many studies as they could find that examined the effect of mood on life satisfaction judgments and they reported that these studies had an average of just 11 participants per cell---a sample size that could only detect very large effects.

Second, the effect sizes that are typically found are arguably too large to be plausible given the hypothesized processes that underlie these effects. The effect of a mood induction procedure on life satisfaction judgments should result from the multiplicative effect of the induction on mood and the subsequent effect of mood on life satisfaction judgments. In turn, this means that the effect of a mood induction on life satisfaction judgments will necessarily be smaller than the effect of the induction on mood or mood on life satisfaction. Furthermore, one could derive plausible expectations for effect sizes from what we know about the typical effect sizes for mood induction procedures and for the association between mood and life satisfaction. As Yap et al. (in press) showed, however, effect sizes for the effect of mood induction procedures on life satisfaction judgments have typically ranged from *d*s of 1 to 2.5, which are equal to or even exceed the typical manipulation check effect sizes for mood inductions themselves (Westermann, Spies, Stahl, & Hesse, 1996)!

Finally, there is considerable evidence of analytic flexibility across studies, where different analyses are used and different effects emphasized (e.g., interaction versus simple effects) even when very similar designs were used. Together, these patterns suggest that large-sample replications would be needed before strong conclusions about the replicability and robustness of effects from the judgment-model tradition can be drawn.

Partly in response to these concerns, researchers have begun to reexamine classic effects from the judgment-model tradition using much larger sample sizes than in the originals. For example, Yap et al. (in press) conducted nine replication studies with sample sizes that were five to ten times as large as those from the originals to examine the effect of mood on life satisfaction judgments. Effects were typically not significant, and those that were significant were considerably smaller than those from the original studies. Overall, meta-analytic estimates from the nine studies were less than one-tenth the size of the average effect from the original work (with *d*s around .15). These studies suggest that mood has only weak effects on life satisfaction judgments.

Moreover, these replication studies are consistent with other large sample studies investigating context effects on SWB judgments. For instance, Lucas and Lawless (2013) used a sample of almost one million U.S residents to examine the effect of current weather conditions on life satisfaction judgments. Even though they had considerable power to detect ever very small effects, they found no evidence that weather systematically influenced satisfaction judgments. In addition, in a study specifically designed to examine the extent to which naturally occurring fluctuations in mood were associated with fluctuations in life satisfaction judgments, Eid and Diener (2004) assessed both multiple times over a three-month period. They showed that although mood fluctuated considerably across occasions, life satisfaction judgments did not. Furthermore, the transient component of life satisfaction was only weakly associated with changes in

mood, confirming with a different designs the results from Yap et al. (in press).

Additional studies have examined other context effects predicted by the judgment model and have had similar problems replicating the original findings. Most notably, Schimmack and Oishi (2005) conducted a number of studies examining item-order effects, in which the association between satisfaction with a specific domain and satisfaction with life as a whole varies depending on whether the domain was assessed prior to or after the global judgment (e.g., Strack et al., 1988). Schimmack and Oishi failed to replicate the large differences found in the original studies, and they showed in a meta-analysis that most studies that have tested for item order effects show only small differences across conditions. Schimmack and Oishi concluded that manipulating the order of items should, theoretically, not have large effects, as domains that are likely to be considered in global judgments (such as health or romantic relationships) are typically chronically salient, and thus will be included in global judgments even if the context does not make them salient. On the other hand, domains that are not chronically salient (e.g., the weather, local public transportation) are unlikely to be considered relevant for global life satisfaction, and thus will not affect satisfaction judgments even when made salient. Thus, they argued, item order effects should not be expected to be pronounced; a prediction that is supported by their large-sample studies and meta-analysis.

It is true that at least one large-sample context effect was found that had more than a modest effect size. Deaton (2012) showed that in Gallup data, asking questions about politics before a question about subjective well-being led to a moderate drop in life satisfaction, compared to a condition where these political questions were omitted. Although the mechanisms underlying this effect have not been determined (see, e.g., Lucas, Oishi, & Diener, 2016), the fact that this effect emerged in a large sample study must be acknowledged. Importantly, however, Deaton also showed that the effect was eliminated very easily simply by asking a buffer question that returned focus to the person's life before asking the well-being question. Future research can clarify when and how these effects emerge or can be prevented.

Research from the judgment model is valuable in that it pushes well-being researchers to consider the processes by which respondents formulate and report responses to questions about their SWB. The theory itself is straightforward and elegant, and it is likely that the processes identified by judgment-model researchers can impact life satisfaction judgments (as they have been shown to affect judgments in a wide range of circumstances). The important practical question, however, is not whether these processes exist, but how much they affect the psychometric properties of well-being judgments. It is possible, for instance, that the heuristics that the judgment-model researchers have identified represent just one of many processes that people can use to formulate well-being judgments, and any problems for validity that these processes introduce are outweighed by more straightforward and intuitive processes that positively impact the validity of these measures. Thus, it is important not only to look for evidence of underlying processes posited by the judgment model, but also to explicitly test the extent to which these processes undermine the validity of these measures as typically used. The research reviewed above suggests that context effects predicted by the judgment model tend to be very small; a conclusion that is supported by the considerable evidence for reliability and validity of SWB measures.

Comparing the Psychometric Properties of Global and Experiential Measures

If the two main categories of self-report measures of well-being are global measures and experiential measures, then a final issue to consider concerns the comparison between the two in terms of their psychometric properties. Remember, the idea behind the latter experiential measures is that assessing affective reactions at the time they occur (or very soon after) reduces memory problems and prevents biases that result from aggregation. Thus, it is often argued that such measures will have more desirable psychometric properties than global measures (Kahneman, 1999). However, it is possible that these methods have unique psychometric problems that don't affect global measures. In addition, the relatively high level of respondent burden means that respondents are often assessed over a very short period of time, which can lead to concerns about the stability of results that are obtained. In other words, if respondents are asked to complete a day reconstruction method report for a single day of their lives, will the affect they experience generalize to other days and reflect a stable sense of well-being?

In their initial development efforts, the researchers who proposed the day reconstruction method did not assess long-term stability, but recent efforts have begun to provide information on this topic. For instance, Krueger and Schkade (2008) tested short-term stability and found that it was comparable to global measures of life satisfaction, even when only a single day of experiences was sampled. Similarly, both Hudson, Anusic, Lucas, and Donnellan (in press) and Hudson, Lucas, and Donnellan (2016) tested four-week stability of DRM measures, with results showing moderate stability, with correlations in the range of .40 to .60. Hudson, Lucas, and Donnellan (2016) used four waves of data, each separated by a year-long interval, to test the long-term stability of the day reconstruction methods. Again, even though just a single day of experiences was sampled, year-to-year stabilities were moderate and only slightly weaker than those

from global measures like a single-item life satisfaction scale. Thus, it appears that relatively stable, trait-like measures of well-being can be obtained even from a single day's worth of reports.

These studies have also begun to compare the convergent and construct validity of global and experiential measures using large samples of participants. Anusic et al. (2017), for instance, used data from a three-wave study to examine the correlations between global and day-reconstruction-based measures of well-being and informant reports and relevant criteria (also see Hudson et al., 2016, for a similar study with similar conclusions). These studies show that global self-reports typically correlate as strongly or even more strongly with alternative measures and relevant criteria as compared to experiential measures derived from the day reconstruction method.

Given the theoretical arguments for the superiority of experiential measures over global measures, why don't experiential measures show enhanced validity when compared directly to global measures (at least in these initial studies)? One possible reason is that the two types of measures assess two distinct underlying constructs. For instance, Diener and Tay (2014) suggested that global measures are better at tapping experiences that are contextualized within a person's life schema, and that this allows these measures to predict a wider range of meaningful outcomes than more experiential measures that lack such contextualization.

Alternatively, it is possible that the unique demands of the experiential measures create specific threats to validity that do not apply to global measures. For instance, Watson and Tellegen (2002) argued that when respondents are asked to repeatedly respond to affect questions, unwanted response-style variance can, because of aggregation, get amplified relative to the variance that taps the underlying construct. Furthermore, additional research shows that asking respondents to repeatedly answer the same question over and over again can change respondent's interpretation of the questions.

For instance, Baird and Lucas (2011) examined this issue in a different domain: the repeated assessment of personality across different situations. They found that respondents reported more variability and greater impact of situational features when they were asked to report their personality multiple times in different situations than if they were asked to report on their personality in just one situation. In other words, when asked how extraverted they were in a specific situation, respondents exaggerated the effect of the situation when they were asked about multiple situations than when they were asked just about one. It is possible that experiential measures like experience sampling or day reconstruction methods communicate to respondents that they should emphasize the *changes* that occur from situation to situation rather than the *stability* that they experience. If so, this may affect associations between experiential measures and stable predictors of well-being. All in all, although experiential measures are especially useful when assessing changes in affective experiences over short periods of time, they do not have a clear advantage over global measures when used to assess stable levels of well-being. Of course, more research that directly compares the psychometric properties of these two forms of measures is needed.

Conclusion

The domain of SWB, by definition, focuses on people's subjective evaluations of their lives. Thus, there is a strong emphasis within SWB research on self-reports of the construct, as such subjective evaluations may best be assessed by asking the subject themselves. However, the subjective nature of the construct does not mean that self-reports are an unimpeachable source of information about the construct. As with all measures, the psychometric properties of these instruments must be assessed.

Fortunately, existing research suggests that SWB measures typically have desirable psychometric properties, including relatively high levels of reliability, convergent, discriminant, and construct validity. To be sure, these measures, like all self-report measures, are not perfect. Research from traditions such as the judgment model of SWB provide the means of testing some of the processes underlying well-being judgments, and when combined with more traditional approaches to evaluating psychometric properties, this research can help clarify the relative strengths and weaknesses of these approaches. Thus, research on the properties of self-report measures can not only strengthen conclusions from research that uses those methods, but can also help clarify what SWB is and how people go about evaluating their lives.

Non-Traditional Measures of Subjective Well-Being and Their Validity: A Review

By Christie Napa Scollon, Singapore Management University

Citation
Scollon, C. N. (2018). Non-traditional measures of subjective well-being and their validity: A review. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

This chapter reviews a variety of methods for assessing subjective well-being beyond traditional global self-reports. The chapter examines indicators of SWB such as brain activity, smiling, cognitions, memory, and momentary experience. The author discusses the practical costs and benefits of each. Lastly, the chapter reviews new forms of data such as social media and internet searches and how they can reveal information about the subjective well-being of groups. While no single measure is perfect, this chapter aims to equip researchers with the knowledge to make informed decisions in their research designs and projects.

Keywords: Measurement, Assessment, ESM, DRM, Twitter, Facebook

Traditionally, subjective well-being (SWB) has been measured with global self-reports. There are good philosophical foundations for using self-reports of SWB. After all, the construct refers to subjective, not objective well-being, and who is best to judge how someone feels about her life other than the person herself? Global self-reports such as those captured by life satisfaction questions are especially relevant because it is these broader cognitive evaluations of one's life as a whole that are arguably at the heart of SWB. Similarly, other self-reports such as frequency and degree of positive and negative emotions provide information about the affect component of SWB. Nevertheless, there are good reasons to explore alternative measures of SWB. For example, global self-reports of SWB can be vulnerable to memory biases, social desirability, or focusing illusions. Another reason is that newer technologies may allow scientists to collect SWB data through less burdensome, more economical means. No matter the case, alternative measures of SWB can complement traditional self-reports. This chapter will explore these alternative measures and their validity.

Brain Activity

Since the 1990s techniques such as functional magnetic resonance imaging (fMRI) and electroencephalogram (EEG) have revolutionized the field of psychology. What can a window into brain processes reveal about SWB? Specifically, can fMRI and EEG be used to measure SWB? In order to address this question, we must first determine whether reliable patterns of brain activation exist for happiness or other emotions. Feldman Barrett and Wager (2006) pointed out that conditions such as consistency (i.e., activation that is not due to emotion induction procedures) and specificity (i.e., activation patterns that are non-overlapping for various states) must be met in order to establish the validity of the measures.

A handful of studies have used meta analytic techniques to examine the many fMRI and positron emission tomography (PET) studies to identify neural profiles for happiness and other emotions. Unfortunately, there remains no consensus among meta analytic studies. For example, Murphy, Nimmo-Smith, and Lawrence (2003) identified the rostral supracallosal anterior cingulate cortex (ACC) and dorsomedial prefrontal cortex (PFC) as highly involved in happiness, whereas Phan, Wager, Taylor, and Liberzon (2002) identified the basal ganglia as consistently involved in happiness. More recently, Vytal and Hamann (2010) used a more sensitive meta-analytic method to determine if any consistent activation exists for specific emotions. For happiness, the most frequently activated structure was the right superior temporal gyrus (STG).

Often it is difficult to separate activation due to the emotion itself and activation due to other cognitive processes invoked during the emotion induction procedure. For example, Suardi, Sotgiu, Costa, Cauda, and Rusconi (2016) reviewed 15 studies which used fMRI and PET on subjects who had been asked to recall happy memories. They found that remembering happy autobiographical events was associated with activation in the PFC, ACC, and insula. However, these structures were also implicated in the experience of negative emotions. Indeed, autobiographical recall is a complex task that requires memory retrieval, self-referencing, and cognitive processes such as appraisal. Not surprisingly, these very regions (PFC, ACC, and insula) have also been identified as relevant to these complex processes.

Similarly, Phan et al. (2002) identified the medial PFC as generally involved in emotion processes, and activation of the ACC and insula as due to emotion recall procedures.

Despite the vast number of studies, neuroscience has yet to converge on any clear brain markers of happiness or any other emotion for that matter. In fact, the most agreed upon finding is that the amygdala is involved in fear (Murphy et al. 2003; Phan, et al. 2002), but even then, there is disagreement among scientists. For instance, the conditions of consistency and specificity have been hard to meet. There are conditions under which amygdala activation occurs which do not involve fear and sometimes even involve positive stimuli (see Feldman Barrett & Wager, 2006).

Part of the challenge in identifying which brain structures are associated with happiness is that most structures are involved in multiple emotions and serve multiple functions. Few distinct patterns exists that characterize a particular state or trait. However, there is evidence to suggest neural correlates of broader affective categories as there appear to be differences in brain activation in approach-related emotions (e.g., happiness, anger) as compared to avoidance-related emotions (e.g., fear, sadness). For instance, Richard Davidson's lab uses EEG to measure asymmetry of frontal lobe activation. His team has consistently found that greater left than right PFC activity is associated with positive affect (Urry et al., 2004). Similarly, Feldman Barrett and Wager (2006) noted that some studies found greater left-side activation for approach-related (as opposed to avoidance-related) affect. The findings are consistent with Gray's (1970) neurobiological theory which posits the existence of a Behavioral Activation System that governs appetitive, reward seeking behavior, and a Behavioral Inhibition System that governs avoidance behavior.

Smiling

What can a smile reveal about a person's SWB? Two detailed studies provide strong evidence that smiling in photographs is a valid measure of SWB. Harker and Keltner (2001) examined yearbook photos of women from the Mills College Study. Expert raters used the Facial Action Coding Scheme (FACS: Ekman, Friesen, & Hager, 1978) to rate the photographs, including the extent to which the women exhibited Duchenne smiles, or genuine smiles. Photographic ratings correlated with self-reports of personality and emotion. Individuals who expressed more positive emotionality in their yearbook photos reported less negative emotionality—and this relation held over time even when comparing self-reported emotionality 20 years after the photographs were taken. Photographic expressions also correlated with scores on the Well-Being Scale of the California Psychological Inventory (CPI: Gough, 1990) which contains items about emotional and physical health and has been shown to be highly related to life satisfaction.

Another study by Seder and Oishi (2012) compared photographs from Facebook profiles and self-reported life satisfaction. Expert raters judged participants' photographs for displays of positive emotionality. Smile intensity not only correlated with concurrent life satisfaction, but it also predicted changes in life satisfaction. Individuals with greater and more genuine smiles at Time 1 had greater increases in life satisfaction over a two-year period than those with less intense or no smiles. Moreover, it was demonstrated that the effect was not due to extraversion.

Abel and Kruger (2010) and Scollon, Sim, Shin, Koh, and Stevens (2016) also used smiling in photographs as a measure of SWB, but these studies did not have self-reported data to validate their measure. They did, however, find that smiling predicted longevity (Abel & Kruger, 2010) and teaching performance (Scollon et al., 2016)—results which are consistent with a broader literature demonstrating the links between positive emotionality and desirable life outcomes (e.g., Danner, Snowdon, & Friesen, 2001; Lyubomirsky, King, & Diener, 2005). These authors have argued that the photographs indeed capture stable individual differences in SWB.

Other research suggests a need for caution when making inferences about smiling. Labroo, Mukhopadhyay, and Dong (2014) demonstrated that people differ in their lay theories about smiling. Whereas some people smile when they *are* happy (emotion expression theory), others smile in an attempt to *become* happy (emotion regulation theory). In a series of experiments, Labroo et al. (2014) found that smiling made people with the expression theory feel happier (probably based on a facial feedback mechanism) whereas smiling made people with the regulation theory feel worse. By this rationale, smiling might be less informative about the SWB of a person who holds the emotion regulation theory, compared to people who hold the expression theory. Labroo et al. (2014)'s study, however, was a laboratory experiment where smiling was manipulated. Assessing smiling in photographs may be less of a problem because there is a strong expectation to express how one feels, rather than regulate internal states at that moment.

In short, smiling appears to be a valid indicator of SWB. Relative to other measures, smiling is not widely used as a measure of SWB in research. However, as the technology for automatic coding of facial expressions improves, reducing or removing the need for human coders, the science of SWB may see more

studies using smiling in the future (see big data section).

Experience Sampling Methodology

Experience Sampling Methodology (ESM) involves participants answering questions about their affect and activities in real-time several times a day over several days. For example, respondents in a typical ESM study may receive 4-7 signals or alerts during the waking day. When respondents receive an alert, they complete a brief questionnaire about what they are doing at that moment, how they are feeling, etc., that typically takes less than a minute to complete. Technologies such as smart phones or personal data devices (e.g., Palm Pilot) make it easy for scientists to sample affect, behaviors, and time use by automatically sending alerts to participants and storing participants' responses either directly on the device or on a server. Smartphone technologies can even allow researchers to capture multimedia data and location information as well. These advances have made ESM more convenient for participants and reduced error and data loss leading to a greater response rate overall. Smart phones in particular are convenient for both researchers and participants. A 2015 Pew Survey found that 68% of Americans now own a smartphone. Among smartphone owners, 81% report that they keep their smartphone near them almost all the time during waking hours, and more than 70% report checking their smartphone a minimum of once per hour (Gallup, 2015). Never before in the history of social science research have scientists been able to track daily lives so closely and frequently. For a comprehensive review of ESM see Scollon, Kim-Prieto, and Diener (2003).

The advantage to using ESM is that respondents report on their feelings and activities in real-time or close to real time. This reduces the memory biases that often plague retrospective or global reports of well-being (Feldman Barrett, 1997; Oishi, 2002; Robinson, Johnson, & Shields, 1998; Scollon, Diener, Oishi, & Biswas-Diener, 2004). The richness of the repeated measures also allows scientists to investigate dynamic and within-person processes (e.g., Tov & Lee, 2016).

To examine the validity of ESM, we need to consider not only the psychometric evidence but also the philosophical underpinnings of the construct of SWB and its measures. The studies that have measured both ESM and global self-reports of SWB have shown there is a positive moderate correlation among the measures (Scollon et al., 2004). The less than perfect correlation either means that ESM and global self-reports are not exactly the same, or that one or both of these measures is poor. Because ESM relies on repeated measures, the aggregated data yield high reliability estimates, typically in the .90s. Therefore, the assumption is usually that ESM is the gold standard and that global self-reports are the fallible measure.

Assuming ESM is the gold standard, what can it be compared to for validation? Ultimately, researchers need to look at the entire nomological network of measures. Wirtz, Krueger, Scollon, & Diener (2003) examined ESM, global/retrospective ratings, and behavioral choice in their study which tracked students before and after a Spring Break experience. Students reported on their feelings before, during, and after the vacation. Three weeks after returning from their vacation, respondents reported the extent to which they would like to have a similar Spring Break experience to the one they just had. Wirtz et al. (2003) found the expected intercorrelations among all the SWB measures. However, and most intriguingly, ESM reports during the vacation were completely unrelated to wanting to repeat the experience. Only students' memories of the vacation predicted wanting to repeat the same (or similar) experience. At first glance, the findings may seem to defy conventional wisdom, not to mention behaviorism which posits that human beings should seek to repeat experiences they enjoy and avoid experiences they didn't enjoy. However, the results highlight the fundamental difference between what Kahneman (2010) calls experienced versus remembered utility. ESM captures experienced utility, the enjoyment that occurs during an experience, whereas global and retrospective reports capture remembered utility, how one remembers an experience. Whereas experienced utility is fleeting and lasts only as long as short-term memory lasts, remembered utility remains and continues to influence behavior long after the experience is over. The two types of utility are independent, and although ESM may have greater veracity or accuracy for experience utility, it is not necessarily superior depending on the outcome measure.

Unlike global self-reports of SWB, ESM has a greater potential for reactivity effects. Because the methodology draws attention to the respondent's internal states, perhaps with high frequency and intensity, ESM may actually change people's well-being during the course of a study. For example, depressed participants in a two-week experience sampling became less happy over time with greater frequency of emotion reporting (Conner & Reid, 2012). By contrast, non-depressed participants showed the opposite pattern and became happier over time with greater emotion reporting.

There are practical limitations to ESM as well. First, the methodology is intensive. Participants can find the frequent questioning to be invasive, even irritating. For this reason, researchers must keep the number of questions in each momentary assessment to a minimum. Second, the methodology requires considerable compliance from participants, which means some groups will be over-represented in ESM

studies (e.g., conscientious people with not too chaotic lives), and even then researchers must typically offer good incentives for people to participate. Technological advances that make ESM more convenient for participants (such as using a smart phone app on the participant's own phone) will help narrow the gap between those who can and those who cannot complete an ESM study, but there are some limitations which will always remain. For scientists interested in starting their first ESM study, see Conner and Lehman (2012).

The Day Reconstruction Method

The Day Reconstruction Method or DRM (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004) has been heralded as offering the richness of ESM with the convenience of a single-time assessment. The DRM guides respondents through a detailed moment-by-moment reconstruction of the previous day's activities. Participants record the location, duration, and affect experienced during each episode. Experienced affect can be weighted as a function of duration, and researchers can estimate affect in specific activities (e.g., childcare, commuting). The DRM is designed to minimize memory biases by being close in proximity to the previous day's experiences and by relying on cued recall. Several studies have now examined its validity.

Individual Difference Studies

Responses on the DRM consistently correlate with individual difference measures in expected ways. Depressed patients report more negative and less positive affect in the DRM compared to non-depressed patients (Bylsma, Taylor-Clift, & Rottenberg, 2011). Likewise, the relation between PA and Extraversion has been replicated using the DRM (Srivastava, Angelo, & Vallereux, 2008). Diurnal patterns of affect using the DRM (Daly, Delaney, Doran, & MacLachlan, 2011; Kahneman et al., 2004) mirror studies using ESM. Other studies have shown that the DRM can be used successfully and meaningfully in a variety of cultures (Caballero et al., 2014; Mellor-Marsa et al., 2015). On the other hand, Hoffenaar, van Balen, and Hermanns (2010) compared the DRM and global measures in a sample of women pre- and post-partum and found only modest convergence among the two types of reports. The authors concluded it is important to measure both global and experienced affect.

Is the DRM a Good Substitute for ESM?

In order to answer this question, researchers need to directly compare ESM data and DRM data. Dockray et al. (2010) was one of the few studies to have done this, and they found consistent within-person variation in affect across the two types of measures. Specifically, affect, especially reports of happiness, in both the DRM and ESM corresponded with one other over the course of the day. Fisher R to Z correlations were generally around .60, before adjusting for unreliability, lending strong support to the idea that the DRM may, in fact, provide equivalent information to ESM. However, Diener and Tay (2014) pointed out that completing the ESM together with DRM may inflate the convergence of measures. By drawing attention to people's emotions using ESM, responses on the DRM may be more accurate than usual.

Bylsma et al. (2011) found moderate to strong correlations among ESM and DRM measures in a sample of depressed and non-depressed participants. They also tested for reactivity to events and found reactivity effects replicated across the two methods. Srivastava et al. (2008) also tested for reactivity using the DRM and found that extraverts do not display greater reactivity to social events. Srivastava's study replicated what Lucas and Baird (2004) established using ESM, lending further support to the DRM as a decent substitute for ESM.

Abbreviated DRM

Although the DRM is significantly less time intensive than ESM, it still takes typically one hour to complete, which makes it impractical for large scale studies. Anusic, Lucas, and Donnellan (2016) examined the validity of a random sampling DRM. In this abbreviated format, respondents list the previous day's episodes or events, similar to the original DRM. However, instead of providing affect ratings for all episodes, respondents rate a randomly selected subset of episodes. Most promising, the shortened version of the DRM was shown to converge with other SWB measures and yielded results comparable to the original DRM studies.

Caveats

At the heart of these validation studies lies a more fundamental question about what specific measures mean within a theory of subjective well-being. In comparisons of the DRM with ESM, the assumption is that ESM is the gold standard. As described earlier, ESM has been shown to be a poor predictor of behavioral choices (Wirtz et al., 2003). If the DRM is supposed to yield ESM-like data, is there any reason to suspect that the DRM would be any better at predicting behavioral choices?

Another limitation of the DRM is the common practice of weighting affect by duration of the

episode. While there is a logic to this practice, it also presupposes that psychological duration can be counted in the same units as time. Lastly, one of the chief advantages of the DRM over ESM is that the DRM can provide nearly as much information as ESM without the time/resource intensity. However, smart phone apps and more widely available passive data may erode this gap or at least narrow it.

Memory Measures

A memory task can be a subtle, yet powerful way to assess SWB as demonstrated by Sandvik, Diener, and Seidlitz (1993). They gave subjects 2 minutes to recall all the positive things that had happened in their lifetime, and later another 2 minutes to recall all the negative things that had happened. The balance of frequency of positive memories over negative memories was shown to correlate with self-reports of life satisfaction. In other words, happy people recalled a preponderance of positive events over negative events compared to unhappy people. Seidlitz and Diener (1993) found this individual difference was stable across samples, and the mechanisms behind the effect stemmed from differences in experience and interpretation of events. Happy people simply experience more positive events than unhappy people in general, and happy people interpret the same events as more positive than unhappy people. The belief that happy people recall more positive events because they are in a happy mood at the time of recall was not supported. There was also little evidence for the notion that happy people rehearse positive information more, thereby strengthening their retrieval of happy events.

From a practical standpoint, memory measures have a lot to offer researchers with little cost. Because they are an indirect indicator of SWB, they are not susceptible to social desirability artifacts the way asking someone how happy they are can be. Memory measures can also be implemented easily, cheaply, and quickly. To avoid priming effects, however, researchers should place memory tasks before other items that may influence accessibility of positive or negative information. Relative to other types of SWB measures, memory measures are underused in the literature, but the evidence shows they may be a good alternative.

Cognitive Accessibility

Two studies suggest that people with higher SWB organize positive emotions differently from their less happy counterparts, and this may point the way toward innovations in measurement. Robinson and Kirkeby (2005) devised a method of measuring cognitive organization based on a reaction-time paradigm. In their study, people with high life satisfaction were faster to report their positive emotions when the question followed another question about positive emotion. For example, they were faster to report how much joy they experience in general if this question followed a question about how much excitement they experience in general. By contrast, when a question about negative emotion was followed by a question about positive emotion, happy people were relatively slower to respond (e.g., how much anxiety do you experience in general, followed by how much happiness do you experience in general). The decreased reaction times suggest that positive emotions are organized in a tighter associative network for happy people.

In an independent set of studies, Koo and Oishi (2009) adapted the classic Deese-Roediger-McDermott "false memory" paradigm to examine how people organize happiness-related concepts. For example, participants learned several word lists, one of which included words related to happiness (e.g., excited, joy, smile). Importantly, each list omitted a critical word that was associated with the content of the rest of the words. In the case of the happiness-related list, the word happiness (known as the 'critical lure') was intentionally omitted so participants would not study it. Compared to unhappy people, happy people falsely recalled "happiness" as being part of the studied word list. In other words, they were more susceptible to having false memories but only for a category related to positive emotions. They were no more likely to have false memories for other categories.

These two studies demonstrate that activation of happiness-related concepts may automatically lead to activation of other parts of an associative network in happy individuals. Although no studies have used cognitive accessibility or the false memory paradigm to capture stable individual differences in SWB, these two studies show how they can be useful.

Informant Reports

Most theories of SWB hold that the individual is the best judge of his or her own happiness. Nevertheless, can other people be a valuable source of information about a person's happiness? Most studies show modest to moderate correlations among self-reports and informant reports of SWB. For instance, Zou, Schimmack, and Gere (2013) compared students' self-reports of SWB with parents' reports of the student's SWB and found convergent correlations of .30 to .36. In a meta-analysis, Schneider and Schimmack (2010) found an overall correlation of .42 among self and informant reports of life satisfaction. Similarly, Koydemir and Schütz (2012) also found moderate convergence (*r*s .42 to .46) among informant

and self-ratings of life satisfaction. The highest convergence (in the .5s) was from Sandvik et al. (1993) whose participants had a minimum of 7 informants each, including at least one parent and one friend. Sandvik et al. (1993) noted that more informants and more items increase the convergence of self and informant reports.

Informant reports have even been used to study the well-being of primates (Robinson et al., 2016; Weiss, King, & Perkins, 2006). Of course, primates cannot supply self- report ratings to compare with the informant reports. However, primate studies of SWB demonstrate the psychometric reliability of observer measures. Weiss et al. (2006) reported an intraclass correlation (equivalent to Cronbach's alpha) of .83 for chimpanzee SWB when at least 3 raters provided judgments about the animal.

Importantly, however, the degree to which SWB is visible may vary by person and culture making informant reports a better indicator for some than others. Saeki, Oishi, Maeno, and Gilbert (2014) examined the convergence of self and informant reports of SWB and personality in Japanese and American samples. While self and informant reports converged in general, the convergence was lower among Japanese samples than among American samples. Self and informant reports of life satisfaction also had lower convergence than traits such as extraversion. Their findings highlight the unobservable nature of SWB, which appears to be less visible than say extraversion, and which may be more or less visible depending on one's culture.

Implicit Measures

The implicit association test (IAT) was first developed by Anthony Greenwald and colleagues (1998) to measure implicit or unconscious racial bias. The IAT uses reaction times to measure the strength of positive and negative associations towards a particular category, such as African Americans, the elderly, women, obese people, the self, or even one's own life. The Implicit Life Satisfaction (ILS: Kim, 2004) measure adapts the original IAT framework by pairing "my life" with the evaluative categories of "good" versus "bad" to measure an individual's automatic evaluation of his or her life. Whereas self-reports of life satisfaction often invite socially desirable responses, implicit measures of SWB can circumvent this problem.

Kim (2004) reported that the ILS showed reasonable internal consistency (*r*s ranging in the .70s and .80s) and modest test-retest correlations (r = .41). Implicit life satisfaction did not correlate with self-reported life satisfaction. In general, many of the IAT variants have low test-retest correlations, especially in comparison to their explicit counterparts. In addition, within the IAT paradigm, implicit measures are not necessarily expected to correlate with explicit measures as they are independent processes.

Interestingly, individuals who recently escaped North Korea had higher levels of explicit life satisfaction compared to South Koreans or resettled North Korean defectors (Jang & Kim, 2011). The high explicit life satisfaction was attributed to the recent dramatic and positive changes in defectors' living conditions. However, both recent and resettled North Korean defectors showed similar low levels of implicit life satisfaction, which the authors attributed to chronic negative living conditions. Although results from this unique study are consistent with theories of SWB and IAT research, more studies are needed to confirm the validity of the ILS.

As to whether respondents can fake responses on the ILS, Kim (2004) found that respondents could suppress their implicit life satisfaction scores when instructed to do so by slowing down their responses. However, respondents could not enhance their responses to achieve higher life satisfaction scores by responding faster. Thus, while the ILS may not be susceptible to socially desirable responding, it is not entirely immune from conscious control.

Big Data

One of the most exciting areas to provide new insight and ways of measuring SWB is through big data, particularly big data from social networking sites such as Facebook and Twitter or search engines such as Google. Big data have been described as having high "volume, velocity, and variety," (Laney, 2001) making them rich sources of information about human behavior. Information can be obtained unobtrusively on millions of users, enabling social scientists to overcome methodological problems such as under-powered designs, non-representative sampling, participant selection and fatigue, etc. This sounds like a social scientist's dream, but it may be worth taking a closer look at the validity of such measures. To date, a handful of studies have examined the validity of Facebook status updates or Twitter tweets as sources of information about a person's SWB.

Facebook

Wang, Kosinski, Stillwell, and Rust (2014) correlated Facebook Gross National Happiness scores with daily life satisfaction scores from Facebook users in 2009 and found few significant correlations. The

authors concluded that Facebook status updates were not a valid way of measuring well-being or mood. However, the daily FBGNH ratings were not necessarily derived from the same Facebook users who provided the life satisfaction ratings, which may explain why Wang et al.'s results were inconsistent with data reported by Facebook scientist Adam Kramer (2010).

Kramer (2010) also compared the SWLS with the FGNH in a group of over 1,000 of the same respondents. According to Kramer (2010), life satisfaction correlated 0.17 with positivity in status updates. Considering the sample size, the magnitude of the correlation was surprisingly weak. Lending to its face validity, however, FGNH overall showed an increase during holidays and dips during national tragedies. Also, consistent with traditional studies of SWB (Larsen & Kasimatis, 1990), FBGNH showed a cyclical day-of-the-week effect where mood is highest on Fridays and lowest on Mondays.

Perhaps one explanation for the weak correlations between social media posts and life satisfaction is that social media biases users to post positive content. Liu, Tov, Kosinski, Stillwell, and Qiu (2015) postulated that self-presentation norms increase people's desire to post positive status updates, rendering positive updates less indicative of a person's true SWB. However, negative emotions are more 'honest' reflections of SWB because they are not subject to self-presentational concerns. Indeed, they found that negative, but not positive, emotion in Facebook status updates were related to life satisfaction. In addition, only status updates from the past 9 months or earlier were related to life satisfaction, a finding which corroborates Suh, Diener, and Fujita (1996) who found that only recent events contribute to SWB.

Twitter

Yang and Srinivasan (2016) directly sampled a subset of Twitter users who tweeted life satisfaction content and completed the SWLS. People who made more life satisfaction tweets had higher life satisfaction scores than those who tweeted dissatisfaction (e.g., "I hate my life"). High life satisfaction also related to tweeting more positive and fewer negative words overall, and using fewer first-person singular pronouns. Overall, the number of life satisfaction tweets was low compared to the total number of tweets (only .13%). This is not surprising given that researchers have to rely on the spontaneous mention of life satisfaction in tweets, which may make for unnatural language in the Twitter world. This may explain why there are more Twitter studies using affect instead of life satisfaction, although life satisfaction and affect tweets showed discriminant validity. Importantly, researchers need to select their words for searches carefully when trying to examine SWB from tweets.

Yang and Srinivasan's study (2016) also revealed that Twittered life satisfaction did not fluctuate with events over two-year time frame, consistent with the stability of traditional life satisfaction measures. Replicating the findings that religiosity contributes to SWB, Twitter users with high life satisfaction also posted more about religion than unhappy ones. Like Kramer's study, these findings indicate good face validity of tweets as a source of information about SWB. Unfortunately, Yang and Srinivasan (2016) only had a response rate of .46% in their study. Responders might conceivably be more consistent overall than non-responders. In any event, there appears to be promising evidence that Twitter can be used to gather meaningful data about life satisfaction.

Using a different approach, Schwartz et al. (2013) examined Tweets from over 1,000 U.S. counties with at least 30,000 Tweets per county. Their data spanned a period of 14 months and compared the Twitter data to surveys of life satisfaction from people in the same counties. Like Wang et al. (2014), the Twitter users were not necessarily the same individuals who provided the life satisfaction data. Nevertheless, the two sources were correlated, and Twitter word use predicted county level life satisfaction above and beyond demographic variables such as median age and income. Moreover, topics that were most strongly associated with life satisfaction—for example, physical activity, social engagement, and prosocial activity—were the very ones that have consistently been found to be related to well-being using more traditional data sources.

In addition to Facebook and Twitter, other platforms such as Instagram have potential as well because the information posted by individuals are publicly available. Given the usefulness of smiling in photographs (e.g., Seder & Oishi, 2012), researchers could easily gather smiling data from Instagram as a measure of the user's SWB. With improvements in machine learning technology, the extraction of psychological information will become easier and easier, eventually removing the need for human coders entirely. Some commercially available software already exists (e.g., Noldus). To give one example of what can be done, Redi, Quercia, Graham, and Gosling (2015) identified the ambience of cafes using profile pictures of the cafes' customers. For example, a hipster café might attract more customers who wear glasses. Cleverly, the researchers used machine learning to teach computers to extract visual information from profile pictures that had previously been found to correlate with ambience. Other sources of big data, even those that are outside the realm of social media or those that have yet to be invented, may also prove to be useful to SWB science. The possibilities are endless and only constrained by our

imagination.

Google Searches

Whereas Kramer (2010) described the Facebook status update as a "self-descriptive text modality, optimized and designed to elicit updates about the self," and the "strongest signal of the emotional well-being of the poster," Ruths and Pfeffer (2014) cautioned that social media distorts human behavior. Not only are the platforms themselves explicitly designed to shape human behavior (e.g., social network sites aim to increase homophily through the recommendation of friends and sites), but there is a heightened sense of self-presentation in social media (e.g., Liu et al., 2015), which may lead to the data not accurately reflecting people's true thoughts and feelings. By contrast, when people conduct internet searches, they do so in privacy, making the study of internet searches one of the rare glimpses into private behaviors that is available to scientists. Furthermore, unlike self-reports internet searches do not require introspection. Thus, by examining what people in a population are searching for on the internet, researchers may be able to estimate the well-being of that population.

Ford, Jebb, Tay, and Diener (2017) were the first to examined Google search activity and its relation to well-being. Indeed, regions with greater frequency of searches containing words such as *depression*, *afraid*, or *anxiety* had lower self-reported affect and more incidences of coronary heart disease and depression. This pattern emerged at both state and metropolis levels. Although internet searches are a powerful and inexpensive way of capturing people's deepest concerns, there are limitations on the capacity of internet searches to represent SWB. Mainly, people whose search queries include words such as *depression* are likely to be experiencing negative emotions and thus seeking ways to resolve them. By contrast, someone with high life satisfaction is unlikely to Google positive emotion terms. Ford et al.'s study, in fact, was limited to internet searches of negative terms.

Overall, big data have enormous potential for understanding SWB, and they are constantly being generated with no incentives at all from scientists. Compared to surveys or ESM which can be very costly, social media data and internet searches are potentially economical sources of information. Despite these advantages, there are limitations. For instance, social media users will tend to be younger and more tech savvy than the general population. In addition, Twitter only releases a small sample of tweets to the public. Twitter also limits the number of words users can post. However, these limitations are small in comparison to the enormous information big data can provide.

Skepticism and Caution

These new forms of data are already raising some novel and potentially serious ethical concerns for scientists. Privacy, consent, and data ownership, are just a few of the known challenges, and these too are constantly evolving. With just a bit of reflection on the amount of passive data generated by modern individuals, it is easy to sense the "creep factor" of big data (Gumbus & Grodzinsky, 2016). Unlike in a traditional survey design or laboratory experiment, when people generate social media content (such as posts and likes), do they even realize they are providing data? Chances are not. Often no explicit consent is obtained from those who provide data. In the case of internet searches, there is no way for potential subjects to opt out, short of not searching for the information in the first place. Even if it is possible to obtain consent from users for social media content, participants may not grasp the details of the research at the time of consent because in some cases, the data precede the research questions. Even when data are anonymized, people may be uncomfortable with their social media data being used for research purposes. Scholars have warned of inequities in accessibility to big data and proprietary algorithms for public data that may over represent or under represent some populations or behaviors (Ruths & Pfeffer, 2014) and potentially widen disparities between groups (Gumbus & Grodzinsky, 2016). Not to mention, if big data fall into the wrong hands, there is enormous potential for misuse. Even if there were a way to solve these problems, there may remain broader implications of conducting research in a big data world. For instance, does the datafication of our lives erode free will? For this reason and others, psychologists should forge a dialogue with ethicists, social media experts, and ordinary users to understand how best to use big data, especially as social norms evolve and new forms of data arise.

Conclusion

Thanks to advancements in technology researchers now have at their disposal many new methods for measuring SWB. While neurological approaches to assessing SWB remain far from useful or practical at present, other techniques such as big data and momentary assessments are growing more economical and accessible each day. These non-self-report methods can, at times, reduce the social desirability and introspection inherent in self-reports of SWB. However, it is important to consider that all the measures offer different vantage points of the underlying phenomenon, and no single method is a direct measure of SWB. A variety of methods allows researchers to triangulate on a picture of SWB, but they should not entirely replace self-reports of SWB. After all, the construct is *subjective* well-being.

What do Subjective Well-Being Judgments Mean? Sources and Distinctions, Processes and Mechanisms

By Michael D. Robinson & Robert J. Klein, North Dakota State University

Citation
Robinson, M. D., & Klein, R. J. (2018). What do subjective well-being judgments mean? Sources and distinctions, processes and mechanisms. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

How do people decide how happy they are? In principle, a number of models are possible and the current chapter highlights three of them. People could subdivide their life into various domains, consider their progress in these domains, and then integrate the results of this bottom-up activity. Alternatively, people could omit such a systematic process and simply base their judgments on whatever information is currently accessible. Finally, it is possible that people already know their happiness levels, in which case they could directly retrieve such evaluations. The plausibility of these models is examined with respect to issues of stability, change, and context in well-being judgment. People have fairly stable ideas about how happy they are and well-being judgments seem somewhat resistant to priming. Nonetheless, well-being sometimes changes in response to life events. Accordingly, some combination of judgment models might be necessary to fully account for current findings.

Keywords: Happiness, Judgment, Heuristic, Systematic, Life Events

For most people, happiness is not just a pleasant occurrence. Rather, it is a guiding principle in their lives. People want to be happy more than they want more specific things like love, wealth, or health and happiness is the presumed goal of many of their other pursuits (Kim-Prieto, Diener, Tamir, Scollon, & Diener, 2005). This emphasis on happiness is not misplaced in that there are many benefits to being happy, including in the realms of love and work as well as physical functioning (De Neve, Diener, Tay, & Xuereb, 2013; Lyubomirsky, King, & Diener, 2005a). For example, happy people attract marital interest and they are less likely to get divorced (Marks & Fleming, 1999). Even beyond the individual level, happiness can be used to track societal changes (Frey & Stutzer, 2010) and to compare entire societies (Diener & Seligman, 2004).

Given the importance of happiness to individuals as well as societies, it is important to understand its basis. A first point worth making here is that happiness is a subjective phenomenon. People make judgments of happiness and we consider them happy to the extent that they report themselves to be happy, potentially independent of the circumstances of their lives (Myers & Diener, 1995). A second point worth making is that happiness, in the form of subjective well-being (SWB), encompasses both emotional experiences and cognitive evaluations (Diener, 1984; Tay, Chan, & Diener, 2014). People are happy when they have more frequent experiences of positive emotion, less frequent experiences of negative emotion, and when they evaluate their lives more favorably (Myers & Diener, 1995). The present chapter is primarily concerned with life evaluations rather than emotional experiences.

People have been asked to evaluate their lives in a number of ways. They have been asked to choose rungs of a ladder or faces to represent how happy they are (Andrews & Withey, 1976). Another commonly used happiness item asks people whether they are very happy, pretty happy, or not too happy "these days" (Bradburn, 1969). Alternatively, people might be asked how satisfied they are with their lives, "all things considered" (Wagner, Frick, & Schupp, 2007). Such single-item measures are used both because they are convenient and because they seem to capture the construct in an efficient manner (Lucas & Donnellan, 2011). In addition, though, a number of multi-item measures of life satisfaction exist. One asks people to make several general life satisfaction ratings before rating satisfaction with more particular domains like health and standard of living (Weinberg, Seton, & Cameron, in press). Another asks people whether they agree or disagree with statements such as "I am satisfied with my life" (Diener, Emmons, Larsen, & Griffin, 1985). These different measures tend to correlate fairly highly with each other (Kobau, Sniezek, Zack, Lucas, & Burns, 2010), and constitute the primary data of interest.

In principle, people could engage in a number of different strategies in answering these questions. Campbell, Converse, and Rodgers (1976) posited a somewhat complex mental calculus. When deciding one's overall level of happiness, one could enumerate the various domains of life, consider one's progress in those domains, compare that progress to multiple standards, and compute an overall well-being score that averages across these efforts. Somewhat similarly, Michalos (1985) suggested that people make an

extensive set of comparisons (e.g., between what one has and what one expects to have in 5 years, between what one has and what one expected to have 3 years ago) and then integrate the results of these comparisons before deciding what their well-being is. To us, these perspectives implicate a level of thoughtfulness and extension that is unlikely to characterize the typical effort to determine one's well-being. That is, these perspectives seem inconsistent with modern views of decision making (Gigerenzer, 2015) and social cognition (Fiske & Taylor, 1991), which hold that people aim for efficiency when making their decisions and judgments.

At another extreme, some social psychologists emphasize the malleability of attitude judgments in general (Erber, Hodges, & Wilson, 1995) and life satisfaction judgments in particular (Deaton & Stone, 2016; Schwarz & Strack, 1999). On the basis of priming studies (Bargh & Chartrand, 1999), some of which are reviewed below, the suggestion seems to be that people do not essentially know their levels of life satisfaction. Rather, they construct such judgments on the basis of whatever information happens to be accessible in the moment of judgment (Schwarz & Strack, 1999). Both survey researchers and well-being researchers should be interested in these sorts of influences. However, the possible presence of priming effects does not preclude the additional presence of more stable sources of information in well-being judgment. The fact is that well-being judgments are fairly stable over time (Eid & Diener, 2004) and priming perspectives on judgment seem insufficient in accounting for such sources of stability (Anusic & Schimmack, 2016). People know a fair amount about their lives and are likely to retrieve this information when deciding how happy they are (Eid & Diener, 2004).

Indeed, it is reasonable to propose that people think about their lives a lot of the time and they think about happiness in this connection (Myers, 1992). This renders it possible that asking people about their happiness is asking them to answer questions that they have already answered, for an internal audience. If so, people may not need to construct an answer when they are asked about their life satisfaction. Rather, they may be able to recall a pertinent answer more-or-less directly from memory. This perspective overlaps with the accessibility model of attitude strength, which posits that previous experience evaluating an attitude object (in this case, one's life) changes the evaluation process in favor of direct attitude retrieval (Fazio, 1995). For example, asking the novice coffee drinker how much they like coffee could lead to a complex mental calculus. Asking the experienced coffee-drinker the same question, however, may lead to the answer "a lot" without a great deal of deliberation. It is feasible that some people, if not many, think of their lives in a way akin to an experienced coffee drinker.

To summarize, there are at least three perspectives on life satisfaction judgment that deserve attention (see Table 1). Under some circumstances, people will think about their standing and standards in various life domains before giving a life satisfaction judgment (Campbell et al., 1976). However, people are efficient thinkers and may curtail some of this activity in favor of quicker, more heuristic ways of answering the question (Gigerenzer, 2015). Under some circumstances, primed thoughts and feelings could influence the life evaluation process (Schwarz & Strack, 1999). However, these contextual influences are not likely to be strong because people know a great deal about their lives and are likely to consult this information independent of priming influences (Schimmack & Oishi, 2005). Finally, we have suggested that people who have thought about their lives extensively may be able to evaluate them somewhat directly, thereby omitting a lengthy deliberation process at the time of judgment. The last perspective should assume that life satisfaction judgments are stable, much as accessible attitudes are (Fazio, 1995). We will revisit these three perspectives, in one way or another, throughout the course of the review.

Table 1

Three Models of Well-Being Judgment and Their Characteristics

	Integrative	**Constructivist**	**Direct Retrieval**
Relevant Citation	Campbell, Converse, & Rodgers (1976)	Schwarz & Strack (1999)	Fazio (1995)

Description	When making well-being judgments, people enumerate their life domains, review their progress in each life domain, compare that progress to standards, and average across these computations.	People do not know how happy they are "in general". When they are asked such questions, they use whatever information is currently accessible and are therefore vulnerable to temporary and irrelevant priming factors.	People have thought about how happy they are previously. When making well-being judgments, they directly retrieve these pre-stored evaluations.
Processing Mode	Systematic	Heuristic	Heuristic
Retrieval Direction	Bottom-Up	Bottom-Up	Top-Down
Strength 1	Can explain why life events matter	Highlights potential influences due to mood and communication rules	Can explain the stability of well-being judgments
Strength 2	Can account for well-being change	Can account for contextual influences	Is consistent with cognitive miser perspectives
Weakness	Presumes too much mental calculus	Overemphasizes the malleability of well-being judgments	Does not specify the basis of happiness levels

Do Life Circumstances Matter?

It is intuitive to think that life satisfaction judgments should be about life. That is, they should reflect life's circumstances and the situation in which one finds oneself. Demographic factors like sex, race, and age should matter and social and economic factors like one's income should matter as well. Although there clearly are relationships between social-demographic factors and happiness, these relationships can be surprisingly small (Diener, Suh, Lucas, & Smith, 1999). In an older but comprehensive effort, Andrews and Withey (1976) concluded that demographic and life circumstance factors collectively explained less than 10% of the variance in happiness judgments. Later, the figure rose to 15% or so (Argyle, 1999), but the point remains that factors like age, race, income, and socioeconomic status explain only a relatively small portion of variance in well-being judgments (Diener et al., 1999; Lykken & Tellegen, 1996).

The relationship between age and well-being is an illustrative example. As we age, we lose mobility, encounter disease more often, and lose fluid intelligence as well (Rook, Charles, & Heckhausen, 2011). Furthermore, people in America (including older people) hold a pessimistic view of aging (Hummert, Garstka, Shaner, & Strahm, 1994). One could therefore expect some decreases in well-being with age. Instead, the relationship between age and well-being seems puzzling. One contention is that both positive and negative affect decrease with age (Diener, Sandvik, & Larsen, 1985). However, another contention is that well-being increases with age (Carstensen et al., 2011), perhaps excepting a late-life decline (Gerstorf et al., 2008). A third perspective, though, contends that there are curvilinear relations between age and well-being, with the lowest levels in middle age (Blanchflower & Oswald, 2008). It is difficult to make sense of these divergent ideas and the truth of the matter may be that aging effects are either subtle or sample-dependent. Thus, the most general conclusion could be that age does not impact well-being as much as one might think or even much at all (Lykken & Tellegen, 1996; Myers & Diener, 1995).

Further, there are data to suggest that even somewhat radical changes in life circumstances can have surprisingly small effects on long-term well-being (Loewenstein & Schkade, 1999). Along these lines, Gilbert and colleagues have conducted several studies showing that people quickly habituate to seemingly terrible events such as tenure denial (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998). Under many circumstances, they also seem to adapt to the positive features of their lives as well (Sheldon & Lyubomirsky, 2007). In a famous study of this type, Brickman, Coates, and Janoff-Bulman (1978) compared the happiness levels of lottery winners, controls, and people who had encountered fairly serious

spinal cord injuries. The authors concluded that the lottery winners were not happier than the control group and the paralyzed accident victims had rebounded such that their happiness levels were surprisingly high. When combined with other life event/well-being studies (e.g., Headey & Wearing, 1989; Robinson, 2000; Suh, Diener, & Fujita, 1996), the conclusion seems to be that happiness levels can often be insensitive to bottom-up, life circumstance factors (Lykken & Tellegen, 1996). Such considerations led to a different, top-down view of well-being judgment (Diener, 1984).

Are There Top-Down Influences?

Top-down influences are sources of belief, affect, or disposition that stabilize well-being judgments, potentially in a way that is independent of objective life circumstances (Diener, 1984; Watson, 2000). There are several basic properties of well-being judgment that seem consistent with top-down influences. First, the average person does not have neutral levels of life satisfaction. Rather, the average person is more satisfied than dissatisfied with his or her life and this is true across many measurement instruments and countries (Cummins, 2003). The consistency of these findings suggests that there is a sort of default that favors non-neutral levels of happiness for most people under most circumstances (Diener, Lucas, & Scollon, 2006). Second, life satisfaction is stable over time (Eid & Diener, 2004) and consistent across situations (Watson, 2000). That is, people who are more satisfied with their lives tend to remain more satisfied with their lives across time and circumstance (Watson, 2000).

Thus, there seem to be dispositional (stable, but person-varying) top-down influences on life satisfaction judgments that warrant serious attention (Diener et al., 1999). These top-down influences could reasonably be due to one's personality traits. For example, Costa and McCrae (1980) maintain that extraversion and neuroticism, two personality traits linked to affect, could determine one's "set point" or stable level of well-being. In support of these ideas, extraversion and neuroticism are good predictors of well-being (Watson, 2000) and these personality traits tend to be more stable than life satisfaction or emotion (Anusic & Schimmack, 2016). Alternatively, top-down influences could follow from self-esteem given that a number of theories of well-being implicate processes concerning the self (e.g., Michalos, 1985) and self-esteem is also a good predictor of well-being (Diener & Diener, 1995). These perspectives can be combined when it is recognized that extraversion and neuroticism are loaded with self-evaluative variance and this self-evaluative variance is highly correlated with self-esteem (Anusic, Schimmack, Pinkus, & Lockwood, 2009).

The link to self-evaluative processes seems appealing in another way. There are pronounced cultural differences in well-being (Diener, Oishi, & Lucas, 2003) and there are also pronounced cultural differences in self-evaluation (Heine, Lehman, Markus, & Kitayama, 1999). In particular, people from Asian cultures like China, Japan, and Korea tend to report lower levels of life satisfaction (Diener et al., 2003) and these cultures also favor greater modesty in self-presentation (Heine et al., 1999). Processes concerning the self (Markus & Kitayama, 1991) and self-evaluative tendencies (Suh, 2000) could therefore constitute a sort of top-down influence on well-being judgments that diverges across cultures. Top-down influences should be particularly apparent for global or retrospective reports of well-being (Tay et al., 2014) and there is some evidence to suggest that these are the sorts of well-being judgments that display the greatest variations across culture (Oishi, 2002; Saeki, Oishi, Lee, & Maeno, 2014). This model will not be sufficient in accounting for all cultural differences in well-being, many of which can be ascribed to objective features of the culture (Diener, Diener, & Diener, 1995), but it could account for some of them (Diener, Napa Scollon, Oishi, Dzokoto, & Suh, 2000).

We are generally convinced that there are top-down influences on well-being judgment. However, the framework is not entirely satisfactory. To ascribe well-being to personality traits, or to self-esteem, does not explain where personality traits or self-esteem come from. Moreover, self-evaluative processes, including those linked to personality or culture, may constitute some uncertain mix of style and substance (Paulhus & John, 1998). This renders it possible that at least a portion of the link between personality and well-being, or between culture and well-being, could be due to variations in self-presentation rather than more substantive factors like temperament (Davies, Connelly, Ones, & Birklund, 2015). Finally, both personality and well-being change over time (Anusic & Schimmack, 2016) and some consideration of bottom-up factors seems necessary to account for these changes (Headey, Muffels, & Wagner, 2010). In the context of top-down factors, we therefore revisit the question of whether life circumstances matter, this time while considering the "set point" idea of well-being.

Are There "Set Points" for Well-Being?

In the well-being literature, the set point is a sort of happiness default that one might return to in the absence of unusual events. For the vast majority of people, the set point seems to favor happiness over unhappiness (Diener, Kanazawa, Suh, & Oishi, 2015). Consistent with this idea, Cummins (2003) converted a number of happiness and life satisfaction measures to a 0 to 100 scale. The average life

satisfaction score was about 75, or roughly ¾ of the happiness/satisfaction maximum. The person's set point could vary by culture, in that cultures differ in their average ratings of happiness (by as much as 14 of 100 points in Cummins, 2003). Of more pertinence, one's set point would vary by personality traits such as extraversion and neuroticism (Costa & McCrae, 1980). Events that are more pleasant (unpleasant) than typical for one's personality would temporarily shift happiness in a positive (negative) direction, but happiness would return to one's dispositional level thereafter (Headey & Wearing, 1989).

The set point idea seems somewhat necessary, both to cover the polarized nature of normative happiness ratings (Cummins, 2003) and to cover marked individual differences (Watson, 2000) as well as genetic influences (Lykken & Tellegen, 1996). Nonetheless, we may never know what a person's set point is because they are always interacting with the environment and therefore always in flux to a certain extent (Headey & Wearing, 1989; Robinson, 2000). Further, it should be recognized that life satisfaction changes over longer periods of time, though in different directions for different people (Anusic & Schimmack, 2016). This probably means that set points also slowly change, either due to maturation processes or lifestyle choices that create new personal trajectories. Along these lines, Headey et al. (2010) estimate that a sizeable minority of people (25-30%) had different apparent set points in the 1980s than they did in the 2000s.

To gain a more detailed perspective on set points and adaptation levels, recent research has revisited the idea that life events typically fail to influence our happiness levels for any appreciable length of time (McCrae & Costa, 1994). In contrast with classic research in this area (e.g., Brickman et al., 1978), this more recent research has typically used longitudinal designs rather than quasi-experiments and has sometimes employed sophisticated methods to deal with maturational trends (Anusic, Yap, & Lucas, 2014). In one study of this type, Clark and colleagues (Clark, Diener, Georgellis, & Lucas, 2008) found that people adapted to marriage and widowhood within about 3 years, but unemployment appeared to undermine well-being for a longer period of time. Using a different sample and somewhat different methods, Anusic et al. (2014) reported adaptation for marriage and childbirth, but a seeming permanent change due to disability. Summarizing a number of studies of this type, Lucas (2007) suggests that people adapt to changes in marital and family status, but may not be able to fully recover from periods of unemployment or disability.

Thus, there could be an asymmetry with respect to positive and negative events. Positive events like marriage or promotion (or winning the lottery: Brickman et al., 1978) can influence our happiness for a period of time, but that influence will probably dissipate. On the other hand, some negative events – such as unemployment or disability – can have a lasting impact (Lucas, 2007), possibly because they permanently alter our capacity to pursue our goals. Cummins (2010) makes a related point when he suggests that especially low levels of life satisfaction reflect homeostatic defeat rather than normal fluctuations about one's set point. Even within normal ranges, though, people fluctuate in their happiness levels from time to time (Eid & Diener, 2004). These fluctuations suggest that it may be more accurate to characterize the set point as a "set range" – a range of possible well-being scores for the individual rather than one specific level (Sheldon & Lyubormirsky, 2007; Watson, 2000). Provided that one is not at the top of this range, improvements in well-being may be possible (Sheldon & Lucas, 2014; Watson, 2000).

However, improving one's well-being appears to be difficult. Seeking pleasure can backfire (Schooler, Ariely, & Loewenstein, 2003) and mere behavioral change does not seem sufficient (Sheldon & Lyubomirsky, 2007). Rather, one must engage in the right activities for the right reasons while varying their form and timing so that hedonic adaptation is forestalled (Lyubomirsky, Sheldon, & Schkade, 2005b). Also, positive events and activities, per se, do not seem to be sufficient. Rather, the positive events and activities must contain elements of novelty and they must implicate core self-motives such as autonomy, competence, and relatedness (Sheldon & Elliot, 1999). These perspectives suggest that we have the opportunity to intentionally increase our well-being, but considerable skill may be necessary in doing so (Lyubomirsky et al., 2005b; Sheldon & Lyubomirsky, 2007).

To summarize, well-being is conservative, such that it remains remarkably stable over time even as our lives change (Anusic & Schimmack, 2016). Much of this stability seems to be due to global beliefs about ourselves and to personality factors, both of which compel us to give similar answers about our happiness over time (Lykken & Tellegen, 1996). Alternatively, people may develop fairly fixed ideas about their happiness that they can retrieve whenever they are asked (Robinson & Oishi, 2006). In either case, there are top-down influences that keep happiness judgments within acceptable, accustomed ranges (Cummins, 2003). Yet, such fixed ideas about happiness are not entirely insensitive to recent life events (Robinson, 2000) or to significant life changes (Lucas, 2007). Altogether, then, we suggest that there are both top-down (dispositional) and bottom-up (event-based) influences on well-being judgment, though the top-down influences tend to dominate (Anusic & Schimmack, 2016; Eid & Diener, 2004).

Are Life Satisfaction Judgments Plagued by Context Effects?

Experimental research conducted in the 1980s suggested that our judgments of life satisfaction can be biased by somewhat irrelevant and temporary factors such as finding a dime in the copy machine, the weather, the outcome of a recent soccer match, or the order in which life satisfaction questions are administered (Schwarz & Clore, 1983; Schwarz, Strack, Kommer, & Wagner, 1987; Strack, Martin, & Schwarz, 1988; for a review, see Schwarz & Strack, 1999). Some of this research gave rise to a very influential theory of mood (Schwarz & Clore, 1996) and the Strack et al. (1988) paper can be highlighted for its fascinating analysis of the role of communication norms (such as to avoid redundancy) in the potential inferences that people make when answering self-report questions (Schwarz, 1999). Yet, the research adopted a puzzling view of well-being. The contention, more or less, was that people rarely evaluate their lives as a whole and are therefore susceptible to a range of biases when making life satisfaction judgments. This radical constructivist view does not seem consistent with the highly stable nature of well-being (Pavot & Diener, 1993) or with the top-down factors that seem endemic to well-being judgments (Cummins, 2003; Diener et al., 1999; Heller, Judge, & Watson, 2002).

The idea that people consult their affective states when deciding how happy they are (Schwarz & Clore, 1983) has intuitive appeal. Moreover, this idea is clearly correct at some level. Personality traits like extraversion and neuroticism predict happiness in part because they predict dispositional levels of positive and negative affect (Costa & McCrae, 1980). Also, trait reports of affect are strong predictors of well-being, even after controlling for personality traits and cognitive predictors (Blore, Stokes, Mellor, Firth, & Cummins, 2011). Nevertheless, people can distinguish momentary affective states from their more general tendencies to experience positive and negative affect (Watson, 2000) and they may discount the former when making dispositional inferences (Lucas, Dyrenforth, & Diener, 2008). Consistent with these ideas, Eid and Diener (2004) found that subjective well-being (SWB) was strongly trait-like over the period of 12 weeks and momentary mood states had small, largely inconsequential influences on SWB judgment (also see Yap et al., in press). Similarly, Lucas and Lawless (2013) revisited the idea that transient weather patterns can influence life satisfaction judgments (Schwarz & Clore, 1983). In a large-scale study, current weather conditions did not predict life satisfaction judgments in any straightforward manner, and most weather conditions did not predict them at all. Hence, life satisfaction biases due to current mood seem to be slight (Lucas et al., 2008).

Turning to item-order effects, Strack et al. (1988) examined the correlation between dating happiness and general happiness in three conditions. When the general happiness item was answered before the dating happiness item, the correlation was $r = .16$, suggesting that people do not consider dating much when rating their general happiness. When the dating happiness item preceded the general happiness item, by contrast, the correlation rose to $r = .55$, such that participants may have based their ideas about their happiness in general on primed information about their dating lives. In a third condition in which it was made clear that there were two separate questions (one about dating and one about life in general), though, the correlation dropped to $r = .26$ even when the dating item occurred first. These results indicate that it may be possible to alter happiness judgments by priming more specific sources of information first (e.g., about dating), but that people may resist this influence when the two judgments seem different from each other (also see Schwarz, Strack, & Mai, 1991).

In the domain of happiness judgments, it appears that priming effects can either take the form of assimilation (increased use of primed information) or contrast (decreased use of primed information). Moreover, it is often difficult to state, a priori, which sort of priming effect is more likely (Schwarz & Strack, 1999). This has resulted in complicated findings. For example, Eiser and de Mey (1993) found complex priming effects depending on whether positive or negative sources of information were first recalled and whether the recalled information was vivid or not. The exact form of the results did not seem expected. It is also not always obvious where priming effects end and communication effects begin or what inferences people will make about the communication context (Tourangeau, Rasinski, & Bradburn, 1991). Concerning the relationship between marital happiness and general happiness (Schwarz et al., 1991), researchers have found assimilation effects (Smith, 1982), contrast effects (Schuman & Presser, 1981), or no effects (Turner, 1984). Further, when priming effects are found, the results involving correlations and means can differ. Thus, a wider reading of this literature suggests that item-order effects are confusingly temperamental (Schuman & Presser, 1981; Tourangeau et al., 1991).

There are also reasons to wonder about the typical magnitude of item-order effects (Lucas et al., 2008; Lucas, Oishi, & Diener, 2016). Theoretically, they can occur when (a) people do not know, ahead of time, how happy they are, (b) the primed source of information is deemed relevant, and (c) the primed source of information would not have been accessed in the absence of the priming manipulation (Schimmack & Oishi, 2005). To the extent that people know how happy they are, or to the extent that they would have retrieved the relevant information anyway, item-order effects would be considerably less likely

(Schimmack & Oishi, 2005). In speaking to this literature, Schimmack and Oishi (2005) conducted a meta-analysis and several replication attempts. The meta-analysis revealed that item-order effects were heterogeneous across 16 previous studies. Furthermore, several direct replication attempts failed to produce significant findings and the authors concluded that item-order effects may typically be fairly small in effect size. When these studies are considered in light of inconsistencies among previous studies (e.g., the contrasting results of Smith, 1982, and Schuman & Presser, 1981), this seems a reasonable conclusion (also see Weinberg et al., in press).

What Do People Think About When Making Well-Being Judgments?

Thus far, we have primarily examined how people make well-being judgments by examining questions of process – stability, personality correlates, vulnerability to contextual influence, etc. However, it might also be possible to ask people what they think about when making life satisfaction judgments. Although the sources of knowledge mentioned might not overlap perfectly with those actually contributing to their judgments (Nisbett & Wilson, 1977), this is a worthwhile type of data to consider.

A first point worth making is that people typically recall more positive than negative events from their personal past (Seidlitz & Diener, 1993) and they also have more favorable than unfavorable thoughts about their lives (Luhmann, Hawkley, & Cacioppo, 2014). This degree of positivity could follow from factors like self-enhancement (Sedikides & Gregg, 2008) or it could follow from the fact that we typically inhabit hospitable rather than hostile environments (Cacioppo, Gardner, & Berntson, 1997). In either case, greater positivity in recalled events or in thoughts about our current life could partially explain why life satisfaction tends to be polarized in a positive direction (Cummins, 2003).

With respect to time frames, Ross, Eyman, and Kishchuck (1986) found that people primarily thought about their present lives when making life satisfaction judgments, suggesting that life satisfaction judgments should display some sensitivity to recent life events (Robinson, 2000). Following a focus on the present, people said they were focused on the future (Ross et al., 1986). This makes sense because well-being is intimately related to our goals and goals are future-oriented entities (Sheldon & Lyubomirsky, 2007). Finally, people did not report thinking about the past as frequently when making life satisfaction judgments (Ross et al., 1986).

The sorts of life domains that people report thinking about also make sense. Relationships are important to well-being (Myers & Diener, 1995) and people report thinking about relationships (e.g., family relationships, friendships) when making well-being judgments (Luhmann et al., 2014). They also report thinking about their academic and career success and some mention their health (Luhmann et al., 2014). In one study, for example, Schimmack, Diener, and Oishi (2002) asked people what they thought about while making life satisfaction judgments and found that 33% mentioned family, 26% mentioned friends, 22.5% mentioned romantic life, 20% mentioned academic life, and 12% mentioned health. Financial concerns and social comparisons were not mentioned as frequently.

Schimmack and colleagues (2002) have reported additional intriguing evidence in favor of this thought-listing method. What people report thinking about correlates highly (r = .67) with importance ratings for the relevant source of information. This suggests that people tend to think about important domains of their lives, rather than whatever happens to come to mind, when making life satisfaction judgments (Schimmack & Oishi, 2005). Furthermore, people who report using a source of information ("users") display higher correlations between that source and general well-being than those who do not ("non-users"). For example, Schimmack et al. (2002) reported that the correlation between family satisfaction and life satisfaction was higher for people who reported thinking about family (r = .44) than for people who did not mention this domain (r = .12).

There are clearly limitations to this method, though (Nisbett & Wilson, 1977). People do not mention their personalities as a source of life satisfaction judgment despite the importance of personality influences (Costa & McCrae, 1980). And they do not mention cultural norms, even though cultural norms have been heavily implicated in life satisfaction judgment (Diener et al., 2003). Thus, people do not seem aware of some of the important top-down influences that are guiding their judgments.

Some Distinctions in Well-Being Judgment

There are different ways of measuring well-being and some of these distinctions are important in understanding what a given sort of judgment reflects. In that spirit, we review some useful distinctions, particularly with respect to their ability to elucidate judgment processes. These distinctions can also be useful, however, in thinking about personality and culture and in comparing different views of what happiness should consist of.

Online Happiness versus Recalled Happiness. Online reports of happiness focus on current emotional experiences and how they are influenced by factors such as social setting, events that have

recently happened, or time of day (Bolger, Davis, & Rafaeli, 2003). These emotions are typically in flux and have a noticeably reactive character to them (Bolger et al., 2003; Conner, Tennen, Fleeson, & Barrett, 2009). They are also highly dependent on setting. Some settings and activities are more "fun" than others and people tend to report greater happiness when they are engaged in leisure or socializing relative to work or childcare (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004). In the short run, in fact, one could be happier when unemployed than when not because unemployment can bring greater leisure (Knabe, Rätzel, Schöb, & Weimann, 2010). In the long-run, by contrast, unemployment would tend to undermine self-esteem and, perhaps because of this, life satisfaction (Clark et al., 2008).

Nonetheless, an advantage of online reports is that they are closely tied to both events and actual experiences (Robinson & Clore, 2002a). This seems to render them, relative to retrospective or trait reports of emotion, less prone to belief-driven top-down biases (Robinson & Clore, 2002a). For example, Oishi (2002) observed that Asian/European American differences in happiness were greater for recall-based measures than for online measures, and similar results have been found using Day Reconstruction methods (Oishi, Whitchurch, Miao, Kurtz, & Park, 2009). One interpretation of this pattern of findings is that Asians believe that they are less happy than European Americans and such beliefs differentially contribute to retrospective and trait reports of happiness relative to online reports (Robinson & Clore, 2002a). If this is true, one could actually study top-down factors in terms of the discrepancy between online reports of happiness and retrospective reports.

Even so, online reports of happiness should not always be favored. They may focus too particularly on the person's ecological reactions to events, and on hedonic factors, relative to broader forms of well-being such as meaning and purpose (Diener & Tay, 2014). Averaging a person's happiness across moments could therefore provide a somewhat misleading picture of a person's global, more cognitive sense of life satisfaction (Tay et al., 2014).

Domain Satisfaction versus Global Life Satisfaction. There are only 24 hours in a day and people have limited capacities to achieve everything that they might wish to achieve (Baumeister, Heatherton, & Tice, 1994). There can therefore be tradeoffs such that one succeeds in some life domains (e.g., work) but not others (Heidemeier & Göritz, 2013). Despite these potential tradeoffs, there tend to be positive correlations among life domains such that satisfaction in one life domain tends to predict satisfaction in another (Campbell et al., 1976; Diener, 1984). These correlations can be small, though. Along these lines, the correlation between marital satisfaction and job satisfaction may be as low as $r = .16$ (Heller, Watson, & Ilies, 2004). By averaging across a number of life domains, however, one can compute a domain-derived life satisfaction measure that correlates highly with a more generic (domain-unspecified) one (Campbell et al., 1976; Weinberg et al., in press).

Regardless, people consider different sources of knowledge when making domain satisfaction ratings versus when rating their satisfaction with life in general. Developments within a particular domain (e.g., a raise at work) are more likely to affect satisfaction with that domain (e.g., work) than satisfaction with life in general, indicating the presence of bottom-up influences (Heller et al., 2004). Conversely, there are top-down influences that matter more for global reports of well-being, even after controlling for satisfaction with particular domains. Personality factors and dispositional positivity are among these (Diener et al., 2000). Thus, one way to isolate dispositional positivity is to subtract domain-specific satisfaction ratings from domain-general satisfaction ratings, with larger differences indicating greater positivity (Diener et al., 2000).

Relatedly, happy people self-enhance. That is, they view their lives more positively than seems to be justified (Wojcik & Ditto, 2014). Happy people also treat the domains of their lives differently than unhappy people. They invest effort in the areas of their lives that are improving and divest effort from other, more problematic life domains (Carver & Scheier, 2014). In related terms, happy people emphasize the areas of their lives that are going well. This point was made in a set of studies by Diener, Lucas, Oishi, and Suh (2002), who first isolated a person's "best" (highest-rated) and "worst" (lowest-rated) life domains. The best domains were more predictive of global well-being for happy people and the worst domains were more predictive of global well-being for unhappy people. These results are consistent with the idea that happiness biases the selection of life domains to consider when rating happiness in general. One could avoid these biases somewhat by measuring life satisfaction in terms of the average of multiple, more specific life domains (Weinberg et al., in press). Alternatively, biases such as these are central to more global conceptions of life satisfaction (Tay et al., 2014).

Bottom-Up versus Top-Down Influences. Bottom-up models contend that happiness is built on the particulars of life, including circumstances, events, and progress in specific life domains (Diener, 1984). Top-down models instead emphasize factors like personality and self-enhancement, which are likely to influence life satisfaction as a whole as well as life satisfaction in particular domains like work, marriage,

and leisure (Heller et al., 2002). Bottom-up factors will lead to changes in well-being when life circumstances change; by contrast, top-down factors will tend to promote stability over time (Headey & Wearing, 1989). These models are not mutually exclusive and one can find evidence for both bottom-up and top-down influences in the same study, which Brief, Butcher, George, and Link (1993) did in the area of health satisfaction. Similarly, job satisfaction is influenced by the circumstances of one's job, but also by personality factors like extraversion and neuroticism (Watson, 2000).

Consistent with top-down paths, personality traits have been linked to satisfaction with particular life domains like one's job or marriage (e.g., Heller et al., 2004). Moreover, controlling for personality traits often reduces the correlation between satisfaction with a domain (e.g., one's job) and life satisfaction, suggesting that at least a portion of the relationship can be ascribed to personality (Heller et al., 2002). Although it is intuitive to think of top-down influences in terms of judgmental biases like dispositional positivity or self-enhancement (Wojcik & Ditto, 2014), top-down influences can also be more substantive. Along these lines, several studies have shown that personality traits can predict the occurrence of positive and negative life events (Headey & Wearing, 1989; Magnus, Diener, Fujita, & Pavot, 1993) and global life satisfaction can prospectively predict latter success in particular domains like health and work (Lyubomirsky et al., 2005a). Happy people, for example, attract marital partners, are happy in their marriages, and are less likely to become divorced (Marks & Fleming, 1999).

Support for bottom-up paths can also be found, however. Changes in the relative proportion of daily positive and negative life events can shift well-being in a corresponding direction, at least in the short term (Robinson, 2000; Suh et al., 1996). And more serious changes in one's life situation – such as unemployment or disability – can have a lasting impact on well-being, even for multiple years (Diener et al., 2006). Furthermore, there are age-related changes in life satisfaction that are consistent with bottom-up rather than top-down influences (McAdams, Lucas, & Donnellan, 2012). Most notably, satisfaction with health decreases with age while satisfaction with income increases (McAdams et al., 2012). We can also alert the reader to more complex longitudinal models that either conclude that different life domains follow different models (Headey, Veenhoven, & Wearing, 1991) or that there are both top-down and bottom-up influences that are apparent in how people make domain satisfaction judgments (Lucas, 2004).

Future Directions

Both social psychology (e.g., Schwarz & Strack, 1999) and personality psychology (e.g., Eid & Diener, 2004) have contributed to our understanding of how people make life satisfaction and happiness judgments. Nonetheless, there are under-explored sorts of manipulations that may be useful in this enterprise. As a way of studying motivational influences, Wojcik and Ditto (2014) told some participants that happiness was linked to positive outcomes (e.g., better relationships), but told other participants that happiness was linked to negative outcomes (e.g., unwarranted risk-taking). People tended to report greater happiness in the positive outcome condition than in the negative outcome condition, though such trends were particularly apparent at higher levels of self-enhancement. It seems to us that manipulations of this type can be used to study some of the motivational factors that have been implicated in the personality and culture literatures (Diener et al., 2003).

There are reasonable questions about whether people make life satisfaction judgments in more heuristic or more systematic ways (Schimmack & Oishi, 2005; Schwarz & Strack, 1999). We would guess that people use both sorts of strategies, and that the relative balance of the strategies may vary by person (e.g., as captured by need for cognition) and situation (e.g., as captured by time of day or cognitive busyness). Similarly, the relative influence of top-down (e.g., self-concept) and bottom-up (e.g., life events) factors in life satisfaction judgment could vary by factors such as self-esteem (Diener & Diener, 1995) or culture (Diener et al., 2003). Some clarity into these different routes to judgment could be achieved by manipulating processing style, how much time people have to respond, or by manipulating cognitive busyness (e.g., see Van Boven & Robinson, 2012). In an interesting study of this type, Trent and King (2010) asked participants to make meaning in life judgments either rapidly or thoughtfully. Meaning in life had different correlates under these different conditions and results of this type could be used to better understand the typical process of judgment. For example, if the correlates of untimed happiness judgments look more similar to a "rapid" condition than a "thoughtful" condition, one might conclude that heuristic strategies tend to dominate (for related work, see Erber et al., 1995).

Perhaps most straightforwardly, reaction time (RT) methods could be used more extensively in the happiness and well-being literature (Robinson & Compton, 2008). In one sort of paradigm, Robinson and Clore (2002b) showed that people switched from a data-driven to belief-based (top-down) judgment strategy when rating their emotions over the period of several weeks or longer. A similar relationship between time frame and judgment speed could occur for life satisfaction or happiness judgments. Priming-related paradigms can also be used. Bottom-up theories would be supported if judging one's satisfaction

with a specific life domain speeds judgments of life satisfaction in general; by contrast, top-down theories would be supported if the opposite pattern is found (for one application of similar logic, see Schell, Klein, & Babey, 1996). Finally, if life satisfaction is a type of attitude (Pavot & Diener, 1993), then cognitive models of attitude strength (Fazio, 1995) could be used in understanding it. Faster life satisfaction judgments are likely to implicate a top-down path to judgment that should be more particular to some individuals than to others. Among other consequences, this literature would lead us to predict that people making these judgments more quickly, in comparison to more slowly, should report levels of life satisfaction that are more stable over time (Fazio, 1995).

Conclusions

In the introduction, we contrasted three different models of well-being judgment. According to a bottom-up, systematic model, people may carefully consider their standing in a number of life domains before making life satisfaction or happiness judgments (Campbell et al., 1976). According a second constructivist model, people may lack solid ideas about their general levels of happiness and therefore seize onto whatever happens to be accessible in the moment (Schwarz & Strack, 1999). According to a third model, people might judge their lives in the same way that they judge very familiar objects – by direct retrieval of their evaluations, potentially independent of corroborating evidence (Fazio, 1995). After having reviewed multiple sources of evidence, we are inclined to think that some combination of these models seems necessary, with strengths and weaknesses outlined in Table 1. People have very stable ideas about their happiness, consistent with the third model, but they are also responsive to changes in their lives, consistent with the first. Further attention to how people make these judgments could sharpen the models, in turn allowing us to understand how variations in culture, personality, and life events get translated into variations in well-being.

The Cornerstone of Research on Subjective Well-Being: Valid Assessment Methodology

By William Pavot, Southwest Minnesota State University

Citation
Pavot, W. (2018). The cornerstone of research on subjective well-being: Valid assessment methodology. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

This chapter focuses on the process of obtaining valid assessments of Subjective Well-Being (SWB) from individuals, primarily with conventional self-report methodology. A brief review of the SWB construct and its constituent facets is followed by a discussion of some of the factors, both stable and transient, that may influence an individual's response to questions about their SWB. Several examples of measurement instruments, ranging from single-item measures to multi-faceted questionnaires, are briefly reviewed. The issues of scale reliability and validity are considered. General design strategies for optimizing the "fit" between assessment and the goals of the research follow. Some conclusions regarding SWB research, as well as additional resources and guides that are available to researchers new to SWB assessment are in a final section.

Keywords: Subjective Well-Being, Assessment, Self-report, Reliability, Validity

Research on Subjective Well-Being (SWB) continues to be a thriving inter-disciplinary interest area. Even a brief examination of the chapter topics in this volume confirms the breadth and depth of SWB-related investigation. This level of interest is quite remarkable for a topic that was almost unheard of three decades ago. In the interim, an impressive database has been gathered in an attempt to discern the structure, correlates, and sources of SWB.

Theoretical research focused on the structure and sources of SWB continues, but the application of SWB research for the improvement of the quality of life has become an important additional growth area. Many nations, for example, have begun to recognize that the assessment of the SWB of their citizenry can provide an important social indicator for policy and decision making, over and above the more traditional sources, such as economic indicators (Diener, 2000; 2006).

Despite the rich diversity of research related to SWB, some concerns are common: How accurate are the observations upon which the conclusions of the investigator are based? What are the potential strengths and weaknesses of the research design employed? Are the findings widely generalizable? Regardless of the goals of the researcher, the fundamental building block continues to be dependable and accurate data obtained from valid assessment methodologies. The present chapter will examine some of the issues involved in the assessment of SWB, with a specific focus on traditional self-report measures.

The first section of this chapter will briefly discuss the major components of the SWB as they have emerged from early research. The second section will review and discuss some of the measurement issues that may influence the validity of self-reports of SWB. Examples of some of the best-known instruments for the assessment of SWB are presented and discussed in the third section of the paper, and, in the fourth section, issues of establishing the reliability and validity of assessment instruments are considered. Some design considerations for future assessments of SWB appear in the following section, and some conclusions and suggested resources are presented in the closing section.

The Structure of SWB

The structure of SWB can be conceptualized as having two, three, or four facets, depending on the specificity required to address the research question(s) of interest. At a very fundamental level, SWB can be divided into two facets: One facet would include the affective or emotional aspect of subjective experience, and a second facet that would represent the cognitive, evaluative or reflective aspect. This structure is intuitively appealing and straightforward. But early findings by Bradburn (1969), and later confirmed by Diener and Emmons (1984) indicated that the experience of positive emotion and negative emotion are largely independent of each other. As a result, most contemporary researchers tend to consider positive emotion/affect and negative emotion/affect as separate facets, and tend to use a three-facet model of SWB (e.g., Arthaud-Day, Rode, Mooney,& Near, 2005). Additionally, depending on the goals of the researcher, the cognitive/evaluative/reflective component may sometimes be further divided as well. Frequently, investigators are interested in an individual's overall evaluation of their life as a whole, usually

referred to as life satisfaction. However, if the research is focused on a particular aspect of a person's life, such as their employment or their marriage, it may be useful to examine the individual's evaluation of a particular domain of their life. Thus, the evaluative component can be divided into a judgment of overall life satisfaction, or one or more specific aspects of life with domain satisfaction.

Issues in the Measurement of Subjective Well-Being

On the surface, the assessment of SWB may seem (perhaps deceptively) simple. In many cases, a single, clear question is asked, such as "Overall, how happy are you in life?" The respondent is typically asked to make a rating of their happiness using a Likert-type response scale (e.g., ranging from "1", indicating a low level of happiness to a "10" indicating a very high level of happiness). The researcher's assumption is that the response provided is an accurate reflection of the respondents overall and relatively stable subjective experience. To an extent, a very large body of empirical evidence has supported the validity of this assumption. But previous research has also revealed that a number of factors can, under specific circumstances, exert influences on the response given, possibly biasing the response in a positive or negative direction, and thereby reducing the validity of the data obtained.

Random transient influences on self-reports of SWB. A potential concern to researchers attempting to assess SWB is the influence that relatively random, contextual and/or situational factors might have on an individual's response. These transient influences might include current mood, the situation surrounding the assessment situation, or the influence of questions or items that are presented prior to the SWB item(s) within a given questionnaire arrangement.

Transient affective/mood states. One well-known demonstration of the potential for current mood to influence self-reports of SWB was provided by Schwarz and Clore (1983). Using induced positive or negative mood states (e.g., memory searches for good or bad events; obtaining responses on sunny versus rainy days) these researchers were able to influence respondents judgements of overall happiness and satisfaction with life. Subsequent research (Pavot & Diener, 1993a; Eid & Diener, 2004; Lucas & Lawless, 2013; Yap et al., in press) has shown that these effects are generally minimal, if not nil, and can be further reduced with methodological safeguards; nonetheless, the potential influence of current mood on self-reports of SWB, while generally small, is noteworthy.

Transient situational/contextual factors. It is also possible for self-reports of SWB to be influenced by transient factors in the situation or the context surrounding the response. A face-to-face interview, for example, could yield reports of greater SWB, when compared to responses on an anonymous survey, due to the effects of the social desirability of happiness. In situations where an item intended to measure SWB is embedded in a larger survey, the content areas of the proceeding items in the survey might influence the response to the specific SWB question. The order in which questions are presented can have an influence on an individual's response (Strack, Martin, & Schwarz, 1988).

While it is important to recognize and acknowledge that these random transient factors can influence self-reports of SWB; it is also important to point out that these influences are generally limited, and can be minimized with careful design and methodology. In very large survey designs, for example, transient mood effects are likely to have minimal influence on group levels of reported SWB. Barring some major crisis or world event with sweeping emotional impact, the effects of the transient negative mood state of one individual is likely to be effectively cancelled by the transient positive mood state of another. The effects of item placement on response can be minimized by presenting survey items in a random order. In smaller scale studies specifically focused on an aspect of well-being, transient effects can be minimized by assessing SWB on more than one occasion, and then computing an average score across those occasions. While some transient effects will likely always be part of self-reported SWB, careful methodological planning can substantially reduce their impact.

Stable situational /contextual factors. In addition to the potential influences of transient situational and contextual factors may exert on self-reports of SWB, investigators must also be mindful of more stable influences as well. A differential cultural perspective between respondents, for example, might well be a source of consistent variation in assessments of SWB. Although several studies (e.g., Balatsky & Diener, 1993; Scollon, Diener, Oishi, & Biswas-Diener, 2004) have indicated that SWB measures do have a reasonable level cross-cultural validity, other reports (e.g., Vitterso, Roysamb, & Diener, 2002) have indicated that the reliability and underlying factor structure of life satisfaction measures can vary across cultures. Examining nations using a general individualist versus collectivist cultural categorization can provide an illustration. Using two large international data sets, Suh, Diener, Oishi and Triandis (1998) found life satisfaction more strongly correlated with emotions in individualist nations as compared to collectivist nations. In collectivist nations, social norms were equally as strong as emotions in the prediction of life satisfaction reports. Thus the sources of information that are accessed in the formulation of life satisfaction judgments can vary across cultures.

An additional factor, less clearly identified yet likely no less influential, is the potential for differential "cohort effects" between age groups (Diener & Suh, 1997). Individuals of the same chronological age (same "cohort") share not only age-related physical developmental changes as they progress through life; they have also experienced social change and major historical events together. These shared experiences likely serve to help each cohort group develop its own "scale" of positive and negative life events that is to some extent unique. For example, a cohort that has experienced severe economic depression or a world-wide conflict likely has a somewhat different scale of negative events than members of a cohort without these experiences.

Another factor that can influence responses to SWB measures is the particular facet of SWB that is assessed by the measure. Measures of the evaluative facet of SWB (i.e., judgments of life or domain satisfaction) appear to be influenced to a greater degree by contextual factors than measures focused on the affective facets of SWB (Tay, Chan, & Diener, 2014).

Memory Issues and Biases

Another potential influence on self-reports of SWB involves the memory processes used by the respondent in formulating their subjective report. "Traditional" self-report instruments for assessing SWB rely on global retrospective reports from respondents. Unfortunately, human memory is not perfect, and a number of factors may work to create biases in retrospective reports. For example, the data indicate that people tend to formulate reports of emotion that are more strongly correlated with the amount of time they have experienced an emotion, rather than on the intensity of the emotional experience (Diener, Sandvik, & Pavot, 1991).

One methodological innovation intended to address the problems inherent in retrospective reports is the Experiential Sampling Method (ESM; Csikszentmihalyi & Larson, 2014). This method involves obtaining a large number of reports of emotion and SWB at random moments during each day, while the respondents are having these subjective experiences. Such an approach can eliminate the retrospective element of the self-report, and therefore presumably eliminate the problem of memory bias. The ESM method is discussed in detail in another chapter of the volume.

Representative Examples of SWB Self-Report Instruments

Rutt Veenhoven has created a large and highly informative database of SWB research, the World Database of Happiness. One section of this database focuses on existing measures of happiness, which number more than eleven hundred catalogued examples (Veenhoven, 2017). It is not possible to review these measures in detail; it is possible, however, to sort potential instruments into general groups, and prominent examples of each general group are reviewed in this section.

Single-item broadband measures. Most of the measures that have been included and catalogued in the World Database of Happiness are single-item measures, usually presented to respondents in a survey format (Veenhoven, 2017). Many of these single-item measures are "broadband" in design; all facets of SWB are assessed by this single item, in the form of a statement or question. Usually the stimulus item is focused on the generic terms of "Happy" or "Happiness." A prototypical example of this category is the Fordyce's Single-Item Happiness Question (1977). The Fordyce Scale offers 11 Likert-scale response choices (ranging from "Extremely happy" to "Extremely unhappy") to the query: "In general, how happy or unhappy do you usually feel?"

Another single-item broadband measure of SWB is the Delighted-Terrible Scale (Andrews & Withey, 1976). After prompting the respondent to think about their own life and about "life in this country" over the past year, and their expectancies for the future, the respondent is asked to make one of seven possible responses to the question: "How do you feel about how happy you are?" The responses range from 1 (Terrible) to 7 (Delighted). The Delighted-Terrible scale has been used in conjunction with the World Values Survey (1994), and has demonstrated good psychometric characteristics.

The brevity of single-item broadband measures is obviously a great asset to survey researchers. But there is a significant trade-off involved; single item measures do not provide specific information regarding the separate facets of SWB.

Single-item facet-focused measures. One of the most enduring and widely used single-item measures is Cantril's Self-Anchoring Ladder (SAL; Cantril, 1965). This instrument has been frequently used in large-scale survey studies, perhaps most notably research conducted by the Gallup Organization, both internationally (Helliwell, Layard & Sachs, 2014) and in the United States (Harter & Gurley, 2008) . Data from the SAL is a primary source for the World Happiness Report, sponsored by the Organisation (sic)for Economic Co-operation and Development (OECD). The instructions for the Cantril Self-Anchoring Scale ask the respondent to imagine a ladder with the steps numbered from zero (the bottom step) to 10 (the top step). Then the top and bottom step are identified as representing the best possible life

and worst possible life, respectively, for the respondent. The respondent then chooses the step that is most representative of their life as a whole. The time frame for the response can be adjusted to represent their current life, their future life (i.e., five years from now), or both time-frames can be assessed separately. Single item measures of Life Satisfaction have been demonstrated to have good reliabilities (Cheung & Lucas, 2014), that are comparable to multiple-item scales.

Multi-item comprehensive scales. In some contrast to the single-item survey measures of SWB, which are often used for a broad range of purposes and applications, multiple-item measures tend to be used in research settings with a primary focus on SWB. Multiple-item measures can provide researchers with a more detailed picture of the respondent's SWB, and can be examined in more detail psychometrically.

Most multi-item SWB scales are facet specific; they tend to assess either the affective facets *or* the life satisfaction facet of SWB, but not both. Still, there are examples of multi-item, comprehensive measures of SWB.

The Oxford Happiness Questionnaire (OHQ; Hills & Argyle, 2002), represents a revision of an earlier instrument, the Oxford Happiness Inventory (OHI; Argyle, Martin, & Crossland, 1989). The OHQ consists of 29 items, each a statement to which individuals can respond on a 6-point Likert-type scale. The authors interpret the underlying factor as being uni-dimensional. Correlational comparisons indicate that both the convergent and discriminant validity of the OHQ are somewhat improved over the OHI.

The Subjective Happiness Scale (SHS; Lyubomirsky & Lepper, 1999) is a brief (4-item) measure that is also intended to assess global subjective happiness. Responses to the four items can be made on a 7-point Likert scale, with higher numbers indicating greater SWB. In early validation studies, correlations of the SHS with informant reports were moderate to strong, and test-retest reliability was also strong. The brevity of the SHS, combined with the encouraging initial psychometric data on the scale, suggest that the scale should have good utility when a comprehensive measure is desired.

Multi-item affect scales. Several multiple-item measures have been developed with a specific focus on the affective components of SWB. Although it would be possible to create a scale that was focused on either positive affect or on negative affect exclusively, most of the scales in this category measure both of these facets using separate subscales. This allows for the computation of an index of the affective state of the respondent, commonly referred to as "affect balance" (Bradburn, 1969). The affect balance score represents the difference between the amount of positive affect reported and the amount of negative affect reported (e.g., positive affect – negative affect = affect balance). A positive affect balance would indicate that the respondent has reported a greater amount of positive emotion that negative emotion over a specified time frame and presumably has experienced SWB during that time. It is also possible, of course, to focus on the subscale scores independently as well.

The Bradburn Affect Balance Scale (BABS; Bradburn & Caplovitz, 1965; Bradburn 1969) was the first scale to use the affect balance approach as an assessment of SWB. The 10-item BABS includes PA and NA subscales of five items each. In the original version of the BABS, the respondent is asked to indicate, using a "yes" or "no" response, whether they have experienced any of the positive or negative affects "during the past few weeks." The BABS affect balance index is generally correlated (albeit moderately) to other SWB indices.

The Affectometer 2 (Kammann & Flett, 1983) uses an approach that is similar to the BABS, but incorporates an expanded array of 40 affect items, intended to assess ten facets of SWB. The Affectometer 2 also replaces the "yes" or "no" responses of the BABS with a frequency response scale for each item. The combination of larger number of items and a frequency response scale are psychometrically appealing, but the length of the Affectometer 2 might be an obstacle in some research designs.

Researchers have frequently used another multiple-item affect measure, the Positive and Negative Affect Schedule (PANAS; Watson, Clark, & Tellegen, 1988), in recent years. The PANAS includes 10 affective adjectives in each of its two subscales. Respondents indicate the degree to which they have experienced each emotion, using a 5-point scale. The time-frame can be adjusted to reflect the either the current emotional experience of the respondent or a retrospective report (e.g., "over the past few days" or "in the past few weeks"). Both the PA and NA subscales have good psychometric characteristics. The PANAS tends to put emphasis on high activation emotions, and includes some adjectives (e.g., "strong") that may not necessarily reflect emotion exclusively. An expanded version of the original PANAS, the PANAS-X, utilizing 60 items, is also available (Watson & Clark, 1999).

A relatively recently developed scale, the Scale of Positive and Negative Experience (SPANE; Diener et al., 2010), has a number of desirable characteristics. The 12 items (emotion adjectives) of the SPANE, despite the brief format, assess a broad range of both positive and negative affective experience.

The 5-point frequency response scale, ranging from 1 = "Very rarely or never" to 5 = "Very often or always" indicates the relative amount of time that the respondent was experiencing each emotional state. And frequency of feelings, rather than intensity of emotion, tends to be related to other SWB measures, such as life satisfaction measures.

Multi-item satisfaction scales. Probably the best known of the measures in this category is the Satisfaction With Life Scale (SWLS; Diener, Emmons, Larsen, & Griffin, 1985). The satisfaction with life scale has been used in thousands of studies and has been translated into more than 30 languages. The SWLS has been cited in more than 17 thousand published scholarly articles (according to a 2017 Google Scholar search). The SWLS consists of five statements, such as "In most ways my life is close to my ideal," and "I am satisfied with my life." Typically, a seven-point Likert scale is provided for a response to each item, ranging from "strongly disagree" (1) to "strongly agree" (7). The five-item SWLS has demonstrated good internal reliability and moderate temporal reliability. It has been shown to be sensitive to both positive and negative change over time (Pavot & Diener, 1993b; Pavot & Diener, 2008).

The 15-item Temporal Satisfaction With Life Scale (TSWLS; Pavot, Diener, & Suh, 1998) uses essentially the same items as the SWLS, but presents them with three distinct temporal contexts, referring to the past, the present, and the expected future satisfaction of the respondent. The TSWLS thus can be used to gauge future expectancies of the respondent, as well as past and current perspectives.

Population / domain specific measures. Nearly all of the measures of SWB reviewed in this chapter have good generalizability to a very wide range of populations. Most will provide valid SWB data without concern for respondent age, or occupational, economic or other noteworthy social differences. However, some researchers are interested in aspects of life that may be particularly relevant to the SWB of a specific group or age range. Specialized measures of SWB and life satisfaction are available for a number of specific populations. For example, researchers interested in the aging process have developed several measures, such as multiple versions of a Life Satisfaction Scale (LSR, LSIA, LSIB; Neugarten, Havighurst, & Tobin, 1961). Another well-known scale intended for older adults is the Philadelphia Geriatric Center's Morale Scale (PGC Morale Scale; Lawton, 1972, 1975). This scale appears to assess several factors, including loneliness and attitudes toward aging. These scales are well-established and have been used extensively in research focused on late adulthood.

Children and adolescents represent another population that has been the focus of attention for well-being researchers, particularly in their role as students. The Student's Life Satisfaction Scale (Huebner, 1991) and the Brief Multidimensional Students' Life Satisfaction Scale (Seligson, Huebner, & Valois, 2003) are two examples of measures focused on the student population.

Many researchers are interested in assessing satisfaction with specific aspects of life, such as job, marriage, income, religious orientation, government function, or some other specific life domain. Items intended to assess specific domains are numerous (Veenhoven, 2017), and can be adjusted to whatever situation or domain is of interest to the researcher.

Measures of constructs related to SWB. When designing a study focused on SWB, It is often desirable to include additional assessment instruments that provide data on constructs that are related or are believed to be related to SWB itself. An example of one such construct that has relevance for the experience of SWB is Dispositional Optimism. Dispositional Optimism refers to a global generalized tendency to believe that one will generally experience good vs bad outcomes in life (Scheier & Carver, 1985). One measure intended to assess dispositional optimism is the Life Orientation Test (L.O.T.; Scheier & Carver, 1985). The L.O.T. includes eight construct-relevant items (four keyed in a positive direction, and four in a negative direction), along with four "filler" items intended to disguise the specific focus of the scale. Responses are made on a five-point Likert scale. A later version of the scale, the 10-item L.O.T. – R., was developed by dropping two of the construct-relevant items, in order to more clearly distinguish dispositional optimism from neuroticism (Scheier, Carver, & Bridges, 1994). Both versions have good psychometric characteristics, and have been used extensively in research.

The Flourishing Scale (FS; Diener et al., 2010) is intended as a broadband measure of self-perceived well-being across a range of important domains. The FS assess functioning in areas that are key to psychological well-being such as relationships, feelings of competence, and a sense of meaning and purpose in life. The FS includes eight items, and utilizes a 7-point Likert scale for responses.

Another recently developed broadband measure also focused on a range of well-being related domains is the Comprehensive Inventory of Thriving (CIT; Su, Tay, & Diener, 2014). The CIT is composed of 54 total items (18 subscales), and spans a very broad range of domains. For situations requiring a quicker assessment, a 10-item version of the CIT, The Brief Inventory of Thriving (BIT), has also been developed and is included in the same report. Both of these measures were evaluated with multiple samples with diverse demographics. The CIT and BIT demonstrated excellent psychometric

properties and good convergent validity (Su, Tay, & Diener, 2014)

Reliability and Validity of SWB Assessments

Reliability. Reliability refers to the degree to which an assessment instrument produces consistent, dependable results. Several forms of reliability are commonly examined when evaluating an assessment instrument or technique. For the present I will focus on three basic types of reliability. One gauge of reliability is focused on the ability of assessment instrument to produce dependable results over a period of time, and is often referred to as "test-retest" reliability. For example, if we asked an individual to complete a measure of SWB today, and then asked them to complete the same measure one month from now, we would expect that the results would be similar. The degree of agreement or correlation between the two measurement occasions would represent an index of test-retest reliability. A second form of reliability is referred to as "inter-rater" reliability. This form of reliability is an index of agreement between two or more "raters" or "judges." For example, we might ask two (or more) different raters to evaluate the emotion content of a writing sample that a respondent has completed. The degree to which their evaluations agree would serve as an index of inter-rater reliability. A third type of reliability is usually identified as internal reliability or "Alpha" reliability. The "Alpha" identifier is a reference to Cronbach's Alpha (Cronbach, 1951), which is a statistic that is usually computed and reported as an index of internal reliability. Internal reliability is determined by the consistency of response to each of the items on a multiple-item measure. That is, the tendency of individuals to respond consistently to all the items of the measure in a similar way. Thus, the greater the consistency of response across the individual items of the scale, the larger the Alpha statistic will be. There is no absolute standard regarding the minimum acceptable level of Alpha; generally a range of .7 to .75 would be considered a minimal demonstration of internal consistency.

The reliability of most self-report measures of SWB is typically evaluated using either an index of test-retest reliability or of internal reliability. For multiple-item measures, it is usually expected that statistics depicting both indices will be presented. With single-item measures, the index of internal reliability, or Cronbach's Alpha, cannot be computed. In either case, an index of reliability is a critical element in the evaluation of the assessment instrument or method.

Validity. Validity can also be understood from multiple perspectives. Many types of validity have been identified, such as face validity and predictive validity. A full discussion of all forms of validity is beyond the scope of this chapter; it is perhaps more efficient to focus on some central elements. A central form of validity, construct validity, refers to the degree to which an instrument accurately measures the construct it is intended to measure. In other words, a measure of SWB, when completed by a respondent, should be an accurate depiction of that person's experience. Establishing the construct validity of a SWB measure is a complex process. A first step in the process usually involves establishing reliability, because without dependable assessment, it is impossible for a measure to be considered valid. Thus, reliability is a necessary, but not sufficient, condition for validity. Reliability is not sufficient for validity because, unfortunately, it is possible to be reliably wrong. In addition to demonstrating reliability, it is critical that an assessment instrument demonstrate that it is accurately measuring the construct it is intended to measure. Accuracy (construct validity) can be evaluated by comparing the results yielded by the measure to the results of both similar and dissimilar measures obtained from the same sample.

Convergence of similar measures. In order to go beyond reliability and establish the accuracy (validity) of our measurement, we have to rely on established "benchmarks" that can help us determine how well our measure is accurately assessing the intended construct. One type of benchmark is provided by previously established indices that measure the same construct, or at least similar constructs to the one we are interested in. We would expect that such indices would be positively correlated with our measure. To demonstrate such correlations would represent establishing convergent validity. To gauge the convergent validity of a SWB measure, it is necessary to include more than one such measure within a particular sample, and then examine the strength of the correlations between the two (or more) measures of SWB. Measures of other closely related constructs can also be examined. Thus, a measure of flourishing would be expected to be positively correlated to a measure of life satisfaction from the same sample.

An additional advantage of including more than one measure of SWB within a research design is the possibility of creating "composite" SWB scores. That is, if the convergence between separate measures of SWB is high, it is possible, using standard scores such as "Z" scores, to combine the results of the individual measures into one composite measure of SWB. The advantage to this strategy is that a composite score or index tends to have greater stability and reliability than the scores on the individual scales, thus strengthening the results of any further analysis. A potential drawback to this strategy, however, is that the use of composite scores can obscure meaningful differences between measures at the specific facet level. It is desirable, therefore, to report the results of basic analyses of the individual scales before combining them into composite scores.

Convergence of self-reports with other methodologies. In addition to demonstrating the convergence of multiple self-reports of SWB, convergence can also be evaluated by comparing self-reports of SWB to an index of SWB obtained by using another methodology. An often-used alternative methodology is the use of "informant" reports. Informant reports are typically obtained from someone who knows the research participant well, such as a spouse, parent, sibling, roommate, or co-worker. Informant reports tend to increase confidence in the validity of the self-reported data, as they are obtained from an independent source. The validity of self-reported measures of SWB, such as reports of life satisfaction, has been demonstrated by the convergence of such reports with informant reports in a number of studies (e.g., Costa & McCrae, 1980; Pavot, Diener, Colvin, & Sandvik, 1991; Pavot & Diener, 1993b; Lyubomirsky & Lepper, 1999).

Other alternative methodologies include rating based on clinical interviews, ratings based on writing samples (Danner, Snowdon, & Friesen, 2001), and analysis of memory bias for positive and negative events (Sandvik, Diener, & Seidlitz, 1993).

Divergence of dissimilar measures. Another set of benchmarks, in this case measures of dissimilar constructs, could also support the validity of our measure. By demonstrating divergent validity, we can show that our measure is an assessment of a construct that is distinct from other, dissimilar constructs. In the case of divergent validity, we would expect to see either no correlation, or perhaps a negative correlation in the case of a strongly dissimilar (perhaps opposite) construct. For example, a measure of SWB would be expected to have a negative correlation with a measure of psychological distress, such as depression or anxiety. Two often used measures of distress that can be useful in this capacity are a depression scale, the CES-D scale (Radloff, 1977), and the SCL-90-R (Derogatis, 1992), a broader assessment of nine primary symptom dimensions. Scores on measures of anxiety and neuroticism, such as the neuroticism scale on the NEO-PI (Costa & McCrae, 1980).

Considerations for Designing Future Studies

For the researcher contemplating a study focused on SWB, the design and methodological possibilities are many. Clearly, a wide array of self-report instruments for the assessment of SWB is available. Choosing a measure, or a battery of measures, and the specific method of employing these measures to best advantage are critical questions. The question of which, if any, additional dimensions to add to a design is important as well. It may be useful to review some of these considerations.

In its most basic form, the assessment of SWB might be accomplished by a single question at one point in time, such as an item embedded in a larger survey of social attitudes. Despite the simplicity of this approach, useful data, albeit at a very general level, can be obtained in this way. This might be the only feasible choice for very large -scale survey efforts, and has been used quite successfully in many such situations, such as compiling the World Happiness Report. The difficulty with this approach is the lack of specificity and detail in the assessment. As these surveys are generally not given to the same individuals at an additional occasion, we have no sense of the stability or the dynamics of the respondent's subjective experience, nor do we know the specifics of the quality of the subjective experience. Still, the very general snapshot of SWB might well be useful in monitoring the overall SWB of a large group, such as monitoring the overall reaction to a recent change in public policy.

For those interested in a more finely grained assessment, more sophisticated measures may be in order. Two or more SWB measures might be used in concert, and perhaps some additional variables (e.g., personality factors, measures of distress) could be included, to provide a system of benchmarks, to examine convergence or divergence of the measures. If the SWB measures are multiple-item scales, information on internal reliabilities can also be obtained.

Another level of complexity can be added to the analysis if the research participants are surveyed at more than one point in time, with an interval of one or more months between. With assessment on multiple occasions, we can obtain test-retest reliability data, and look for stability (or change) over time. For example, a meta-analysis of such data has shown test-retest reliabilities for global SWB tend to range from .70 over a one-year period, and then decrease to approximately .50 for a 5-year interval (Anusic, & Schimmack, 2016). If the entire original sample cannot be retested, it may be possible to conduct a retest on a subsample of the original group.

A still more sophisticated design might include the collection of informant reports, in addition to the self-report measures of SWB. Informant reports that show good convergence with the self- reports of the study serve to greatly increase the confidence in the findings of the research. A detailed discussion of the sources of self-report and informant-report agreement is available in a meta-analysis by Schneider and Schimmack (2010).

Thus, a longitudinal research design with multiple measures of SWB assessed on multiple occasions

and including informant reports is likely to be desirable for those who want a complex, sophisticate data set of the first order. Obviously the cost to achieve that goal, in terms of time, resources, and effort is going to be high. Conversely, a single-item survey assessment can likely be obtained quickly and economically, but will only provide a very general level of data. For many researchers, a design that falls somewhere between these points is a likely solution. A gradual validation of a finding from a series of studies is as valuable (if not more valuable) than a single "answers all the questions" effort. Replication of previous findings is usually not sensational, but it is essential for building a strong empirical database. A programmatic body of research, in which each study replicates and builds upon previous work, is a valuable tool for advancement.

Summary and Additional Resources

Fortunately, there are many additional sources and examples of the topics briefly presented here. I will list a few of the many options here; there are far too many to enumerate in any comprehensive way.

For those who are new to the study of SWB, and interested in obtaining some general background information, a landmark review article by Ed Diener is a great start (Diener, 1984). After reading the 1984 paper (if you haven't already) I would suggest Diener (2000) as an update, with a particular proposal for a national index of SWB. An edited volume (Kahneman, Diener, & Schwarz, 1999) also provides much greater depth on many of the issues raised in this chapter. For a review focused on the assessment of SWB, Diener (1994) is a good choice; Pavot (2008) also discusses assessment issues. A more recent discussion of the validity of life satisfaction scales is available in Diener, Inglehart and Tay (2013).

For those readers interested in developing and validating their own measures, it may be valuable to review the work of others who have previously engaged in the process. For some good examples of the scale validation process, I would suggest Lyubomirsky and Lepper (1999), Seligson, Huebner, & Valois, (2003) or Diener et al. (2010). The article by Pavot, Diener, Colvin, & Sandvik (1991) is an example of validation of a self -report scale with informant reports. Before you begin the complex process of developing and validating a new measure of SWB, I would encourage you to access the World Database of Happiness (Veenhoven, 2017) on the internet (website: http://worlddatabaseofhappiness.eur.nl). This is an outstanding resource for anyone interested in any aspect of research on happiness or SWB. As noted earlier in this chapter, more than eleven hundred measures have been catalogued and are listed in the "measures" section of the database. It is possible that a previous researcher has already developed a measure that may well suit your needs. Guidelines for researchers interested in using SWB assessments for specific purposes (e.g., general assessment of well-being at the national level) are available (Diener, 2006).

There is no single "correct" way to assess SWB across all research situations and purposes. Nevertheless, it is very possible to optimize the validity of assessment in any given study by a careful consideration of the parameters of the research situation, the resources available, and the proximal and distal goals of the particular research program.

It is important that future researchers continue to pursue both theoretical and applied questions regarding SWB. The topics listed in the table of contents of this handbook are indicative of the many possible directions a program of research might take. At the basic research level, questions from the evolutionary, biological, cognitive, and social perspective are the subject of current study, and will continue to be so for the future. Applied research ranges from the development of interventions at the individual level to social policy at the national level. In terms of the assessment of SWB, future research could focus on the further development of alternative methodologies to compliment the already extensive array of self-report measures that are available.

Abstract

This chapter gives an overview of modern latent variable models for well-being (WB) research. After a short introduction into the importance of measurement error and methodological artifacts that can be produced by measurement error, the basic principles of four types of latent variable models are described: item response theory, latent class analysis, factor analysis, and latent profile analysis. Then, latent variable models for multidimensional data structures are discussed and it is shown how the models can be used to define general WB measures and facet-specific factors. It is pointed out how these models can be applied in multimethod WB research and how the convergent and discriminant validity can be measured in this context. Finally, a very general model for analyzing variability and change in WB is presented and it is discussed how this model and special cases of this model can be applied in WB research.

Keywords: latent variable models, item response theory, classical test theory, latent class analysis, latent profile analysis, confirmatory factor analysis, measurement error, g-factor, bifactor model, longitudinal data analysis

Over the last decades, there has been an enormous progress in the development of advanced statistical methods in the social and behavioral sciences. This chapter will give an overview of some important methods that are relevant for well-being (WB) research. It will focus on measurement models that are appropriate for representing the specific characteristics of WB measures. These measurement models can be used in more complex models to analyze the causes and consequences of WB.

As the chapters of this handbook show there are many measures of WB that have been developed over time. If a researcher uses, for example, two different measures in a study, she or he will realize that these two measures will not perfectly coincide. It would not be possible to perfectly predict interindividual differences in WB on one measure using another. Even if one measures the same individuals repeatedly using the same WB measure it is likely that the results are not perfectly the same. To interpret the empirical results of WB research appropriately, it is necessary to understand the reasons for the divergence of WB measures, to estimate the degree of divergence, and to consider the sources for these degrees of divergence. This can serve to avoid methodological artifacts that could lead to invalid conclusions.

There are several reasons why two well-being measures do not perfectly coincide. A first reason is measurement error. Whenever we measure something in science we cannot avoid unsystematic influences that affect the measurement process. For example, if we weigh ourselves in the morning repeatedly using the same balance, the results might differ depending on how we stand on the balance. A second reason might be method effects. If one measure is a self-report of WB and the other measure is an observational method the measurements might differ because these assessment methods have peculiarities that are not shared. A third reason can be that the two different WB measures assess different components of WB, for example, cheerfulness and calmness. A fourth possible reason is that WB has changed between the two measurements. In order to separate these different sources of variability in WB scores, measurement models are required. This chapter gives an overview of measurement models that can be applied to analyze WB data, and gives answers to the following questions:

1. Why is it important to consider measurement error?
2. How can measurement error be considered?
3. How can the multidimensional structure of WB measures be modelled?
4. How can method effects be measured?
5. How can change in WB be measured?

The approaches presented assume that a random sample is drawn from a population of interest. In some research contexts, sampling is more complex. One example is cross-cultural WB research in which random samples are taken from different nations. Another example is organizational WB research, in which a multilevel sampling process is usual. In a two-level sampling process, for example, first organizations (e.g., companies, schools, villages; level-2 units) are drawn from a population of

organizations and then for each organization a random sample of individuals (level-1 units) is selected. At the end of this chapter it is discussed how the approaches presented can be extended to these more complex research designs.

Why is It Important to Consider Measurement Error?

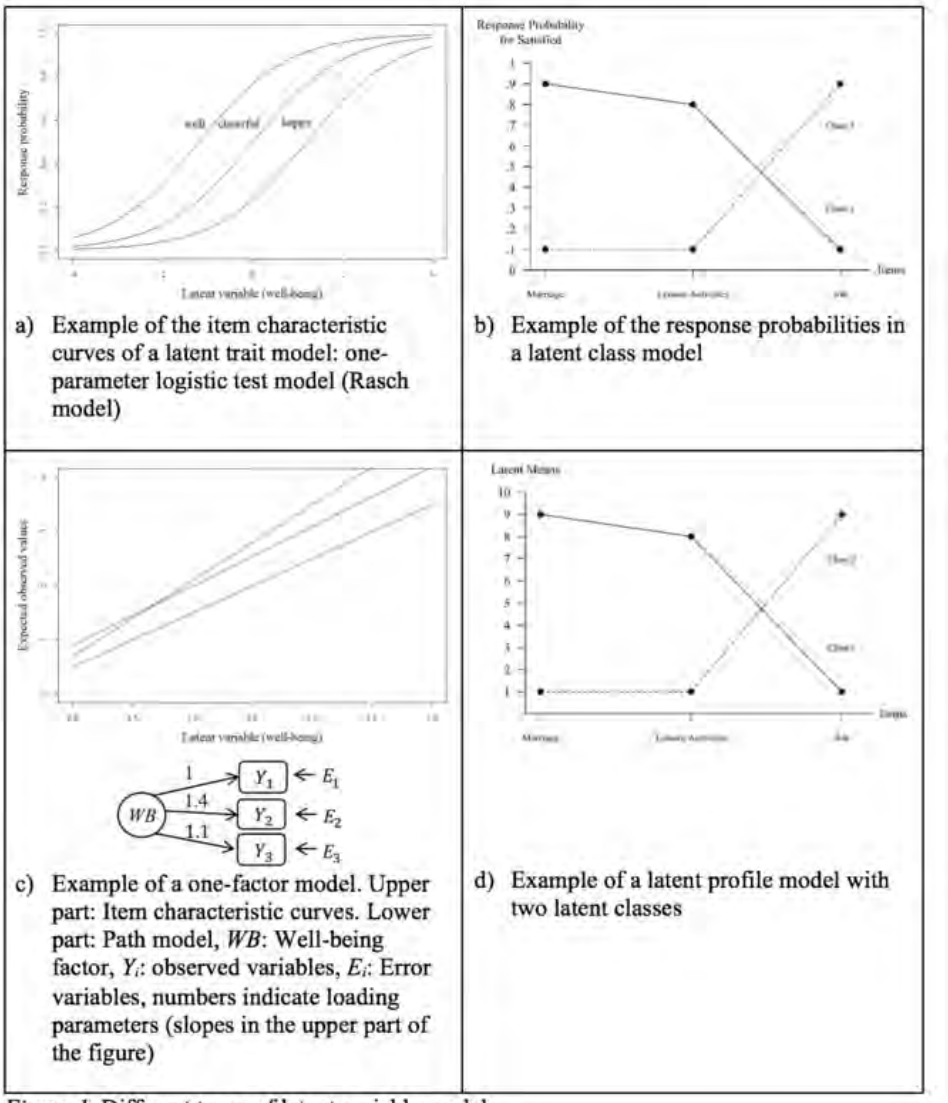
Measurement error cannot be avoided in any empirical science. Because of measurement error one would get different scores for the same individual even if one theoretically could measure the same individual with the same instrument repeatedly at the same time. In measurement error theory (classical psychometric test theory, Lord & Novick, 1968) one decomposes the observed score of an individual into a true score and a measurement error score. The true score is the score of an individual one would get if one could measure the individual repeatedly and calculate the mean score across all replications. Because it is not possible to repeatedly measure the same individual at the same time, measurement models have been developed to separate measurement error from true scores that are built on more viable research designs. The separation of measurement error from true scores in these measurement models is important for different reasons. First, it allows estimating the reliability of the measurements and judging whether measurement error is low enough so that the measures can be trusted. Second, measurement error can cause many methodological artifacts. Consider, for example, that a researcher has conducted an intervention study to increase WB. She is interested in whether there is a correlation between the WB scores before the intervention started (pre-scores) and the change of the WB scores (WB after the intervention minus WB scores before the intervention). She finds a negative correlation between the change scores and the pre-scores and is very happy about this result, because this indicates that individuals with a low pre-test WB score have profited more than individuals with a high pre-test score. However, this could be a pure methodological artifact as it can be shown that measurement error decreases the true correlation between the change scores and the scores before the intervention (Rogosa, 1995). Even if the true change scores and the true pre-scores are unrelated, measurement error will produce a negative correlation and can lead to wrong conclusions.

Table 1. **Types of latent variable models (Bartholomew & Knott, 1999)**

	Latent variables	
Observed variables	Metrical	Categorical
Categorical	Latent trait models	Latent class models

Also in quasi-experimental research, measurement error can produce serious artifacts. Consider the evaluation of a WB intervention in which random assignment was not possible but participants assigned themselves to the intervention vs. control groups. People being high in WB might have chosen the intervention group more often because they are more active and more interested in WB issues. In this case of self-selection, a researcher has to correct for group differences in the pretests in order to evaluate the intervention appropriately. Assume that there is a positive (but not perfect) correlation between the observed pre-test and the post-test scores and that each member of the control and the intervention shows exactly the same increase of true WB scores (no treatment effect). If this study is analyzed by a regression analysis with the independent variables *pre-test* and *group* there could be a significant effect of the group factor indicating a treatment effect that would be an artifact caused by measurement error (Lord, 1967). It is important to note that this effect does not show up if a repeated measures analysis of variance is applied. This difference between the two analysis methods is called Lord's paradox (Lord, 1967). Lord's paradox shows that even the regression coefficient of an independent variable in a regression analysis that is measured without error (group membership: intervention vs. control group) can be distorted if the measurement error of another independent variable (WB pre-test scores) is not appropriately corrected for. These two examples demonstrate why it is important to correct for measurement error in WB research.

How Can Measurement Error Be Considered?



a) Example of the item characteristic curves of a latent trait model: one-parameter logistic test model (Rasch model)

b) Example of the response probabilities in a latent class model

c) Example of a one-factor model. Upper part: Item characteristic curves. Lower part: Path model, *WB*: Well-being factor, Y_i: observed variables, E_i: Error variables, numbers indicate loading parameters (slopes in the upper part of the figure)

d) Example of a latent profile model with two latent classes

Figure 1. Different types of latent variable models

In order to consider measurement error psychometric models are necessary. In general, four types of psychometric models can be distinguished (Bartholomew & Knott, 1999, see Table 1). This distinction is based on the type of observed variables (categorical vs. metrical) and the types of latent (error-free) variables (categorical vs. metrical). Models with metrical latent variables are dimensional models whereas models with categorical latent variables are typological models. In dimensional models, it is assumed that individuals as well as items can be ordered on one (or more) continuous variables, whereas this ordering is not necessary for typological models. The basic ideas of these types of models are explained with respect to one simple representative of each type.

Latent Trait Models

In Figure 1a the one-parameter logistic test model (also called the Rasch model; Rasch, 1960) is shown. This model is a model for dichotomous observed variables (items) measuring a continuous latent variable. Consider the (hypothetical) example that participants rated their momentary WB using the three items *well*, *cheerful* and *happy* and a two-category response format (no, yes). In the Rasch model, it is assumed that the probability to choose the category *yes* depends on a value of an individual on a continuous WB dimension (see Figure 1a). The higher the value of an individual on the WB dimension (latent variable) the higher is the probability to choose the category *yes*. However, the probability will never be perfectly 1 (or 0) because of measurement error. Because the probability of the response *no* is 1 minus the probability of the response *yes*, it is sufficient to consider only one response probability. Individuals differing in their WB will differ in their values on the latent WB variable and can be ordered on

the latent dimensions. These values are not known but can be estimated given their responses to all items. Also, the items can be ordered on the latent dimension according to their difficulty. The item *happy* in Figure 1a is more difficult than the item *well* because an individual needs to have a higher value on the latent WB dimension to obtain a high probability for the category *yes* than it is the case for the item *well*. The item *cheerful* is located on the latent WB between the two other items. An item difficulty parameter is defined as the value of the latent WB dimension that is linked to a response probability of 0.50. These difficulty parameters are not known but they can be estimated given the response patterns of the participants. The Rasch model assumes that the curves describing the response probabilities as functions of the latent WB dimension (so-called item characteristic curves) do not differ in their forms between items. Moreover, the model assumes that the latent dimension explains the observed associations (correlations) between the items perfectly (assumption of local independence): The items are correlated because they are measuring the same construct (latent variable). Their correlations, however, are not perfect because of measurement error. The assumption that the items are fulfilling the assumptions of a Rasch model can be statistically tested and there are several ways to relax the assumptions of this model. For example, it can be allowed that the item characteristic curves differ in their steepness by integrating a discrimination parameter in the model (so-called two-parameter logistic model or Birnbaum model; Birnbaum, 1968). Dimensional models for categorical response variables have been extended to more than two response categories. There are special models for items with ordered response categories (for an overview, see Nering & Ostini, 2010; Ostini & Nering, 2006). In the partial credit model, for example, there is a probability function for each category of an item (category characteristic curve) that describes the probability to give a response in this category as a function of the latent dimension (Masters, 1982). As the latent dimension is also called latent trait, this family of models is called *latent trait models*. Because the item responses are modelled in these models, they are also called models of *item response theory*. Latent trait model also exist for items with unordered response categories (e.g., nominal scale model; Bock, 1972).

Latent Class Models

An important property of the model in Figure 1a is that all items and individuals can be ordered on the same continuum. This implies, for example, that the item *happy* is more difficult than the item *well* for *all* individuals and items. The assumption that all items and all individuals can be ordered on a common latent dimension might not be appropriate for all individuals. Consider, for example, the assessment of domain life satisfaction with the three items *marriage*, *leisure activities*, and *job* and a dichotomous response format (satisfied, dissatisfied). Applying the Rasch model, for example, to these three items would require that the three domains are ordered for all individuals in the same way. For example, the ordering *marriage*, *leisure activities*, and *job* would imply that all individuals would have a higher probability to be satisfied with their marriage than with their job or leisure activities. However, there might be individuals being happier with their job than their marriage and their leisure activities, and other configurations are possible. In areas of research where it is theoretically and/or empirically not possible to order items on a dimension in a way that is obligatory for individuals, a typological model with a categorical latent variable is more appropriate. Latent class analysis (LCA) is a typological model for observed categorical variables (Lazarsfeld & Henry, 1968). In Figure 1b, a (hypothetical) latent class model for the three satisfaction items and two latent classes is presented. LCA assumes that the whole population consists of subpopulations (latent classes) that differ in the response probabilities for the categories of the observed items. Each individual of the population has to belong to one, but only one latent class. The number of latent classes is not known but can be estimated given the observed response patterns of individuals. The membership of an individual is also not known but the probability of belonging to the different classes can be estimated for each individual (assignment probabilities) and individuals can be assigned to the latent class for which the assignment probability is maximum. All members of the same latent class show the same response probabilities for the item categories. The members of different latent classes differ in the profiles of their response probabilities. The latent class structure explains the associations (correlations) between the observed items perfectly. That means that within each latent class the items are independent and observed response differences between individuals belonging to the same class are due to measurement error. In the model in Figure 1b, the first class is characterized by high probabilities for being satisfied with *marriage* and *leisure activities* and for being dissatisfied with the *job*. Class 2, on the other hand, is described by high probabilities for being satisfied with the *job* and dissatisfied with *marriage* and *leisure activities*. Whether a latent class model fits the data and how many latent classes are necessary can be statistically tested.

LCA can be easily extended to items with more than two categories. In the case of multiple categories, the class-specific response probabilities are estimated for all categories of an item. LCA can also be applied to items with ordered response categories (e.g., Rost, 1985). An overview of LCA and their applications is given by Hagenaars and McCutcheon (2002). Similarities and differences between latent

class and latent trait models are discussed by Heinen (1996). Figures 1a and 1b show important differences between dimensional and typological models. These models have different areas of applications and a researcher has to decide which type of model is more appropriate for analyzing the research question and data structure considered.

Models of Factor Analysis

Models for metrical observed variables are based on the same principal ideas as the models for categorical observed models. In dimensional models for metrical response variables the item characteristic curves are not curvilinear such as in latent trait models (see Figure 1a), but linear. In Figure 1c the item characteristic curves for three items and one latent dimension is presented. In this model, the (conditional) expected value of an items is considered as a function of the latent dimension (factor). The deviations of the observed values from the item characteristic curves are due to measurement error. The observed values (not shown) scatter around the line (item characteristic curve). The models are called *factor analytic models* or factor models (e.g., Bartholomew & Knott, 1999). These models are applied to metrical variables such as scale scores or response times. The model in Figure 1c is a one-factor model. The straight lines (upper part of Figure 1c) differ in their slopes (factor loadings). In this model, an observed variable is decomposed in one part that is predicted by the latent dimension (factor) and measurement error. The measurement error variables are assumed to be uncorrelated. This implies that the factor explains the correlations of the observed variables perfectly. As in latent trait models, the observed variables (e.g., scales) are correlated because they measure the same construct but they are not perfectly correlated because of measurement error. Factor analytic models are often depicted as path models (lower part of Figure 1c) in which the latent variable (factor) is shown as a circle or oval having an influence on the observed variables (squares). The error variables are denoted by the letters *E*.

Latent Profile Analysis

Typological models for metrical observed variables are called latent profile models (Lazarsfeld & Henry, 1968). Like in LCA it is assumed that the population consists of different subpopulations. The subpopulations, however, differ in the profiles of the mean values of the metrical observed variables. If the three domain satisfaction items were measured on a continuous scale, the result of a latent profile analysis can look like the result in Figure 1d. The first class is characterized by high expected mean values on the items *marriage* and *leisure activities* and a low expected mean on the item *job*, whereas it is the other way around in Class 2. In classical latent profile analysis, it is assumed that the observed variables are normally distributed in all latent classes and that the observed variables are independent within latent classes.

Other Models

The four models presented in Figure 1 are prototypical models. Over the last years, the development of psychometric models have made enormous progress and it is possible to extend and to combine these models in different ways. LCA has been combined with other statistical models to detect subpopulations that differ in the parameters of a statistical model (so-called mixture distribution models, e. g., Hancock & Samuelsen, 2008). For example, LCA can be combined with latent trait or with factor models to scrutinize whether there are subpopulations differing in item difficulty parameters or factor loadings. Factor analytic models have also been extended in such a way that different types of observed variables (e.g., metrical, ordinal) can be simultaneously analyzed (e. g., Jöreskog & Moustaki, 2001).

Computer Programs

There are many computer programs available for analyzing latent variable models. There are also several packages of the computer program R that can be downloaded at no charge from the internet. The R internet page *Psychometric Models and Methods* (https://cran.r-project.org/web/views/Psychometrics.html) gives an overview of currently available R packages for latent variable modeling.

How Can the Multidimensional Structure of WB Measures Be Modelled?

Well-being is a construct consisting of different components. For example, subjective well-being (SWB) typically comprises the three constructs *life satisfaction* (*LS*), *positive affect* (*PA*), and *negative affect* (*NA*). How distinct are these three constructs? Is it necessary to consider them all in an empirical study? How can their relationships be explained? How can the information that is represented by the three traits be combined to predict dependent variables such as health and longevity? To scrutinize these important research questions the models presented in Figure 1 have to be extended to multidimensional models. The basic structure of these models will be explained only for metrical observed and latent variables [models of confirmatory factor analyses (CFA)] but the basic idea of these models can be transferred to other variable types (for multidimensional IRT models see, for example, Deboeck & Wilson, 2004; Reckase, 2009; for models of CFA for ordinal variables see, for example, Jöreskog & Moustaki, 2001; for multidimensional LCA, see, for example, Hagenaars, 1993).

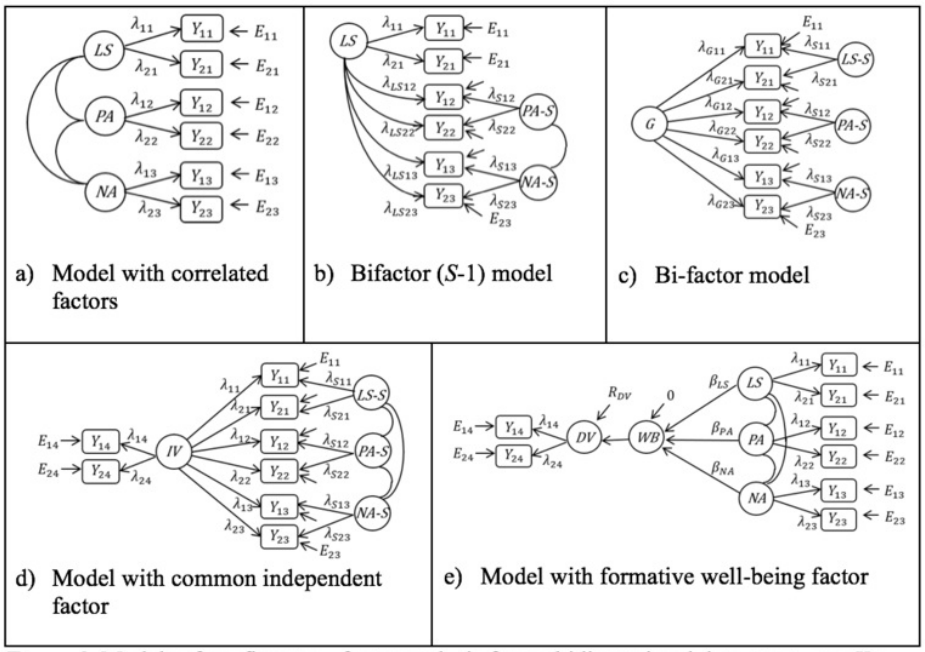


Figure 2. Models of confirmatory factor analysis for multidimensional data structures. Y_{ik}: observed variables, *i*: indicator, *k*: facet. λ: loading parameters. E_{ik}: residual (measurement error) variables. *LS*: life satisfaction, *PA*: positive affect, *NA*: negative affect, *WB*: well-being, *DV*: dependent variable, *IV*: independent variable, -*S*: specific factor.

In Figure 2a, a multidimensional model with three latent variables (factors) for the three facets of SWB is depicted. For simplicity, only two observed variables (indicators) for each latent variable (factor) are presented. This model allows for analyzing the latent correlation between the three factors. These correlations are higher than the correlations between the observed variables because they are not distorted by measurement error. This model allows (a) to test whether the non-perfect correlation between the observed variables is only due to measurement error or whether the three facets are distinct, (b) to estimate the degree of discriminant validity [indicated by a (low) correlation coefficient], and (c) whether the different indicators are distinct indicators of the different latent variables (indicated by no cross-loadings). The parameters of the model can be estimated and the goodness-of-fit of this model – as all other models in Figure 2 – can be evaluated by statistical tests and fit indices that have been developed for structural equation models (SEM; for an overview see Hoyle, 2012; Mulaik, 2009; Schumacker & Lomax, 2010). Several computer programs have been developed for analyzing SEM. One of them is the publicly available R-package lavaan (Beaujean, 2014; Rosseel, 2012) that can be downloaded at no charge from the internet.

If the different components are distinct, researchers are often interested in the specific part of a component that is not shared with the other components. Moreover, the causes of these differences can be analyzed, and it can be investigated whether the components have a unique contribution to predicting and explaining other dependent variables. There are several ways to define a specific part of a component. One way is to select one component as a reference component and to define the specific part of another component as that part that cannot be predicted by the reference component. This approach is depicted in Figure 2b. In the model in Figure 2b, the latent *LS* variable is taken as reference factor that predicts all other observed variables. That latent part of *PA* that cannot be predicted by *LS* is represented by the specific factor *PA-S* that is uncorrelated with the *LS* factor. The *PA-S* factor is a residual factor like a residual in traditional regression analysis and can be interpreted accordingly. It always has a mean of 0. A positive value of an individual on the *PA-S* factor indicates that this individual shows a higher *PA* than one would expect given the *LS* of this individual. A negative value indicates that the person's *PA* is lower than is expected for a person with this latent *LS* score. An analog interpretation is true for the specific factor *NA-S*. The correlation between *PA-S* and *NA-S* is a partial correlation. It indicates that part of the association between *PA-S* and *NA-S* that is not due to *LS*. The variance explained by the *LS* factor and the specific factors can be compared. The proportion of variance of an observed variable by a factor (that is uncorrelated with another one) equals the squared factor loading. The sum of the two squared factor loadings equals the reliability of an observed variable in the model in Figure 1b. The larger the explained variance by a specific factor compared to the explained variance by the *LS* factor the larger is the

component specificity. The partial correlation is 0 if *LS* explains the total correlation between *PA-S* and *NA-S*. The model depicted in Figure 2b is called bifactor-(*S*-1) model and is described in detail by Eid, Geiser, Koch and Heene (2016).

If a specific factor had been defined for the indicators of the *LS* factor in Figure 2b, and if it had been additionally assumed that all specific factors are uncorrelated, the model is called bi-factor model (see Figure 2c; Holzinger & Swineford, 1937). The factor on the left-hand side would then not be the *LS* factor but a general factor (*G* factor). In the case of components of a construct that are not interchangeable, the application of the bi-factor model usually produces problematic results and the meaning of the *G* factor is not well defined (see Eid et al., 2016, for a deeper discussion). The components of a construct, however, are usually not interchangeable (*LS* is theoretically a different construct than *PA* and *NA*), and, therefore, the bi-factor might not be appropriate for these types of applications.

The *LS* factor and the specific factors in Figure 2b can be correlated with other variables in an extended model (not shown here). They can also be modelled as independent and dependent variables in a latent regression analysis. If specific factors are taken as dependent variables in a regression analysis some arrangements (e.g., transformations) have to be made to avoid methodological artifacts (see Koch, Holtmann, Bohn, & Eid, in press, for a detailed discussion and some guidelines).

A second way to define specific factors is to regress all observed variables of SWB on another independent variable (*IV*) as it is done in Figure 2d. Then, residual factors for all facets of SWB can be defined indicating that part of a SWB facet that is not predicted by the *IV*. The values of the specific factors and their correlations have a similar meaning as in the model presented in Figure 2b. Assume, for example, that the *IV* in Figure 2c is *flourishing*. A positive value of *LS-S* would then indicate that the *LS* of this person is higher than one expects for a person having such a flourishing score. Also in this model the variance explained by the *IV* (flourishing) and by the specific factors can be compared to get a measure of the degree of facets specificity. If the facet specificities in Figure 2d were large, this would indicate that flourishing and SWB are quite different constructs.

In some studies, researchers are interested in combing the different facets to a general SWB score to predict a dependent variable (*DV*) such as health or income. In Figure 2e such a model is presented. In this model, the general *WB* factor is a linear combination of the three facets. This makes it necessary to fix the variance of the residual of the *WB* factor in the latent regression to 0. Such a measurement model is called a formative measurement model (e.g., Willoughby, Holochwost, Blanton, & Blair, 2014). An alternative is a reflective measurement model of a general WB factor such as the bi-factor model (Figure 2c). To define a general WB factor in a formative measurement model it is necessary that there is a dependent variable in the model that is regressed on the WB factor. Defining a general WB factor in such a formative measurement model has several advantages compared to a general factor in the bi-factor model. First, the bi-factor model causes many application problems in typical application areas of psychology because it is misspecified for the construct that are typically considered in multidimensional models (Eid et al., 2016). Second, the WB factor in Figure 2e is always the best combination of the three facets *LS*, *PA* and *NA* for the *DV* considered. That means that the meaning of the *WB* factor changes with changing *DV*. *PA* might, for example, having a stronger impact on *WB* than *NA* when predicting creativity, whereas *NA* might have a stronger influence on *WB* than *PA* when predicting reasoning tasks. Although formative factors are rare compared to reflective factors in psychology, they are promising for future *WB* research.

How Can Method Effects Be Measured?

The most widely used assessment method in research on WB is self-report. WB refers to the inner state of an individual and the individual is the person that might best know her or his WB. However, are self-reports valid? Are there other assessment methods that provide important information about the WB of an individual that goes beyond self-report? There are many studies on the validity of self-reports that are summarized in Chapter 5 of this volume and their results will not be reiterated here. One important strategy in validity research is to apply different methods and to analyze their convergent validity (Campbell & Fiske, 1959). These multimethod studies typically show that there are strong method effects. Methods effects, however, are not the "serpent in the psychologist's Eden" (Cronbach, 1995, p. 145) but they represent important substantive effects. Validity research typically focus on estimating the convergent validity but not on understanding method effects. For example, peer ratings of WB are used to analyze their correlation with self-reports but there is less research on the question why peer reports of WB differ from self-reports. In order to get a deeper understanding of the results of WB research, method effects have to be understood. How can method effects be analyzed? In recent research on method effects two types of latent variable models are distinguished that define method effects in a different way (Eid, Geiser, & Koch, 2016). These models are the models presented in Figure 2b and Figure 2c for multidimensional data structures. These models can be applied to multimethod research by replacing the different facets by

different methods. The first model (Figure 2b) is appropriate for structurally different methods, whereas the second model (Figure 2c) is appropriate for interchangeable methods (Eid, Geiser, & Koch, 2016). The difference between these two types of methods can be explained with respect to multiple rater studies. Multiple raters can be considered as multiple methods (Kenny, 1995). Interchangeable raters stem from the same population of raters, for example, different peers rating a common friend, or different students rating the same teacher. Structurally different methods do not stem from the same population. For example, if the WB of a child is measured by a self-report, a parent report and a teacher report, the self, parent, and teacher do not stem from the same population of interchangeable raters, they have different social roles and experience the child in quite different contexts. Other examples of structural different methods are observational methods, physiological measures, reaction time measures, etc. (see Eid et al., 2008; Koch, Eid, & Lochner, in press, for a deeper discussion of these differences and their implications for modeling multimethod data). In the multimethod model in Figure 2b a reference method (e.g., the child self-report) is selected and contrasted with the other methods (e.g., parent report, teacher report). The method factors have a similar meaning as the facet-specific factors. A method factor represents the over- vs. underestimation of trait with respect to the value expected based on the reference method (e.g., self-report). The correlation between two method factors shows whether two methods have something in common (e.g., common view of different raters) that is not shared with the reference method. In the multimethod model in Figure 2c there is a common factor underlying all interchangeable methods. If the three methods considered are, for example, three peer ratings (three friends of a target) and the peers are randomly assigned to three groups, the general factor measures the expected trait value of a target across all interchangeable raters. The method factor represents the deviation of the single raters from the expected values across all raters, that means, it represents the rater-specific view. Because the raters are interchangeable and nested within targets the three method factors are uncorrelated (Nussbeck, Eid, Geiser, Courvoisier, & Lischetzke, 2009). In the two models presented in Figure 2b und 2c, the variance explained by the factor on the left hand side (squared standardized loadings of the general factor having an influence on all observed variables) is a measure of convergent validity, whereas the variance explained by the method factors (squared standardized method factor loadings) is a measure of method specificity. The general factor and the method factors of the models can be related to other variables to explain individual trait differences and method effects. The models presented in Figure 2d and 2e can also be applied in multimethod studies in order to explain the convergence of different methods (Figure 2d) and to combine different methods (e.g., different raters and/or different physiological variables) for predicting a dependent variable (e.g., health) in an optimal way (Figure 2e).

The multimethod models in Figure 2b and 2c can be extended to multitrait-multimethod (MTMM) models to estimate not only the convergent but also the discriminant validity (see Eid et al., 2008; Koch et al., in press). A guide to more complex multimethod models is given by Eid, Geiser and Koch (2016). MTMM models for ordinal variables are presented by Nussbeck, Eid and Lischetzke (2006), LCA MTMM models are discussed by Nussbeck and Eid (2015) as well as Oberski, Hagenaars and Saris (2015).

How Can Change in WB Be Measured?

In the analysis of change two general change concepts are considered – variability and change in the narrow sense (Nesselroade, 1991). Whereas variability refers to reversible short-term fluctuations, change in the narrow sense characterizes change processes that are more long lasting and less reversible (Nesselroade, 1991). The variability of WB measures is often analyzed in a state-trait model of WB. Momentary WB states are considered as fluctuations around a stable WB trait (habitual WB level, set-point, well-being trait, e.g., Eid & Diener, 2004). Several studies have shown that intraindividual variability itself can be considered a personality trait as individuals differ in stable way in the variability of their well-being states (e.g., Eid & Diener, 1999).

Examples of change in the narrow senses are developmental processes and trait changes caused, for example, by interventions. The variability of WB states is often analyzed in longitudinal studies comprising many repeated measurements in a relatively short period. Change processes in the narrow sense are often analyzed with larger time lags between repeated measurements and long time periods. However, variability and change (in the narrow sense) are not totally distinct processes, and it might be the more typical case that they overlap. Even the measurement of stable personality traits take place in specific situations that might cause a certain degree of variability (Deinzer et al., 1995; Eid & Diener, 2004). How can both types of change be measured and separated from change due to unsystematic measurement error? Over the last years, the development of latent variable models for analyzing change has been a major topic of psychometric research and not all models can be presented (for an overview see, for example, Collins & Sayer, 2001; Eid & Kutscher, 2014; Laursen, Little, & Card, 2012; Little, 2013; McArdle & Nesselroade, 2014; Mehl & Conner, 2012; Molenaar, Lerner, & Newell, 2014; Newsom, 2015; Singer & Willet, 2003). Instead of presenting different models for specific purposes, the basic principles of latent change modeling

will be presented with respect to a very general longitudinal model for analyzing variability and change (see Figure 3a) that contains various longitudinal models as special cases (Eid, Courvoisier, & Lischetzke, 2012). This model is a combination of latent growth curve models (Bollen & Curran, 2004; 2006; Curran & Bollen, 2001; Duncan, Duncan, & Strycker, 2006) with latent state-trait models (Cole, Martin, & Steiger, 2005; Eid & Hoffmann, 1998; Steyer, Mayer, Geiser, & Cole, 2015).

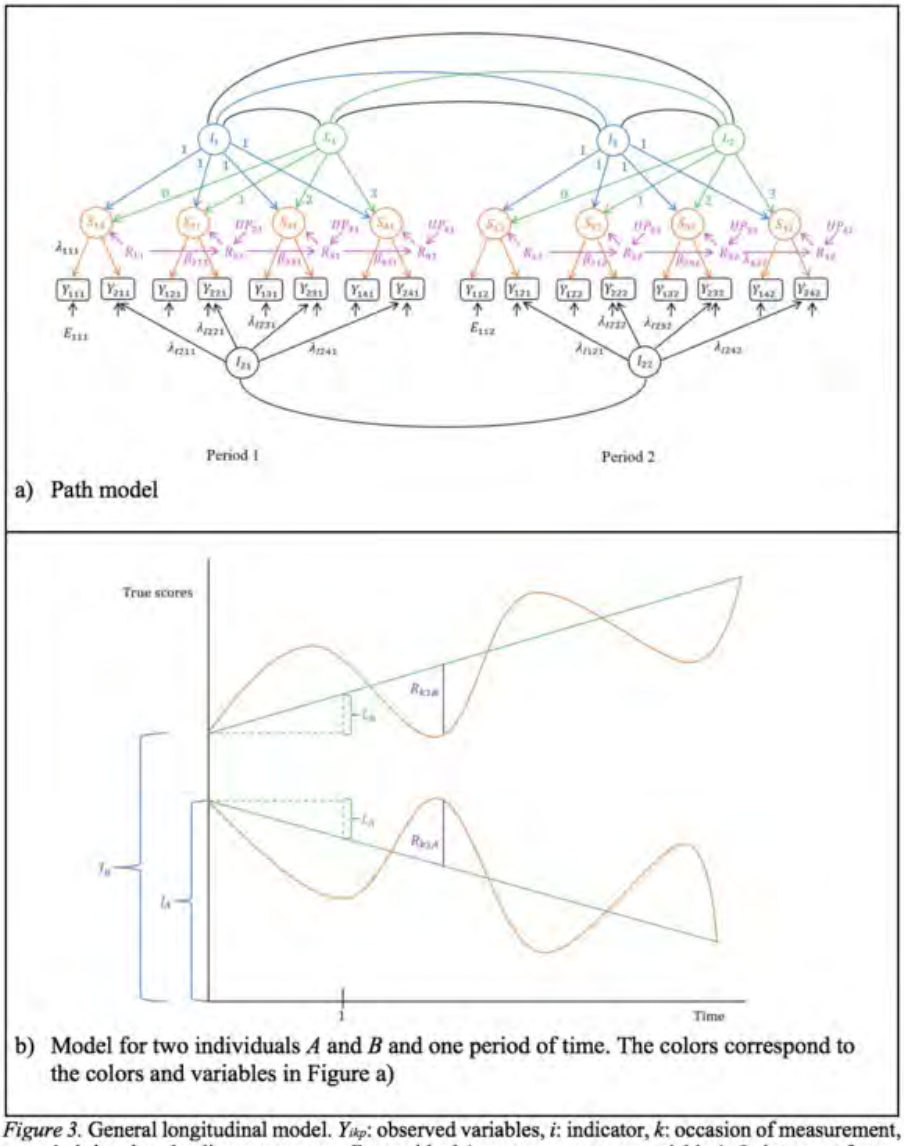

Figure 3. General longitudinal model. Y_{ikp}: observed variables, i: indicator, k: occasion of measurement, p: period. λ_{ikp}, λ_{likp}: loading parameters. E_{ikp}: residual (measurement error variables). I_p: intercept factor, L_p: slope factor, S_{kp}: latent state variable; R_{kp}: occasions-specific residual, U_{kp}: occasion-specific residual indicating unpredictability. $\beta_{k(k-1)p}$: autoregressive parameter. For reasons of clarity not all parameter labels are included.

The model presented is a model for two time periods, for example, the periods before and after an intervention or for two days of an experience sampling study. The model can easily be extended to more than two time periods. Within each time period, there are multiple repeated measurements. For each occasion of measurement there are two indicators of a latent state variable S_{kp} characterizing the true WB state on an occasion of measurement k in a period p. On the level of the latent state variables a latent growth curve structure with a linear trend is specified. According to the linear growth model, the state change of each individual can be characterized by a linear trend. The basic idea of this model for two individuals is depicted in Figure 3b. The intercept and the slope of the linear trend can differ between individuals. The individual intercept is a value of the latent intercept factor I_p. The larger the variance of

this factor, the larger are individual differences in the intercepts. The mean value of the intercept factor represents the mean slope of the change process. The individual slopes are values of the slope factor L_p. A large variance indicates large differences in the linear trends. The mean value of this factor is the mean slope across all individual slopes. If the variance and the mean of the slope factor are 0, there is no linear trend in the data and the growth factor can be removed. In this case, the model reduces to a so-called latent state-trait model with autoregressive effects (Cole et al., 2005; Eid, Holtmann, Santangelo, & Ebner-Priemer, 2017). The intercept factor is then the trait factor characterizing the individual WB level over time. The linear curves do not perfectly determine the change of the state variables because there are residual variables R_{kp}. These residuals indicate momentary deviations from the linear trend (or in the case without a linear trend from the latent trait) are due to occasion-specific influences. In addition, there are autoregressive effects on the level of residuals. These effects represent the inertia of the change process (carry-over effects between two neighboring occasions of measurement. To test the hypothesis that the autoregressive process is time homogeneous the autoregressive parameters can be set equal within and between periods. Fixing the autoregressive parameters also helps to avoid estimation problems. The residual variables (UP_{kp} in Figure 3a) indicate that part of a momentary latent WB state variable that is unpredictable by the intercept and slope factors as well as the state variables measured before. Finally, there is an indicator-specific factor in the model on which the second indicators load. Such a factor is often necessary because the two indicators are not perfectly homogenous (unidimensional). Like in the multidimensional model in Figure 2b the number of indicators is one less than the number of indicators considered (Eid, Schneider, & Schwenkmezger, 1999). If there are more than two indicators and, therefore, more than two indicator factors within a period they can be correlated within and between periods. If the indicators are unidimensional with respect to the latent state variable indicator-specific factors are not necessary. In the case of unidimensionality the assumption of indicator-specific factors can cause estimation problems (because they are not necessary and do not have substantive variance). Therefore, researchers can start with a model without indicator-specific factors and add them if they are necessary because a model without them does not fit the data.

Mean stability and mean change between periods can be analyzed with respect to the period-specific intercept and slope factors. For example, after a WB intervention the mean values of the intercept factor can differ indicating that the intervention might have changed the general WB level. A change of the mean values of the slope factor would indicate that the intervention might have changed the developmental process. For WB research, a model without linear change model might be the more typical model because of adaptation processes that preclude a linear change. Therefore, stability and change of WB might be well represented by a state-trait model (Eid & Diener, 2004).

Measurement Invariance

In longitudinal studies, different types of measurement invariance over time can be considered (Millsap, 2011). Measurement invariance (MI) concerns the question whether the same WB states are measured or whether there is a structural change in the link between the latent and observed variables showing that the psychometric meaning of the WB measures has changed. The lowest level of MI is *configural invariance*. That means that the number of latent variables do not differ between occasions of measurement and time periods. *Weak MI* additionally assumes that the values of the loading parameters of the latent variables do not differ between occasions of measurement and time periods. Weak MI is necessary if one wants to relate the latent variables to other variables in extended models and to make sure that the structurally the same WB factors are measured on each occasion of measurement. *Strong MI* additionally requires that the intercepts of an observed variable do not change over time. The intercepts are not shown in the path models presented in this chapter. Intercepts are additional constants that are specific to an observed variable and mainly determine the mean value of the observed variables. Strong MI is required when one wants to compare latent means over time, e.g., the means of the intercept factors before and after an intervention. If strong MI is not given this would indicate that mean change was indicator specific and is not well-captured by the means of the latent variables. *Strict MI* would additionally assume that the variances of the error variables do not change over time. This is not required for relating latent variables to other variables or testing for mean differences but it is interesting to see whether the quality of WB measurements changes over time. Often it is also assumed that the autoregressive process is time-invariant with non-changing autoregressive parameters and residuals of the UP variables over time.

The measurement model that is shown for one construct in Figure 3a can be extended by including other variables. For example, if there are multiple constructs, a measurement model can be specified for each construct and the mutual influences of the variables over time can be analyzed (e.g., Wickrama, Lee, O'Neal, & Lorenz, 2016). The model in Figure 3 assumes that the time lag between the occasions of measurements is the same between all occasions and for all individuals. This assumption might be violated,

for example, in experience sampling studies in which occasions of measurements are individually selected. In such studies, the loadings of the intercepts and the autoregressive parameters have to consider these individual differences in time lags (Eid et al., 2012). This can be done, for example, in the context of dynamic structural equation modeling (Driver, Oud, & Voelkle, 2017; Asparouhov, Hamaker, & Muthen, 2017).

How Can These Models Be Extended to Analyze Multiple Groups?

The models presented assume that a sample of individuals was randomly drawn from a population. In WB research, the sampling process is sometimes more complex. Often, it is of interest to analyze different groups, for example, nations, intervention groups, schools, companies, etc. There are two ways to consider group differences – multigroup and multilevel analysis. In multigroup analyses different groups are selected because the researcher is interested in exactly these groups. In a replication of a study, a researcher would select samples exactly from the same groups. For example, the researcher might be interested in comparing women and men, China and the US, or an intervention with a control group. In this case, multigroup analysis is appropriate. In multigroup analysis a latent variable model is specified in each group and several hypotheses about between group differences with respect to the parameters of a model (e.g., factorial structure, mean differences, regression parameters) can be tested. The models considered in this chapter can be easily extended to multigroup analysis (e.g., Bock & Zimowski, 1997; Brown, 2015; Eid, Langeheine, & Diener, 2003). If there are many groups testing assumptions across groups (e.g., testing measurement invariance across many nations) can become very cumbersome. In this case, recent developments of methods for analyzing many groups can be applied (for an overview and comparison of different approaches see Kim, Cao, Wang, & Nguyen, 2017).

In multilevel analysis, it is assumed that the groups themselves are randomly selected from a population of groups. For example, a WB researcher might be interested in work satisfaction and randomly select different companies (level-2 units) and employees within companies (level 1 units). The level-2 units are considered interchangeable. In a replication of such a study, the researcher would get a different sample of level-2 units. Like in multigroup analysis, the level-2 units can differ in the parameters of a model. In addition to multigroup analysis, however, the variations of the parameters between groups can be explained by other variables. Because the level-2 units are randomly selected, the parameters of the model have a distribution. It can be estimated how strong the variation of parameters is and to which degree level-2 differences in the parameters can be predicted by other level-2 variables (e.g., the organizational climate of a company). Multilevel extensions have been developed for the different types of psychometric models in Table 1 (e.g., Adams, Wilson, & Wu, 1997; Heck & Thomas, 2015; Skrondal & Rabe-Hesketh, 2014; Tay, Diener, Drasgow, & Vermunt, 2011; Vermunt, 2003; 2008).

Multigroup and multilevel analyses require that the group membership of an individual is known. If a researcher has the hypothesis that the parameter of a model differ between subgroups but the subgroups are not known, latent class analysis can be combined with the models presented so far resulting in mixture distribution models (e.g., Hancock & Samuelsen, 2008). For example, latent variable models of longitudinal research can be extended to latent growth mixture models (Wickrama et al., 2016) or mixture distribution latent state-trait models (Courvoisier, Eid, & Nussbeck, 2007) to detect population heterogeneity with respect to the change process (e.g. degree of variability, mean growth rates).

Conclusion

Latent variable models enable the estimation of unsystematic measurement error from systematic sources of WB differences. This allows avoiding methodological artifacts and estimation biases that are caused by measurement error. They also enable researcher testing theories about the measurement of WB as well as its causes and consequences in a sophisticated way. Latent variable models have been developed for different areas of application and can be combined and extended in manifold ways to fulfill the needs of empirical WB research.

Abstract

This chapter explores the distinct contributions of qualitative wellbeing research in relation to quantitative research, and particularly concerning the many ways in which wellbeing phenomena are 'cultural'. The core contribution of qualitative approaches has been to highlight a 'constructivist' perspective, depicting wellbeing not as a quantifiable essence but as a diverse, fluid, and elusive set of feelings and evaluations. These meanings emerge from interactions among people, and between them and cultural resources. Qualitative research is part of that construction process, not just a tool for extracting data. Its value may lie more in the process - facilitating important conversations and debates - than in particular findings.

Keywords: Qualitative; wellbeing; happiness; culture; ethnography; humanistic; scientism; methodological pluralism; mixed methods; social constructivism; narrative wellbeing; compositional wellbeing

Wellbeing is a Qualitative Cultural Process

Shortly before the rapid rise of happiness studies, the human geographer Yi-fu Tuan wrote that 'culture makes it possible for people to be pleased with themselves: that is in fact one of its principal functions' (1986, p. 1). Since both society and culture are often blamed for many kinds of injustice and suffering, Tuan's observation offers a crucial corrective to pathologism. But in what ways are people 'pleased with themselves'. Pleased relative to what or whom? Based on what criteria or reasoning? How can we tell? And is this really a matter of 'fact' at all, let alone one generalisable across all cultures? Does Tuan's elegant but seemingly ad hoc presentation of evidence warrant such confidence?

Wellbeing research is now proliferating at an astonishing rate, becoming more multi-disciplinary, more multi-cultural, and more diverse in its methods and approaches. At the same time, general publics, administrators, employers, planners, and professional wellbeing promoters are engaging more explicitly than ever before in public discussions about wellbeing worldwide, increasingly blurring the divisions between scholarly research and public learning. At the same time, the kinds of clear and confident findings produced by quantitative wellbeing research are increasingly being complemented by a diversity of qualitative research approaches, most of which raise questions, stoke conversations, and provide impressions and vignettes rather than confident findings. This makes it both increasingly important and increasingly difficult to synthesise practicable lessons from wellbeing research around the world.

All wellbeing scholarship is mainly based on qualitative enquiry, and all the disciplines involved - including psychology and economics which are now mainly known as 'quantitative' and 'positivistic' disciplines - were constituted from qualitative research. But wellbeing scholarship, like most forms of humanistic or anthropological study, has often sought public esteem as a 'science' by displaying signals of rigorous control, expert detachment, and reduction of the objects of study to numerical representations of reality. In late 20th century the rapid rise to prominence of happiness scholarship and positive psychology was almost entirely unconnected to the 'qualitative revolution' (Camic, Rhodes, Yardley, & Bamberg, 2003; Wertz, 2011) that was belatedly spreading through psychology.

Nonetheless, qualitative enquiry also constitutes a socio-political and cultural movement (Wertz, 2011; p. 93). This movement has in common with happiness research a strong desire to promote empathy across cultural and bureaucratic divisions, empowering people to articulate their own views on their own wellbeing. Unfortunately, disciplines like sociology and anthropology with long histories of qualitative research remained until recently oblivious to the wellbeing revolution that was sweeping through psychology and economics (Thin, 2005; Veenhoven, 2006; Bartram, 2012). The same has been paradoxically true of 'liberation psychology', which has explored cultural diversity, qualitative research, and empowerment but from an entirely pathological perspective (Watkins & Shulman, 2008).

In wellbeing research, sometimes the push towards scientific rigour and quantification have resulted in implausible pseudo-scientific claims concerning factual knowledge about elusive phenomena such as 'meaning' or 'spirituality' or 'positivity' that clearly aren't matters of fact (Sink, 2000; Mathews & Izquierdo, 2008a, p. 9; and see e.g. the 2013 critique by Brown, Sokal, and Friedman of Fredrickson and Losada's 'positivity ratio' paper, 2005). In quantitative wellbeing research, sophisticated and fine-grained statistical techniques are commonly based on extremely blunt labels and fragile distinctions, such as those

between 'affective' and 'cognitive' wellbeing, or between 'hedonic' and 'eudaimonic' wellbeing for example (in real life, it isn't actually possible to separate feelings from thoughts, or pleasures from evaluations). Scientism in wellbeing research has also led to the neglect or denigration of qualitative or participatory research. Insofar as expert-led approaches exclude citizens as active learners, the wellbeing research movement may be missing opportunities for scholars to promote wellbeing directly through inclusive collaboration (Gergen, Josselson, & Freeman, 2015).

Happiness surveys, which have produced important new understanding and - perhaps more importantly - have captured the imaginations of publics and politicians worldwide, epitomise the quantitative or 'positivistic' approach. Just as economists have since the 1930s persuaded people to believe in 'the economy' as if it were a measurable thing, so quantitative happiness scholars are now persuading us to imagine happiness as measurable entity that ebbs and flows at national level.

Qualitative researchers, by contrast, emphasise that it cannot be 'scientific' to apply more precision or control than the subject-matter warrants. Their main contribution to the rapid growth and popularisation of wellbeing scholarship has been to strengthen recognition of both the potential but also the limits of systematic enquiry into ultimately elusive and partly ineffable experiences. A related contribution has been the 'cultural turn', highlighting the many uncertainties about wellbeing that derive from its dependence on culturally diverse forms of expression. Qualitative research de-emphasises the question of 'how happy' people say they are, and instead explores how people are happy, and how people think about and pursue happiness (Kavedžija & Walker, 2017). It invites respondents to consider their own explanations and experiences of various aspects of wellbeing, rather than extracting from them the inevitably artificial and simplified answers that survey questions elicit.

Institutionalised downplaying or denigration of qualitative enquiry has been one of the most disappointing aspects of happiness scholarship and positive psychology so far (Rich, 2017; Hefferon & Boniwell, 2011; Gergen, Josselson, & Freeman, 2015). Lack of systematic attention to qualitative dimensions of research is all the more surprising because wellbeing is primarily a qualitative and a cultural concept. It signals evaluation and appreciation of how well people live. Most of the qualities implied are cultural (they are conceived, produced, expressed, and expressed through culturally patterned terms and idioms), interactive (they are produced and understood through interactions among people, not just by and through individuals), contextually intertwined (inseparable from their physical and cultural lifeworlds) and processual (they are dynamic, constantly changing as we observe and comment on them). When we judge ourselves or someone else to be living well, we invoke cultural values and scripts, we discuss those with other people, and those discussions influence the experience of wellbeing. Qualitative enquiry into wellbeing mimics and intensifies the enquiries that all humans do everywhere.

The near-synonym 'quality of life' makes this qualitative assessment explicit: we want to know what life is like for people, not just how long they live or how 'high' they would rate their temporary feelings or self-evaluations. Surprisingly, however, most research on wellbeing or quality of life has emphasised quantification, sometimes at the expense of robust qualitative analysis. Some statistics are relevant to this appraisal in relatively unproblematic ways - longevity, morbidity rates, suicide and murder rates, for example. Other statistics, such as those relating to happiness, cultural values, and poverty, are useful but endlessly debatable. To appreciate their relevance and validity in wellbeing assessment, we need richly qualitative investigations and analyses.

Unlike concepts such as 'longevity', 'morbidity', and 'living standards', which imply quantitative and factual comparisons, both wellbeing and 'quality of life' imply mainly qualitative assessment. The elusive, qualitative nature of wellbeing scholarship becomes particularly clear when we focus on happiness. This term, for which the more scholarly term 'Subjective Well-being' (SWB) is a synonym, refers to 'subjective' or 'inside-out' appreciation of life as a whole. In research on wellbeing, the more emphasis there is on a) subjectivity and b) interactions between personal and collective wellbeing, the more elusive and provisional our findings become. Qualitative approaches are crucial because many important features of the things being assessed (opinions, self-evaluations, self-expressions) are highly uncertain and subject to interactive and situational variation.

Looking at wellbeing research over the past half century or so, we can observe four kinds of bias that have restricted its usefulness and scope, but which conscious application of diverse qualitative approaches to culture and wellbeing could rectify:

- **Scientism:** most of the journals specialising in wellbeing have mainly published work by scholars working mainly within 'positivist,' experimental, and/or quantificatory traditions that privilege facts and numbers over more 'humanistic' or 'interpretivist' approaches emphasising qualitative exploration and analysis (Michalos, 2004; Thin, 2014). Arguably, this has produced a research tradition that steers our attention towards indicators (e.g. national 'levels' of self-reported happiness)

rather than the phenomena themselves (the experienced qualities of people's lives).

- **Western ethnocentrism:** the subjects of wellbeing research have been disproportionately from wealthier and particularly 'western' populations, with consequent risks of cultural bias (Christopher, 1999); it remains worryingly common for North American or British researchers to use the phrase 'our culture' on the assumption that all their readers are culturally homogeneous.
- **Oversimplification of crosscultural contrasts:** insofar as researchers have tried to diversify the cultural backgrounds of research subjects, too much of the crosscultural research has been based on two naïve assumptions: that regional and international comparisons are the most interesting and important forms of cultural contrast; and that such comparisons can be well represented by surveying student populations (Oyserman, Sorensen, Reber, & Chen, 2009; Mathews, 2012; Tsai & Park, 2014).
- **Qualitative pathologism:** insofar as qualitative researchers have explicitly addressed wellbeing themes, they have predominantly done so through a pathological lens. Even the texts they have labelled 'wellbeing' have tended to be mainly about illbeing (Thin, 2005, 2018).

Although these shortcomings are important and problematic, this chapter will demonstrate that many able researchers have successfully adopted qualitative and approaches to exploring interactions between culture and wellbeing. It is also true, although not explored here in any detail, that many primarily 'quantitative' researchers have drawn significant inspiration from qualitative research, and have done a great deal to bridge the unhelpful 'qual-quant' cultural divide.

What is Qualitative Research?

There are two different senses in which wellbeing research can be 'qualitative'. First, all wellbeing research is 'qualitative' insofar as it relies heavily on careful consideration of the many qualities involved in wellbeing assessment and of the interactions between them. For example, 'good' emotional quality might mean excitement or calm, or it might be about relations between contrasting emotions through the day or through the life course. Even so-called 'quantitative' researchers in practice put their most significant efforts into qualitative thinking, and many confess that even the most sophisticated quantitative methods are more art than science. It is therefore extremely unhelpful to take sides in the so-called 'paradigm wars' between quantitative and qualitative research, or to draw a stark division between 'qualitative' and 'quantitative' research. Careful scholars instead consider a variety of qualitative aspects of all wellbeing research.

Second, the term 'qualitative approaches' more typically refers residually to those scholars who don't emphasise tight scientific control or the use of numbers in their pursuit of wisdom. Methods and analytical approaches used by scholars working with the 'qualitative' tradition are extremely diverse, emphasising for example interpretation, personal experience, debate, linguistic analysis, everyday in situ observation, and story-telling as the routes to knowledge. This chapter follows mainly this second way of thinking, on the understanding that other chapters here have much to say about qualitative aspects of more controlled 'scientific' research on wellbeing.

Although we should appreciate the many values of qualitative research, it is also important to be aware of its limitations. For example, narratives and opinions can be biased, and in-depth qualitative interactions such as open-ended interviews and focus groups tend to reach very small samples compared to the representative samples reached by structured questionnaire surveys. And the kinds of 'findings' revealed through qualitative analysis tend to be much less clear and confident than the factual findings from experiments and statistical analyses. In addition, insofar as there remain significant gender differences in methodological preference, both quantitative ('masculine') and qualitative ('feminine') research traditions are prone to different kinds of gender bias (Oakley, 2000; Järviluoma, Moisala, & Vilkko, 2004).

A problem for anyone trying to consider qualitative methods as a system is that in some disciplines, particularly those that welcome both 'social science' and 'humanities' approaches to research, remarkably little is said or taught about methods or systems. In social and cultural anthropology, for example, an 'anything-goes' approach applies equally to the development of questions, empirical field research, secondary research, literature reviews, data analysis, and writing up. Ask a sociocultural anthropologist what their 'hypothesis' is and they will tend to respond with bafflement or laughter. Without hypotheses, anthropologists can proceed iteratively and flexibly, but they are unlikely to develop a clear rationale for how they manage different parts of their research effort. As the entry on 'methodology' in a popular anthropological encyclopedia puts it:

Methodology is not a popular concern in anthropology …few researchers actually know any methods for

collecting information, beyond hanging around with the folks and trying to figure out what is going on. (Salzman 2010, p. 464)

Few anthropologists, even those trying to promote public use of their work, even pause to discuss whether their assertions are 'evidence-based' (Liebow et al., 2013). 'Method,' for anthropologists, amounts to being reasonably thorough and multidisciplinary in doing secondary research; being a good listener and being interactive and observant during fieldwork; and writing up in honest and humanistic ways that bring real lives and cultural diversities to the fore. While considerable gains can be made from so much flexibility and reliance on individuals' common sense, this makes it extremely hard to judge the quality of research design, the thoroughness and rationale of secondary research, and the quality of data and validity of interpretations.

Everything humans do is cultural, and all research on wellbeing is 'qualitative' insofar as it is based on observations and analysis of qualities. We will focus here on the distinctive contributions of research labelled as both 'qualitative' and 'cultural'. Although in theory this might apply to all research, in practice research is called 'qualitative' when it doesn't make substantial use of either quantification or positivistic experimental hypothesis-testing, and it is labelled 'cultural' when it pays explicit heed to patterned and shared learning associated with a distinct population or activity. 'Qualitative' research tends to emphasise exploration and interpretation rather than positive proof, and to employ methods such as participant observation, discursive interviews, life narratives, secondary data analysis, and focus groups. 'Cultural' research may be about one particular cultural context (e.g. a North American school, a Korean business, and African Church), or a religion, or an Internet space, or a community or nation. Or it may be about broad crosscultural comparisons, such as Asia versus Europe.

This chapter will also focus on 'happiness', used here as a flexible term for the subjective experience and evaluative interpretation of wellbeing. Though nowadays mainly associated with personal enjoyment and positive self-evaluation, happiness does still retain broader meanings that were more emphasised in the past, including the goodness and admirability of a person's whole life. It is in common usage a synonym for 'subjective wellbeing', though it can also quite reasonably serve as an extended synonym for 'quality of life' and for 'wellbeing'.

Purposes and Approaches of Qualitative Wellbeing Research

Figure 1 provides a thumbnail sketch situating the main focus of this chapter - empirical qualitative research on wellbeing - within the broader encompassing categories of nonquantitative wellbeing scholarship, wellbeing scholarship in general (all of which is mainly based on a substantial degree of 'qualitative' inquiry, analysis and theorising), and the broader public discourse on wellbeing (whose boundary with 'academic research' is often blurred).

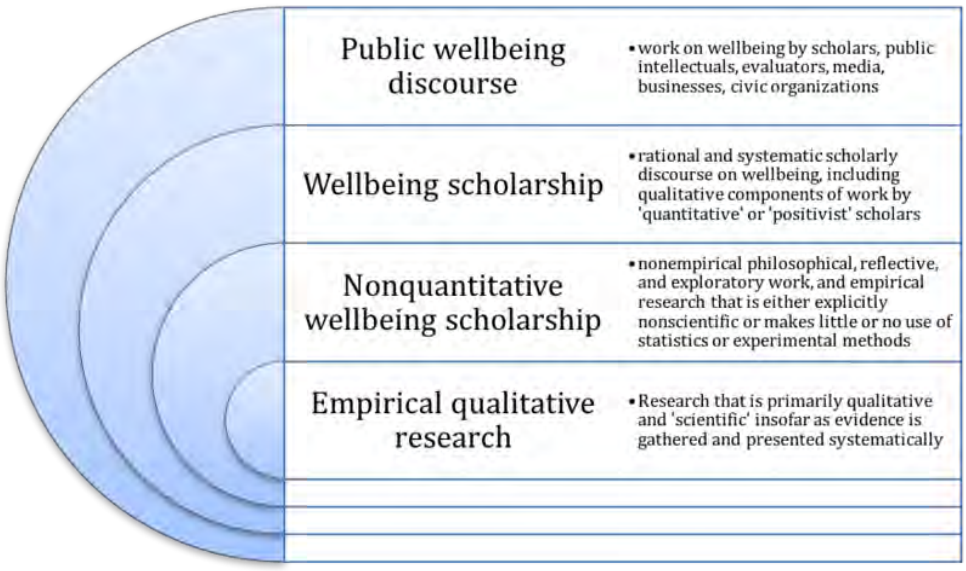

Figure 1: Varieties of qualitative learning about wellbeing

Qualitative approaches are a residual academic category that is in various ways contrasted with the kinds of approach that emphasise hypothesis-testing and scientific rigour through either experimental or

survey-based quantification. These are loose categories and many researchers would be unhappy to be assigned to one camp or another. Even those who have some sympathy with seemingly anti-scientific attitudes of the 'postmodernist' movement and who emphasise interpretive or narrative approaches also consider their research to be empirical, and think of themselves as scientific realists.

Summarising the key arenas of debates between scientific modernists and postmodernism, Susen (2015, p. 2) argues that there are three fault lines: *truth versus perspective; certainty versus uncertainty;* and *universality versus particularity.* Referring these contrasts to wellbeing scholarship, we can usefully outline the core assumptions or beliefs of scholars subscribing to qualitative-interpretive and/or postmodernist approaches to learning about wellbeing:

- **truth versus perspective:** many of the important things worth learning about wellbeing are a matter of personal or cultural perspective rather than universal factual truth
- **certainty versus uncertainty:** many of the important things about wellbeing are highly elusive and uncertain
- **universality versus particularity:** many of the important things about wellbeing aren't universal truths or universal values, but relate to particular situations, conditions, or places

Biological wellbeing - health and longevity - can be fairly adequately represented as facts and captured in statistics. Subjective wellbeing - overall happiness, life satisfaction, self-esteem, or satisfactions with particular domains of life such as home, leisure, and work - is far too complex to reduce to factual representation. SWB statistics are useful, but they are facts about utterances and opinions, not hard facts about the real world. Quantitative research also plays key roles in fostering clear definitions of concepts, and analytical rigour in the development of causal theories. Still, the numbers only make sense in combination with a lot of qualitative analysis.

To appreciate the distinct value of qualitative research, the first requirement is to recognize that it has purposes that tend to be very different from the purposes of statistical or experimental research. Qualitative scholarship tends to be more about 'thinking or talking things through' than about 'finding things out'. Summarising qualitative research purposes, it has been argued that they aim 'to describe and possibly explain events and experiences, but never to predict' (Willig, 2013; p. 52). When we conduct qualitative research on complex aspects of wellbeing, the research purpose is not to accumulate and compare facts so as to prove or disprove hypotheses, but rather to enrich our conversations and our analytical tools so that we understand one another better and appreciate the diversity of human experiences. Qualitative research contributes to these objectives by strengthening our terminological sophistication, translating across diverse languages and cultures, providing analytical tools, proposing interesting questions and causal theories, and humanising the statistics by making them memorable and emotionally salient through real-life stories and vignettes.

Research on wellbeing involves *conceptualisation* (what kinds of thing are we talking about when we discuss wellbeing?); *evaluation* (how well do people live, and how and in what ways to they live well?); *correlation* (what traits, activities, or events are linked with wellbeing?); *explanation* (is it plausible or likely that those correlations may be causal?) and *comparison* (are people living better than before, better than other people, better in some respects than others, better than expected, etc.?). Apart from conceptualisation, which is purely a qualitative matter, all of these may involve a combination of quantitative and qualitative approaches. All are also 'cultural' insofar as there are strong cultural patterns, associated with social processes and institutions, that influences people's attitudes and motivations concerning wellbeing. For example, in one cultural context wellbeing may mainly be conceived as meeting basic survival needs, and in another there may be more emphasis on existential meaning. Qualitative cultural research, as well as the informal cultural knowledge of researchers, provides crucial background analysis to contextualise all wellbeing research.

Given the diversity of qualitative enquiry, it is useful to consider significant variations in its characteristics: the degree to which the approach is explicitly systematic or methodical; degree of emphasis on empirical evidence versus intellectual analysis; primary versus secondary evidence (i.e. whether or not data are by a researcher for specific research projects); study-specific versus research synthesis reports; armchair theorising versus laboratory research versus 'naturalistic' research in everyday life. Although most qualitative authors combine a variety of these characteristics, Table 1 offers a loose classification of books on happiness by qualitative scholars.

Table 1: Varieties of qualitative approach to wellbeing research

Approach to qualitative enquiry	Published examples

Relatively unsystematic and free-flowing but rational exploration of theories and/or evidence from mainly nonacademic writing (e.g. historical accounts, personal documents, local archives, fiction)	Tuan (1986); McMahon (2006); Kosaka (2006); Ehrenreich (2009); Thomas (2009); Ahmed (2010); Pawelski and Moores (2013); Hyman (2014)
Nonscientific but methodical armchair philosophical theorising on wellbeing concepts, norms, strategies, and policies	Haidt (2006); Haybron (2008); S. Bok (2010); Tiberius (2008); Martin (2012); Badhwar (2014)
Interdisciplinary but relatively unsystematic synthesis of academic (empirical and theoretical) studies	D. Bok (2010); Stebbins (2011); Steedman, Atherton, and Graham (2010); Thin (2012); McKenzie (2016)
Mixed-methods, e.g. empirical qualitative analysis of laboratory or other controlled experiments, biographical interviews, and supplementing surveys with secondary research	Baumeister (1991); Vaillant (2002); Gough and McGregor (2007); Mischel (2014); Estes and Sirgy (2017).
Scholarly or journalistic accounts based mainly on personal interviews and/or primary ethnographic research in naturalistic settings.	Csikszentmihalyi (1992\2002); Mathews (1996); Sternberg (1999); Adelson (2000); Overing and Passes (2001); Low (2004); Baylis (2006); Weiner (2008); Calestani (2013); Fischer (2014); Snell-Rood (2015); Sundararajan (2015); Cieslik (2016)

There are innumerable ways of doing qualitative research. Methods are not only extremely diverse, but are also typically inexplicit. Qualitative research texts commonly have little or nothing to say about the methods used (Goertz & Mahoney, 2012; p. 7). Rather than aligning to particular techniques, qualitative researchers tend to follow general approaches or 'traditions'. Five traditions are commonly distinguished (Creswell, 1998, 2017):

- *narrative research* (listening to and co-constructing stories - popular now in all social sciences other than economics);
- (an unnecessarily cumbersome term for mainly obscure, pretentious, and jargon-prone writing on how experience happens - how it becomes meaningful through mental and bodily interactions with particular kinds of sociocultural and physical context);
- *grounded theory* (building theoretical understanding gradually through empirical exploration - an approach common to many qualitative researchers although the term 'grounded theory' has rarely been used outside of sociology and nursing research);
- (embedded observation of social and cultural processes - a term originating in anthropology that has recently become popular in many academic disciplines and non-academic corporate learning strategies); and
- *case studies* (getting into rich details of bounded examples of individuals, events, institutions, etc.).

Since these traditions overlap and many scholars draw on several of them, it is probably more useful to consider broad-brushed differences between the cultural traditions of quantitative/positivistic and qualitative/interpretive scholarship, as indicated in Table 2.

Table 2: quantitative versus qualitative approaches and methods

Quantitative/positivistic	**Qualitative/interpretive**
Rooted in Enlightenment faith in rational discovery of facts and explanations in a largely determinate world	Rooted in counter-Enlightenment or postmodern interest in the radical indeterminacy and uncertainty of many important aspects of life
Deductive approach: hypothesis specified based on theorising in advance of data gathering	Inductive approach: hypothesis implicit, or no hypothesis, but theories developed through engagement with data

'Realism,' emphasising facts and on the reliability and replicability of research; fear of researchers' 'bias'	'Interpretivist' or 'hermeneutic' approaches, emphasising meanings, feelings, experience, and on the relevance and validity of research; welcoming researchers' moral engagement and 'reflexive self-awareness'
Reductionist approach, studying specific isolated variables	Holistic and/or narrative approach, studying individuals, institutions, communities, event narratives, life stories, etc. as 'wholes'
Small number of tightly specified research questions, strict interview protocol, restriction of responses e.g. to 'forced choice'	Larger number of vaguer and open-ended questions, flexible interviewing, scope for creative, elaborate, and surprising responses
'Blueprint' research design, strictly adhered to	Flexible research design responsive to surprises and changing circumstances
Laboratory or clipboard encounters	'naturalistic' settings and semi-natural encounters in everyday life
Larger samples and aggregate generalisation	smaller samples, and/or detailed attention to individual case studies, objects, places, or activities
Methods explicit and specific	Methods implicit and typically diverse or nonspecific
Explicit and strict rules on selection and presentation of evidence	Implicit, informal, optional, and typically nontransparent
Extractive and disengaged: Researcher as detached and impartial expert; informants as instruments who may be kept ignorant of research purposes; scientific research strongly distinguished from nonacademic and everyday 'commonsense' learning	Engaged and participatory: researcher embedded and emotionally involved, often explicitly committed to moral positions or partisan politics; informants as research partners who understand and appreciate research purposes; research only weakly distinguished from normal learning
Standard research reporting structure, basic functional writing style	Idiosyncratic research reporting, sometimes with experimental 'poetic' writing style

Cultural Construction of Wellbeing: Concepts and Values

The most common and persuasive justification for qualitative wellbeing research is that it helps us recognize the many ways in which wellbeing concepts, experiences, and expressions are 'culturally constructed'. Since we are all products of multiple cultural and social interactions, our sense of wellbeing must be understood not as a definable thing but as a complex web of negotiated and provisional meanings and values. No doubt most researchers working in 'positivist' and 'quantitative' traditions do recognize this, yet in practice their scientific discipline require a degree of control and reductionism that steers people towards 'essentialism' - imagining elusive entities such as happiness and cultural traits as if they were fixed things. Scientific aspirations can also steer people towards 'universalism' - imagining human psychology to be more unified than is actually the case.

A 'constructivist' approach to culture and wellbeing (or what might also be called an 'ecological' approach) leads to highlighting the following characteristics of wellbeing:

- being culturally constructed rather than the result of a universal natural process, wellbeing concepts, valuations, experiences, and expressions are extremely varied worldwide, and between different institutions and situations within countries.
- every aspect of wellbeing is dynamic, changing according to different cultural situations and interactions.
- given the diversity and fluidity of ways in which people think and talk about wellbeing, no-one can have a totally secure sense of what wellbeing means to them or how happy they are.

- being products of specific cultural contexts and situations, wellbeing meanings and experiences are best appreciated in situ and are ultimately untranslatable.
- Since experiences are produced through interactions and narrations which usually involve other people and which built on cultural scripts, wellbeing is best understood as co-constructed and public, rather than pre-reflective and private. Thus, for example, if you ask someone about their happiness, the self-report isn't just an expression of a pre-existing self-evaluation, but is in part a product of the question and of the social and physical environment in which it is asked. It is 'elicited' information rather than just a 'given' piece of data.

Of all the personal and social goods that social researchers study, none seems to compare with happiness in terms of its uncontroversially universal value. Not even the most popular of other goods - such as economic growth, education, democracy, freedom, equality, or human rights - is universally valued. While there have been plenty of attempts to denigrate some specific forms or versions of happiness, such as selfish hedonism or idle contentment, it is hard to imagine a plausible sustained argument against the valuation of happiness in general. It is therefore common for popular texts on wellbeing to assert that everyone in the world wants to be happy and that all cultures value happiness.

Both of these claims are true in a rather circular and therefore vacuous sense: insofar as 'happiness' means pursuing, getting, and enjoying whatever it is you want, then by definition happiness is wanted and valued. But the claims are also untrue in an important sense: since most people in the world don't have English as their first language, it isn't 'happiness' that they want and value, it's bound to be a slightly different concept that they have their own labels for. And even in English, concepts and terms associated with 'happiness' are extremely diverse: fine, fun, flourishing, flow, fulfilment, etc., and that's just the terms beginning with F. To assert that happiness is a cultural value really tells us little more than that value is valuable and that people prefer to live well. It doesn't tell us whether people think of happiness as a personal or a collective thing; whether their concept includes afterlife bliss; whether it's mainly about pursuits or achievements; whether people believe they have a soul whose happiness matters; whether they prefer excitement or quiet contentment; or whether progressive achievements are part of their idea of living well.

It is hard to imagine a population lacking terminology for discussion wellbeing, but the ways people conduct such conversations may be instructive, For example, in Bolivia 'there is no local term in Aymara for happiness' but the goodness of life is discussed mainly in terms of either 'Suma Jakaña' (household wellbeing) or 'Suma Qamaña' (communal or national wellbeing) (Calestani, 2013). The terminology of wellbeing domains, too, varies widely by language and situation. What does 'work' mean, for example, for people who aren't employed with regular hours at a separate workplace? What does 'spirituality' mean to an atheist? The language of comparison, too, is nuanced. For example the phrase 'not too happy' (commonly used in happiness surveys), depending on situations and cultural settings, may be taken literally or may be a form of ironic understatement meaning 'slightly or very unhappy'. And 'very happy' may seem dignified and desirable to some, and undignified to others.

So one of the key challenges for qualitative wellbeing research is to reveal and make sense of cultural diversities in the meanings, valuation, and practical implications of different terms and concepts relevant to the pursuit of happiness. Table 3 gives a structured overview of some of the key literature on these various aspects of the cultural inflection of wellbeing.

Table 3: what aspects of wellbeing are culturally variable?

Aspect	**Elaboration**	**Examples of qualitative literature**
Concepts, terms and metaphors	Diversity, overt meanings, and nuances of the terminology used in talking and thinking about wellbeing.	Kovecses (2000); Altarriba, Basnight, and Canary (2003); Wierzbicka (2004); Pflug (2009); Cheng et al. (2011); Goddard and Wierzbicka (2013); Ogarkova (2016); Boster (2017)

Valuations and motivations	Salience of wellbeing in public and private discourse; ideal affect and emotion norms in general and in specific settings and relationships; individualism versus collectivism	Stearns and Stearns (1988); Paul (1990); Grima (1992) Lu, Gilmour, and Kao (2001); Reddy (2001); Lu and Gilmour (2004); Uchida, Norasakkunkit and Kitayama (2004); Tsai (2008); Tsai, Knutson, and Fung (2006); Ehrenreich (2009); Joshanloo (2014); Fischer (2014)
Facilitation or inhibition of the experience of wellbeing	Cultural variety in the degree to which basic requirements for pursuit of wellbeing are supported or restricted (material needs, security, autonomy, opportunities, information)	Edgerton (1992); Hollan and Wellenkamp (1994); Duncan and Grazzani-Gavazzi (2004); Mathews and Izquierdo (2008b); Johnson (2013)
Expression/ narration	Encouragement to express, narrate, mask or self-regulate emotions or self-evaluations in diverse contexts	Wikan (1990); Hollan (1992); Ochs and Capps (1996); Butler, Lee, and Gross (2007); Yang (2013)
Cultural consonance/ mismatch	Variety in the degree to which cultural settings achieve optimal balance between clarity and flexibility, allowing people a sense that they 'fit' with their culture	Lu (2006); Oyserman, Sorensen, Reber, and Chen (2009)

Wellbeing research is largely about *evaluation* - of selves, lives, situations, and cultural practices. For all humans, evaluative dispositions are developed through personal and situational perspectives, and through a variety of cultural values that are patterned by regional populations, social networks, religions, organizations, classes, age cohorts, and so on. Most research that is explicitly about 'culture' tends to reduce this versatile concept to broad-brushed generalisations about regional or national population. Much of the quantitative research on cultural values has focused on contrasts between regional values, particularly between 'East' and 'West', and/or between 'communal' and 'individualistic' cultures.

But rather than being bound to nations or regions, most cultural phenomena are actually associated with other kinds of entity such as professions, activities, tools, built environments, corporations, schools, religions, age cohorts, social media, and social networks. Insofar as wellbeing is 'cultural', it is influenced through these cultural forces, not just through national traditions. Every human is therefore 'multicultural', and qualitative research is needed to reveal the rich variety of ways in which values and preferences are learned, chosen, experienced, and expressed through cultural media (Mathews, 2012; Knoop & Delle Fave, 2013; p. 1). Local ethnographic research helpfully explores these micro-level and situation-specific cultural influences with which every human being interacts.

Culture influences every aspect of the pursuit of wellbeing, including: how wellbeing is conceived and discussed; norms and expectations concerning the experience and expression of wellbeing; perceived options for pathways to wellbeing; and the extent to which personal or collective wellbeing is emphasised, and the extent to which individuals are seen as responsible for their own wellbeing.

Compositional Wellbeing:

Balance, Harmony, and Biographical Holism

Quantitative research both feeds off and promotes thinking about happiness and other phenomena in hydraulic and altitudinal metaphors ('how much'? or 'how full?' or 'how high'?). These metaphors apply not just to emotions and moods, but to 'life satisfaction' surveys which invite people to give a single rating to their 'life as a whole'. Qualitative researchers are less interested in the quantity or altitude of happiness than in its splendid variety, messiness, elusiveness, and ultimate ineffability. Hence, they want to understand better the contexts in which people talk and think about happiness - how it is dynamically composed, displayed and recognized in everyday life. They ask 'how', 'why', 'where', 'when' and 'with whom' questions. And when they ask about lives as wholes, they are looking for holistic insights into how people integrate various domains and life phases, and how they balance self-orientation with self-transcendent concerns.

It is important to appreciate not just how happy people are, but how wellbeing is composed. Just as we talk about the 'compositional qualities' of a picture or a piece of music, so too we can elucidate pursuits of happiness by discussing the compositional qualities of good lives. Commonly, people talk about these qualities, about the integration of various life domains, using metaphors of 'balance' or 'harmony' (Berzin, 1998; Bacon, 2009; Chen, 2009; Delle Fave, Massimini, & Bassi, 2011; p. 13; Ip, 2014; Kavedžija, 2015; Sundararajan, 2015).

The expectation that good things such as positive emotions must be balanced by bad things, and that we should accept such contradictions, has been described as a 'dialectical' theme that is prominent in Chinese folk wisdom (Pen & Nisbett, 1999). But balance metaphors are probably a human cultural universal, reflecting their basis in the bodily experiences of the ongoing challenge of postural correction in response to challenges (Johnson, 1987; Kovecses, 2000). Biographical research on happiness in both USA (McAdams, 2005) and UK (Cieslik, 2015, 2016) shows that most people make ample reference to personal sacrifices and adversities when constructing narratives of the good life: what brings value and dignity is not the avoidance or denial of unhappiness, but coping well with troubles, sharing them through story-telling, and making sense of them.

In some cultural traditions, most notably in parts of Asia influenced by Taoism and Confucianism, it has also been argued that people may value a sense of appropriate balance and moderation between pleasures and pains, rather than valuing or expecting a life of maximum pleasure or happiness (Tsai & Park, 2014). Consequently, people from cultures which value balance are likely to use 'cultural scripts' to 'dampen' their own experiences of positive emotion, as an emotion regulation strategy, in contrast to the 'savoring' of positive emotions commonly promoted in Western culture (Miyamoto & Ma, 2011). A more stark East-West contrast has also been observed in responses to negative emotion, with Asians much less likely to try to respond to adversity by deliberate positivity or denial (Miyamoto, Ma, & Petermann, 2014). Evidently, such contrasting beliefs are very likely to influence the scores people award themselves in self-reports on happiness or life satisfaction scales.

The related but more complex metaphor of 'harmony' refers to interactions between components, rather than just to the proportionality. In a 'harmonious' life, or a 'harmonious' relationship or a 'harmonious' society, the different components complement each other in a pleasing or constructive way, as in the 'harmony' of a piece of music or a picture. Liang and Luo's research in China revealed a discourse of 'harmonious aging', connected with the Yin-Yang philosophy, which contrasts with the western concept of 'successful aging'. Often associated with ageism and with a quantitative evaluation of levels of activity, this western ideal can usefully be contrasted with the Chinese recognition of late-life wellbeing as a complex negotiation of changing motives and experiences as the body ages and as some social connections fall apart. A related metaphor of 'conviviality' emphasizes the cultural salience of harmony as a desirable social quality which may be deliberately cultivated, for example, by ritualised laughter as has been commonly observed for example in Amazonian and other Latin American populations (Overing & Passes, 2000; Calestani, 2013).

Qualitative research has shown how balance and harmony metaphors act as important correctives against the implicit 'more-is-better' assumptions of quantitative evaluation, reminding of the possibly toxic outcomes of overzealously pursuing any one activity or good. In many cultures worldwide, harmony and balance metaphors also commonly allude to negotiations between care of the self and care of the community, and between personal and relational wellbeing (Mccubbin et al., 2013; Delle Fave et al., 2016; Arthur & Mair, 2017).

Ultimately the purpose of most wellbeing research is to evaluate people's whole lives. Conceptually, a 'life' may seem to be a natural phenomenon, but both lives and selves are in fact a cultural and negotiable phenomena, constantly being constructed and reconstructed through interactive story-telling. This universal practice provides us with crucial qualitative data that beg to be analysed. Biographies are not only stories about wellbeing (or illbeing), they also constitute wellbeing.

One of the foremost qualitative psychology researchers is Jerome Bruner, who has made unique contributions to appreciation of the narrative construction and performance of personal identities (e.g., Bruner, 1984, 2003, 2008). Central to his work has been the idea that wellbeing is built up by culturally scripted forms of 'intersubjectivity' - that is, people enjoy their lives if they succeed in everyday life in telling one another stories that give them a comfortable sense of mutual appreciation - 'being able to "know" and share each other's mental lives', but also developing stories to enhance toleration of 'deviations from shared ordinariness' (Bruner, 2008; p. 35). The narrative dimension of social lives, therefore, involves an ongoing dynamic process balancing comfortable convention with individual creativity.

Bruner's work built on the inspiration of Gordon Allport, a leader of the 'humanistic psychology' movement and an important forerunner of positive psychology. In an influential early text on the use of

personal documents in qualitative psychology, Allport (1942) gave a persuasive account of the many ways in which third-person accounts (such as medical records, case studies, and psychological novels or historical accounts) as well as autobiographical materials (such as confessions, diaries, dream accounts, and letters) could provide new empathic insights into subjective experiences, self-evaluations, and motivations. Just as importantly, Allport addressed head-on the many warnings against allowing such documents to support biased or deceptive conclusions, offering a full consideration of evaluative criteria by which we might distinguish plausible from implausible use of personal documents: representativeness; adequacy for a particular scholarly purpose; reliability crosschecked with independent sources; and validity of the interpretations drawn. Although not much of his text is specifically about the study of wellbeing, he did make the important observation that life writing may tendentiously steer our attention towards trouble and suffering: 'As a rule autobiographical writing seems to be preoccupied with conflict, with…the "personality-making" situations of life. Happy, peaceful periods of time are usually passed over in silence.'

In recent years, the leading exponent and promoter of biographical research on happiness has undoubtedly been Dan McAdams, whose work has largely been about the narrative development of personal identities and sense of self-worth in the USA. More clearly than anyone else, McAdams (2005) has demonstrated the intertwining of subjective wellbeing with cultural scripts that are interactively performed by telling stories that enable people to build up a sense of who they are that is publicly affirmed by listeners. Happiness, that is to say, is socially and culturally constructed through interactive self narratives. Adults who are exceptionally 'generative' in midlife use biographical stories not just to record their lives but to structure their lives and strengthen their motivation and sense of meaning. Such narratives have distinct culturally variable flavours: in the USA, a dominant theme is 'redemption' - triumphantly recovering from suffering and/or adversity to achieve a renewed and stronger self. This is important because it shows how even in one of the most 'positive', pro-happiness cultures in the world, substantial attention is paid to the critical roles of suffering and adversity in the good life. Also noteworthy is the substantial use that McAdams makes of secondary cultural and historical research in linking present-day self-narratives with historical figures, religious doctrine, and popular literature such as self-help texts.

A similarly rich synthesis of autobiographical accounts and cultural history is provided by Gordon Mathews' book *What Makes Life Worth Living* (1996), which was the first book-length ethnographic account of happiness. Mathews organized his innovative work around paired mini-biographies of USA and Japanese interviewees, and linked his interpretation of these with a full analysis of recent cultural and socio-economic trends in both countries. In contrast to many of the quantitative East-West psychological comparisons, Mathews offers a more subtle portrayal of cultural values which shows how there is plenty of evidence for both 'individualism' and 'collectivism' in both countries, with individuals working out their own unique ways of interacting with chosen cultural themes and values.

An intriguing portrayal of narrative identity is presented in the folklorist-ethnographer Bénédicte Grima's (1992) account of Paxtun women in Pakistan, who met regularly to compete with one another in miserabilist self-narratives. The ethic is the exact opposite of the north American ethic of compulsory positivity lambasted in Ehrenreich's book *Smile or Die [Bright-Sided]*. For Paxtun women, dignity and respect come from turning events of extreme suffering into a story shared with other women.

Appreciative Inquiry, Participatory Research, and Action Learning: The Intrinsic Value of Wellbeing Enquiries

Like many activities, research can have both *instrumental* value and *intrinsic* value. Typically, scientific research is seen as a means to an end - producing new information in order to take better decisions. The emphasis is on the robustness of the findings rather than on the direct value of the research process itself. Qualitative research that is less detached, more participatory, and more blended with everyday public curiosities and conversations, is more likely to be recognized as having intrinsic or processual value. It can and arguably should make more *direct* contributions through the more immediate life enhancement that participation in research can provide.

This is particularly true of qualitative enquiries on wellbeing, including one-to-one applied work such as life story elicitation and talk therapies, as well as focus group and organizational work that goes under the general label 'appreciative enquiry' (Prilleltensky & Prilleltensky, 2006.) Lewis outlines a set of principles of appreciative inquiry, which include promotion of a 'constructionist' recognition that we all create one another's realities, and 'positive', 'anticipatory' and 'narrative' approaches that build and stories based on successes and enjoyments to foster constructive hope and motivation (2016; p. 126-7). The prospect of participatory research being directly beneficial is also particularly strong when working with categories of people who otherwise lack opportunities for reflection and public self-expression, such as children (e.g., Theron, Liebenberg, & Ungar, 2015; Nastasi & Borja, 2016; Fattore, Mason, & Watson, 2017), older people (Hoban, James, Pattrick, Beresford, & Fleming, 2011), and disadvantaged ethnic

minorities (White & Jha, 2014).

Provision of evidence about the benefits of appreciative enquiry tends to be impressionistic, anecdotal, and far from impartial. Both researchers and participants have a vested interest in demonstrating that they have been a force for good, and the research ethos of positivity points them in this direction (Bushe, 2007). One fairly typical example is Wendy Penney's work in three residential care facilities in rural Victoria, Australia, which invited care staff to describe what they did well to improve residents' lives. This is what is called the 'unconditional positive question' (Ludema, Cooperrider & Barrett, 2008). Researchers found that the process was enjoyable and energising for staff, that it resulted in more positive communication and sense of pride in work, and in potentially beneficial changes to everyday practices. A more sophisticated example is a comprehensive wellbeing enquiry and promotion programme in a USA school, involving a psychology interest group; parent training courses on wellbeing; a formal wellbeing curriculum; a wellbeing club including yoga, mindfulness and Tai Chi activities; and wellbeing courses. Researchers noted the enthusiastic adoption of these activities and were optimistic about benign impacts but were not able to offer evidence actual effects on objective or subjective wellbeing (Waters & White, 2015).

There clearly is potential for qualitative researchers to improve the plausibility of their arguments by providing stronger and more impartial evaluative evidence of real-world changes brought about by participatory research. But we need to be realistic about the inevitable limitations of participatory research in this regard. And we mustn't lose sight of the very plausible arguments about the direct benefits of fostering positive discussion of strengths and enjoyments in diverse social contexts. Bearing this in mind it can be argued, for example, that governments, corporations and civic organizations should support participatory wellbeing research even if there is great uncertainty about the validity and usefulness of its ultimate findings.

A good society, and a good organization, is one which takes the wellbeing of its stakeholders seriously and encourages and enables them to voice their views on the matter. Of course, responsible researchers should make sincere efforts to produce valid and useful findings, but they should also cherish and enhance the values of the research process. Qualitative research approaches have much better potential in this regard. They can encourage active citizen participation in all aspects of the research process, whereas experimental and qualitative research tend to require alienating forms of expert control - even to the extent of hiding the true nature of enquiries.

Toxic Culture, 'Critical' Perspectives, and Pathological Detours

Since wellbeing themes are unavoidably evaluative, wellbeing researchers cannot escape the responsibility to move beyond moral relativism and try to help people make sense of evidence that reveals some cultural contexts and societies to perform much less well at facilitating wellbeing than others do (Thin, 2005; Mathews & Izquierdo, 2008b). Quantitative survey research has revealed very strong geographic patterns of self-reported happiness worldwide, unsurprisingly confirming that most people don't seem very happy in those countries that inhibit freedom or that fail to meet basic needs for food, shelter, and physical security (Helliwell, Layard, & Sachs, 2017; Veenhoven, 2017). It has performed less well at exploring in detail the many forms of cultural toxicity that severely curtails people's ability to live well in many parts of the world.

Sociocultural anthropology, the archetypal qualitative research discipline, has a weak record in fostering explicitly evaluative cultural analysis. Like sociology, the discipline grew out of largely critical approaches to western modernity. Unlike sociology it focused on nonwestern cultures, and until the late 20th century it tended to foster two main principles: 'relativism' (insisting that cultures should be evaluated, if at all, only by their own criteria) and 'adaptivism' (assuming that cultural practices don't survive if they are maladaptive, i.e. bad for survival). As an antidote to colonial triumphalism, many anthropologists have seen it as their moral duty to reveal the beauties and values of nonwestern culture and to avoid 'ethnocentric' use of alien values to criticise aspects of culture. And the 'adaptivist' principle is nonevaluative too, insofar as it is about mere survival, not about wellbeing. Hence the discipline has failed to develop either theories of human flourishing or any sustained analysis or critiques of cultural harms.

The psychological anthropologist Robert Edgerton did produce an impressive collection of crosscultural evidence of cultural harms around the world. In his book *Sick Societies* (1992) presents a catalogue of social ills. He notes that most human cultures have allowed practices to persist which promote physical and mental illness, poverty, unfair inequalities, avoidable suffering, and premature death. The forms of toxic culture which anthropologists have habitually failed to criticise include: warfare; witchcraft; 'honour' killings; torture and severe corporal punishments and humiliations; dowry harassment; human sacrifice; ritualised and sanctified sexual abuse of children; genital mutilation of children and other

harmful bodily mutilations; male dominance; dangerous health practices; poor nutrition; widow-burning; and blood feuds.

Although Edgerton's moral call to arms failed to ignite a new evaluative tradition in anthropology, since the 1970s anthropologists have in general shifted their interests towards researching mainly pathologies much as sociologists have always done. Sociologists, unlike anthropologists, were throughout the 20th century mainly interested in social harms but in a highly restrictive way: for the most part, their critical attention was directed towards western modernity, and by extension towards the metropolitan urban cultures of poorer countries. This kind of bias is flagrant, for example, in a recent sociological text entitled *Social Harm* (Pemberton, 2015), which directs its critical gaze only at those harms that the author believes can be attributed to 'neoliberal' modernity.

A different but analogous kind of bias is evident in a feminist collection on *Harmful Cultural Practices* around the world (Longman & Bradley, 2016), which similarly sounds global in scope but is actually a collection of essays by women scholars who define 'cultural harm' solely in terms of the harms done to female victims. From both an evaluative and a policy perspective, qualitative scholarship on cultural harms would be greatly enhanced if scholars took seriously their responsibility to consider the wellbeing of humanity in general in less partisan ways. In contrast to wellbeing scholars, who are quite happy to generalise, it seems that scholars specialising in the study of harm feel a need to indulge in dichotomous portrayals of victims and perpetrators.

Apart from the problem of selective bias in criticism of cultural and social harms, qualitative research disciplines have also in general reduced their descriptive validity, their moral plausibility, and their ability to achieve benign influence on the world, by failing to theorise or define the opposite of harms and harmfulness, i.e. wellbeing and beneficence. There are innumerable ethnographic monographs on various forms of suffering and injustice, but even apparently neutral or balanced texts such as *Subjectivity: Ethnographic Investigations* (Biehl, Good, & Kleinman, 2007) or *Contentment and Suffering* (Hollan & Wellenkamp, 1994) or *Wellbeing in the Time of AIDS* (Wallman, 1996) or *World Mental Health* (Desjarlais Eisenberg, Good, & Kleinman, 1995) have shown relentless interest in adversities without any complementary ethnography or theorising of wellbeing.

Methodological Pluralism, Mixed Methods, and Research Synthesis

With the rapid proliferation of all kinds of wellbeing research output from an increasing variety of disciplines and countries, the need for persuasive and reliable synthesis research becomes paramount. This is also important as a way of addressing the collective weakness of much qualitative research that remains a somewhat ad hoc collection of one-off local studies based on small samples and idiosyncratic methods. Good synthesis research is needed to move towards viable generalisations and crosscultural comparisons.

Achieving plausible synthesis of qualitative research requires great ingenuity, flexibility, and patient tolerance. Three main features make it extremely hard for scholars, planners, or interested public to draw generalised conclusions from qualitative research:

- The messiness and flexibility of idiosyncratic approaches makes it hard to discern the validity and quality of specific studies.
- The vagueness and uncertainty of research purposes, questions, and findings, and in some cases even a total lack of 'findings,' means that much qualitative research is at best suggestive rather than conclusive.
- The diversity of methods and writing approaches makes it hard to develop any systems for comparison or synthesis

If 'pluralism' is the key benefit that qualitative approaches add to wellbeing research (Gergen, Josselson, & Freeman, 2015), those who try to help us make sense of this plurality must provide some guidance regarding the comparative values of diverse methods. But whereas with quantitative research there are clear and strict protocols for conducting and presenting 'meta-analysis,' qualitative researchers have yet to come up with clear guidelines for synthesis, and secondary research analysis is in practice mainly conducted without any clear system. Although improvements in transparent reporting of approaches and rationales in qualitative synthesis research are possible and desirable, realistically the process is too unwieldy to expect more than a loose set of explanations and justifications. Tight specification of inclusion and exclusion criteria would result in too much loss of flexibility, steering attention towards a narrow subset of those varieties of qualitative writing most amenable to comparison and synthesis.

'Secondary' research methods means using information that was generated for different purposes - whether for personal or bureaucratic record, or for other research purposes. When numerous quantitative

studies are synthesised, this is called a 'meta-analysis' or 'synthesis'. But such research is dependent on finding several studies that match rigorous inclusion criteria so that they are properly comparable. When qualitative research is synthesised, scientifically valid generalisations aren't possible. But this doesn't prevent the formation of useful insights based on high levels of plausibility as opposed to scientific near-certainty.

Most qualitative synthesis takes the form of relatively ad hoc literature reviews (e.g. in the opening paragraphs of articles or books) or introductions to thematic collections which both synthesis crosscutting themes in the collection and link these with other literature. As published information proliferates, and as the boundary between one-off scholarly research and ongoing public learning becomes blurred, future qualitative research scholars can greatly add to the value of qualitative research by coming up with approaches to research synthesis that are reasonably systematic and transparent, but without resorting to the excessively restrictive and exclusionary approaches that dominate 'meta-analysis' in quantitative science.

Conclusions

We have reviewed here a small fraction of the increasingly copious qualitative research output on wellbeing from anthropology, sociology, psychology, linguistics, history, development studies, literary studies, human geography, political science, cultural studies, and philosophy. Most of these disciplines have not made wellbeing as central or as explicit in their research agendas as they should have done, and many have been either ethnocentric or somewhat culture-blind in their approaches. Though there encouraging signs of rapidly increasing quantity and diversity of crosscultural wellbeing research but there is a long way to go in terms of clarifying methods for conducting, synergising and synthesising this research (Tonon, 2015; Bruni & Porta, 2016).

All researchers need to take culture seriously as the environment in which wellbeing develops. To do this, we must pay systematic attention to language, learning, scripting, sharing and interactive display and discussion of wellbeing. For 'subjective' wellbeing, i.e. happiness, this means exploring subjective experience in its full complexity, looking well beyond not only the individual's self-reports or laboratory behaviors to examining the dialectic interactions of everyday life.

But addressing these important complexities in the qualitative dimensions of wellbeing research comes at a high price. Qualitative research is in general slow, scrappy, extremely diverse in its disciplines and methods. Its outputs come nowhere near the clarity and confidence that we see in the outputs from the tactically reductionist research of experimental science and survey-based quantification. Collectively, the persuasions and influences of qualitative research are achieved - if at all - indirectly rather than through provision of clear conclusions from specific studies or research syntheses.

For funders and users of research on wellbeing, or for researchers trying to striking an optimal balance between qualitative and quantitative aspects of their work, this creates difficult strategic decisions. Some themes and questions - generally specific ones about particular kinds of behavior or correlation - can be effectively answered by experimental or quantitative research. All of the most important questions, however, require input from qualitative approaches. Decisions about research methods take place at multiple levels, from the pico-level of specific topics and activities, through the micro-level of individual researchers and projects, the meso-levels of programmes, institutions, and research areas, to the macro-levels of whole academic disciplines and national or corporate research strategies. All we can ask is that all researchers give respectful and intelligent consideration to judicious mixing of methods and approaches.

THEORIES OF SUBJECTIVE WELL-BEING

Cognitive Outlooks and Well-Being

By Seth Margolis & Sonja Lyubomirsky, University of California, Riverside

Citation
Margolis, S., & Lyubomirsky, S. (2018). Cognitive outlooks and well-being. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

The top-down approach to well-being focuses on how people attend to and construe information in their lives and how these processes affect their well-being. In this chapter, we review evidence that attention and construal, broadly conceived, influence well-being. We then discuss specific types of attention and construal (i.e., cognitive outlooks) that affect well-being. Such cognitive outlooks include gratitude, self-esteem, optimism, locus of control/autonomy, competence, connectedness, attributional style, and ruminative style. For each cognitive outlook, we review research that demonstrates an association between the cognitive outlook and well-being. We then discuss evidence for causal effects and theoretical accounts of these effects. We conclude with a brief discussion of questions that future research can explore.

Keywords: Cognitive outlooks, Well-being, Attention, Construal, Top-down approach

Research on the correlates and causes of well-being has yielded two approaches (Diener, 1984). The bottom-up approach emphasizes the role of the objective environment on well-being. Specifically, the bottom-up approach seeks to explain variance in well-being levels by examining the moment-by-moment situations people face. For example, exploring the impact of daily hassles and uplifts on life satisfaction (Lavee & Ben-Ari, 2008) fits squarely under the umbrella of the bottom-up approach to well-being.

In contrast to the bottom-up approach, a top-down approach focuses on subjective processing of the environment to explain variation in well-being. From a top-down perspective, the effect of the environment on well-being is heavily mediated by subjective construal. For example, research taking a top-down approach to explore the effect of divorce on well-being might consider whether a partner views the divorce as freedom from an unhealthy relationship or as the loss of a supposedly lifelong partner. Conversely, a researcher who views well-being with a bottom-up approach may focus on certain features of the divorce, such as its effects on one's living situation and access to immediate family members.

As the science of well-being has grown and matured over the last several decades, most well-being researchers have gravitated toward the top-down approach. This trend is likely the result of robust findings indicating that life circumstances, which are emphasized in a bottom-up approach, explain a surprisingly small amount of the variance in well-being, whereas personality, emphasized in a top-down approach, explains a relatively large proportion of the variance in well-being. Although some researchers initially believed life circumstances would have large impacts on well-being, reviews revealed that they account for only about 10-15% of the variance in well-being (Andrews & Withey, 1976; Argyle, 1999; Campbell, Converse, & Rogers, 1976). By contrast, a meta-analysis found that Big Five traits account for up to 63% of the variance in well-being (Steel, Schmidt, & Shultz, 2008).

Further support for the top-down approach comes from research on general positivity, which has primarily been measured in two ways. One method assesses the degree to which general satisfaction ratings are more positive than the aggregate of specific satisfaction ratings. For example, an individual high in general positivity would score higher on a measure of life satisfaction than measures of work and family satisfaction. Other researchers have used a positivity scale, which contains items regarding optimism, life satisfaction, and self-esteem (Caprara et al., 2012). With both approaches, general positivity is strongly associated with well-being (Caprara, Eisenberg, & Alessandri, 2016; Diener, Scollon, Oishi, Dzokoto, & Suh, 2000; Lauriola & Iani, 2015; Oishi & Diener, 2001).

In this chapter, we review specific cognitive outlooks that show how positive cognitions affect well-being, which fits squarely within the top-down approach. We define a cognitive outlook as a pattern of thinking that comprises one's evaluation of the self and events in the world. Thus, cognitive outlooks are a component of personality and are likely a major reason why personality accounts for a large proportion of the variance in well-being. Consistent with the overwhelming support for the top-down approach, many cognitive outlooks impact well-being.

Construal

Why do life circumstances account for a relatively small proportion of the variance in well-being? Many researchers point to the role played by construal, or one's subjective perception and evaluation of a

situation. Construal research can be traced back to Henry Murray's (1938) distinction between alpha press and beta press. A "press" is an environmental influence on an individual. Alpha press is the objective environmental influence, and beta press is the subjective or perceived environmental influence. For example, Javier may repeatedly glance at Mary during their psychology class. This is the alpha press, as it describes objectively the situation or event that is occurring. The beta press would represent Mary's thinking about why Javier keeps looking at her. Mary might believe that Javier is looking at her because she looks weird today. Alternatively, she might guess that Javier is attracted to her.

As illustrated in this example, the beta press (i.e., construal) can vary widely. Many well-being researchers point to this variability in explaining individual differences in the effects of life events or situations on well-being. For example, Lyubomirsky (2001) argues that the effects of life events on well-being are strongly mediated by cognitive processes. According to Lyubomirsky, situations affect well-being not directly but through cognitive and motivational processes—that is, situations are "processed" (i.e., evaluated, framed, remembered). The modal model of emotion (Gross & Thompson, 2007) offers a very similar explanation. According to this model, situations lead to construals (via attention, as described in the next section), which lead to an emotional response (see Figure 1). This idea can also be stated using Murray's terminology: The alpha press affects well-being via the operation of the beta press. Returning to the example with Javier and Mary: Whether Mary interprets Javier's glances as condemning or flattering will affect how Mary feels.

As people go through their daily lives, they repeatedly form construals, which affect well-being. For this reason, construal style (i.e., one's pattern of construing situations in a particular way) predicts well-being. For example, Lyubomirsky and Tucker (1998) found that happy individuals did not differ from their unhappy peers in the number of stressful and negative life events they reported experiencing, but rather, happier people employed different cognitive strategies than unhappy ones. Happier people rated positive events as making them more happy than did unhappy people, and unhappy people rated negative events as making them more unhappy than did happy people. In addition, when envisioning themselves in hypothetical scenarios, happier people reported more positive evaluations overall—that is, rating the scenarios as being more positive, less negative, bringing them more happiness, and improving their moods.

Although these results are correlational, they form a compelling argument for the effect of construal on well-being. Two experiments tested a causal effect of construal on well-being (Lichter, Haye, & Kammann, 1980). First, a small sample of participants met for eight 2-hour sessions over 4 weeks to discuss a list of irrational/maladaptive thoughts with the aim of combating them (i.e., attempting to shift their evaluations). After this period and at a 6-week follow-up, participants' beliefs were more positive, their affective well-being increased, and their life satisfaction increased more than those of participants in a no-activity control. In a second experiment, participants were randomly assigned to either rehearse positive statements for 2 weeks or to a no-treatment control. Participants who rehearsed positive statements increased in well-being more than control participants. These findings support the above theories, which state that construal causes well-being.

Few studies have focused on general construal and its effect on well-being, although the existing work provides both correlational and causal evidence of this effect. Further evidence of the relatively large effect of construal on well-being resides in research on specific cognitive outlooks. However, these cognitive outlooks are not just characterized by construals, but also have attentional components.

Attention

The modal model of emotion (Gross & Thompson, 2007) indicates that one must direct attention to particular elements of a situation before one construes that situation (see Figure 1). Attention refers to the process by which people select a subset of perceivable information to concentrate on or cognitively process further (i.e., construe). Thus, attention selects the information that is to be construed. This process is necessary because people cannot attend to all the information they perceive. For example, imagine a woman walking into a party with dozens of people and evaluating whether she should stay at the party or leave. The woman cannot possibly attend to all the activity in the party (e.g., she cannot attend to each person's behavior). Instead, she must try to attend to the salient cues in the environment (e.g., the behavior of people she knows, the music, etc.) and make her decision from that information. Although some human universals drive people's attention (e.g., people naturally attend to changes in their visual fields), there are individual differences in what people habitually attend to (Isaacowitz, 2006). Some researchers point to these individual differences to explain the large effect of personality on well-being. Indeed, individual differences in attention are robustly associated with well-being levels. A meta-analysis of 33 studies examined individuals with anxiety and/or depression with eye tracing methods (Armstrong & Olatunji, 2012). Relative to those without anxiety, participants with anxiety displayed increased vigilance for (i.e., attention to) threat during free viewing and visual search tasks, and had difficulty removing their attention

from threat in visual search tasks. Furthermore, relative to those without depression, individuals with depression oriented to positive stimuli less and attended to positive stimuli for shorter times than they attended to negative stimuli.

Figure 1. The modal model of emotion. Adapted from "Emotion regulation: Conceptual foundations," by J.J Gross and R.A. Thompson, 2007. In J. J. Gross (Ed.), Handbook of emotion regulation (pp. 3-24).

Research indicates that the link between well-being and attention is bidirectional: Well-being affects attention and attention affects well-being. The broaden-and-build theory of positive emotions (Fredrickson, 2013) indicates one way in which well-being affects attention. According to this theory, positive emotions serve a functional role in that they broaden awareness, which builds skills and resources. Conversely, negative emotions narrow one's focus. Negative emotions alert individuals that something is not well, and narrowing their attention allows them to search for the problem and focus on solving it. In contrast, positive emotions signal that all is relatively well. In the absence of threats, there is no need to search for and resolve problems; instead, a person with positive emotions has the flexibility to broaden attention. The broaden-and-build theory of positive emotions has held up to empirical testing using experimental methods. For example, one study manipulated positive affect by randomly assigning participants to hear a happy or sad song. Those induced to feel positive (rather than negative) emotions showed increased access to remote semantic associates, as well as increased attention to stimuli outside their immediate focus of attention (i.e., flanking "distractors" in the Eriksen flanker task; Rowe, Hirsh, & Anderson, 2007). In another set of studies, participants randomly assigned to a positive mood induction attended relatively more to reward words during a spatial probe task (Tamir & Robinson, 2007). In sum, a large body of evidence supports the idea that well-being influences attention.

However, the opposite is also true: Attention affects well-being. Several methods of attention modification, including dot-probe training methods, visual search training methods, clinical auditory training tasks, and meditation (primarily mindfulness-based stress reduction), have been used to reorient people to more positive and/or less negative stimuli. These attention-altering tasks appear to have beneficial effects on affective well-being (Wadlinger & Isaacowitz, 2011). More recent research also supports the notion that changes in attention can cause changes in well-being. For example, participants experimentally induced to attend to positive information experienced more positive affect in response to success (Grafton, Ang, & MacLeod, 2012). Furthermore, meditation seems to increase well-being via shifts in attentional processes (Menezes et al., 2013; Pavlov et al., 2015). The well-replicated effect of attention on well-being supports the modal model of emotion, because, according to that model, changes in attention should have downstream effects on emotion and hence well-being.

Before turning to specific types of attention and construal, we would like to note that the effects of attention and construal on well-being are also manifested in another cognitive process—namely, memory. Although evidence that actual recall is affected by well-being is mixed (Lyubomirsky & Tucker, 1998; Seidlitz & Diener, 1993; Seidlitz, Wyer, & Diener, 1997), positive construal of memories has been associated with well-being. In one study, for example, people higher in well-being reflected more positively on their memories than those lower in well-being (Liberman, Boehm, Lyubomirsky, & Ross, 2009). In addition, turning one's attention to positive memories can boost well-being. In one experiment, a small group of participants randomly assigned to reminisce about positive memories increased in well-being, relative to those assigned to simply think about a life event (Bryant, Smart, & King, 2005). Thus, well-being may be associated with memory processes via attention and construal. Although a large literature has examined the relationship between current affective states and memory (Blaney, 1986; Bower, 1981), there is room for much more research on the link between memory processes and more general well-being.

Specific Types of Attention and Construal

As reviewed above, there is a great deal of evidence that attention and construal, broadly conceptualized, impact well-being. However, most research on the links between cognitive outlooks and well-being targets specific cognitive outlooks. These cognitive outlooks are organized in Table 1. With the exception of attributional style, which refers to a specific type of construal, each of these cognitive

outlooks has both attentional and construal components.

Table 1

Cognitive Outlooks Related to Well-Being

Evaluations of the Past and Present	Evaluations of the Self	Evaluations of the Future
Gratitude	Self-Esteem	Optimism
Locus of Control/Autonomy Competence Connectedness		
Attributional Style Ruminative Style		

In this chapter, we review each of these cognitive outlooks. We begin by defining the specific cognitive outlook and then review the research that supports its association with well-being. Next, we examine research that suggests the cognitive outlook has a causal effect on well-being. Lastly, we discuss the leading theories that explain the observed relationships.

Appreciation and Gratitude: Evaluations of the Past and Present

Appreciation and gratitude are closely related conceptually. Generally, appreciation is viewed as a more general form of gratitude. Gratitude has been defined as "the recognition of a positive outcome from an external source, including a felt sense of wonder or thankfulness for benefits received" (Emmons & McCullough, 2003; Nelson & Lyubomirsky, 2016; Roberts, 2004). Gratitude is "a component of appreciation," where appreciation is "acknowledging the value and meaning of something—an event, a person, a behavior, an object—and feeling a positive emotional connection to it" (Adler & Fagley, 2005). Both gratitude and appreciation involve recognizing a positive event. However, gratitude is directed towards a specific source or cause. One may be grateful to one's mother for providing support. Appreciation differs in that it need not be directed towards a source or cause. One may appreciate a beautiful natural scene without attributing the landscape to geological forces or a god. Following these examples, gratitude typically occurs in interpersonal contexts, whereas appreciation can occur in any context with a positive outcome.

Notably, researchers have overwhelmingly focused on investigating gratitude rather than appreciation more generally. However, some factor analytic work suggests that gratitude and appreciation are a singular construct (Wood, Maltby, Stewart, & Joseph, 2008). If this is the case, all conclusions about the association between gratitude and well-being should hold true for appreciation and well-being. Because gratitude is a part of appreciation and most research focuses on gratitude, we discuss the two constructs together.

Unsurprisingly, those with higher levels of gratitude and appreciation tend to have higher levels of well-being (Lambert, Fincham, & Stillman, 2012; Watkins, 2004; Wood, Joseph, & Maltby, 2008, 2009; see Wood, Froh & Geraghty, 2010 for a review). This effect holds across a variety of positive outcomes (e.g., positive emotions) and negative outcomes (e.g., depressive symptoms) in dozens of studies. Evidence supporting a causal effect of gratitude on well-being comes from two longitudinal studies that measured gratitude and well-being at the beginning and end of participants' first semester of college (Wood, Maltby, Gillett, Linley, & Joseph, 2008). Cross-lagged analyses suggested that gratitude leads to well-being and not the other way around.

Experimental studies have provided stronger causal evidence. In these studies, participants typically list things they appreciate or write a gratitude letter to a person towards whom they feel grateful. Those performing one of these appreciation/gratitude activities tend to increase in well-being more than those in a control condition, demonstrating that gratitude causes shifts in well-being (e.g., Boehm, Lyubomirsky, & Sheldon, 2011; Emmons & McCullough, 2003; Froh, Sefick, Emmons, 2008; Layous, Lee, Choi, & Lyubomirsky, 2013; Lyubomirsky, Dickerhoof, Boehm, Sheldon, 2011; Seligman, Steen, Park, & Peterson, 2005; see Wood et al., 2010, for a review). The effect of appreciation/gratitude activities on well-being tends to be meaningful in size, with Cohen's *d*s typically between $d = .2$ and $d = .6$ (Wood et al., 2010, Table 5).

Why or how do appreciation and gratitude impact well-being? Gratitude may cause one to engage in positive reframing (i.e., focusing attention on the positive aspects of a past events to construe the event in a more favorite light), which, in turn, boosts well-being (Lambert et al., 2012). For example, a student may reflect on a challenging English course and feel grateful towards the professor for substantially improving her writing skills. Gratitude may also boost well-being via improved feelings about relationships, particularly the relationship with the target of gratitude (Lambert & Fincham, 2011). These positive relationship feelings may then boost well-being because feelings of connectedness are important for well-being (Ryan & Deci, 2000). Lastly, gratitude seems to boost prosocial behavior (Bartlett & Desteno, 2006; Tsang, 2006), and prosocial behavior increases well-being (Crocker, Canevello, & Brown, 2017). Because these two mediators (i.e., feelings about relationships and prosocial behavior) are inherently social, they may be specific to gratitude's effect on well-being and hence potentially not mediate the relationship between appreciation and well-being. However, we expect that positive reframing would also mediate the relationship between appreciation and gratitude.

Optimism: Evaluations of the Future

Those with an optimistic disposition expect future events to be positive. For example, an optimist may believe that a trip to the DMV will be quick and easy, whereas a pessimist is more inclined to believe that they will be stuck waiting for hours. Research shows that the former person is more likely to be happy than the latter person.

A recent meta-analysis found that across various measures of well-being, optimism is positively associated with well-being (Alarcon, Bowling, & Khazon, 2013). For example, across 50 studies including 19,831 participants, optimism, as measured by the Life Orientation Test (Scheier & Carver, 1985), was correlated with life satisfaction at an average of $r = .43$. Interestingly, the same meta-analysis found that, across 13,593 participants in 36 studies, optimism was positively associated with general physical health at $r = .28$. Optimism may have such strong correlations with both physical and mental health because it offers both physical and psychological resilience. For example, one study sampled middle-aged men before and after coronary artery bypass surgery. The more optimistic men, compared to less optimistic men, used more effective coping styles, recovered from the surgery faster, and reported a higher quality of life 6 months after the surgery (Scheier et al., 1989).

Despite the plethora of correlational research on optimism and well-being, little direct evidence exists for a causal effect of optimism on well-being. A few relevant experiments have had participants envision their "best possible selves"—an exercise that prompts them to form optimistic thoughts about the future—and found subsequent increases in well-being (Layous, Nelson, & Lyubomirsky, 2013; Lyubomirsky et al., 2011; Peters, Flink, Boersma, & Linton, 2010; Sheldon & Lyubomirsky, 2006).

Longitudinal designs can also provide some evidence of causality. One study found that pessimism predicted increases in depressive symptoms over 3 years (Bromberger & Matthews, 1996). In addition, a few longitudinal studies suggest optimism predicts future well-being following or during a stressful period (see Scheier & Carver, 1992, for a review).

Which theories can explain the beneficial effects of optimism? To our knowledge, no explicit theory of how optimism impacts well-being has been put forward. This may be the case because it is rather intuitive that those who believe more positive events will occur are happier. However, we still believe this lack of theory represents a hole in the literature. Although the relationship between optimism and well-being may seem self-evident, there are many distinct ways in which optimism could impact well-being. For example, optimists may be less concerned than others about stressful future events. Alternatively, optimists may experience anticipatory pleasure when thinking about future events. Or do optimists spend more time thinking about the future, leading them to ruminate less about the past or present? Another possibility is that optimists simply hold more positive construals (or appraisals) in general. Alternatively, perhaps it is not optimists' construals that differ from those of other people but rather their attention; in other words, they attend to more positive information, particularly about the future. Lastly, optimists may be goal-oriented, which is associated with greater goal progress, which leads to greater well-being. One or several of these hypotheses could be true. We encourage researchers to identify mediators between optimism and well-being, and more broadly, develop theories that explain why optimism seems to have a causal impact on well-being.

Self-Esteem: Evaluations of the Self

Self-esteem is typically conceptualized as an overall evaluation of one's worth. Individuals with high self-esteem are likely to believe that they are capable and deserve the positive outcomes they experience. By contrast, those with lower self-esteem may believe they have little power to produce good in the world and feel that praise directed towards themselves is unwarranted.

Multiple studies have found a positive correlation between self-esteem and well-being (Cheng & Furnham, 2003a; Cheng & Furham, 2003b; Emmons & Diener, 1985; Hills & Argyle, 2002; Joshanloo & Afshari, 2011; Lyubomirsky, Tkach, & DiMatteo, 2006; Paradise & Kernis, 2002). This effect seems to be quite robust: One study found a positive correlation between self-esteem and life satisfaction in each of the 31 countries sampled (Diener & Diener, 2009). These correlations were rather strong (average $r = .45$) and depended on a country's individualism: The correlation between self-esteem and life satisfaction was greater in more individualistic countries.

Unfortunately, to our knowledge, no studies have used experimental methods to directly test for a causal effect of self-esteem on long-term well-being. Presumably, researchers have judged self-esteem as a stable construct that is very difficult to manipulate in the long-term. However, researchers have used tasks that temporarily manipulate self-esteem as mood induction techniques. These tasks involve receiving positive or negative feedback on some task (e.g., a social skills task or a game; see Martin, 1990; Westermann, Spies, Stahl, & Hesse, 1996, for reviews). The impact of positive and negative feedback on mood suggests that self-esteem causally impacts the affective component of well-being. However, these studies manipulate self-esteem over short durations and the effects on affect are transient.

Some interventions may be effective at boosting self-esteem in the long-term, albeit indirectly. Self-affirmation interventions target self-integrity, which is the belief that one is a good and moral person (Sherman & Cohen, 2006). Because self-integrity and self-esteem overlap conceptually, self-affirmation interventions might boost self-esteem. In addition, self-affirmation interventions may have recursive effects that last for months or even years (Cohen & Sherman, 2014). Thus, self-affirmation interventions may be one way to boost self-esteem for a long duration and observe downstream effects on well-being. Indeed, two studies found that such interventions did boost well-being (Nelson, Fuller, Choi, & Lyubomirsky, 2014; however, see Revord & Lyubomirsky, 2017 for a nonreplication). One should note that these effects were not robust and were found with small sample sizes.

Self-compassion interventions, which teach people to accept their perceived shortcomings, may also boost self-esteem for a relatively long duration. Like self-integrity, self-compassion is distinct from, yet related to, self-esteem (Neff, 2003, 2011). A few small pilot studies and experiments suggest that self-compassion interventions boost well-being (Gilbert & Procter, 2006; Neff & Germer, 2013; Smeets, Neff, Alberts, & Peters, 2014). Future studies can explore whether self-compassion and self-affirmation interventions impact well-being via changes in self-esteem, which would suggest that self-esteem casually impacts well-being.

The direction of causality between self-esteem and well-being has also been examined with longitudinal designs (Ciarrochi, Heaven, & Davies, 2007; Lucas, Diener, & Suh, 1996; Orth & Robins, 2013). One of the largest studies to investigate this effect longitudinally sampled over 1,824 individuals aged 16 to 97 five times over a 12-year period. Cross-lagged analyses suggested that self-esteem was a cause, and not a consequence, of positive affect, negative affect, and depression (Orth, Robins, & Widaman, 2012). Furthermore, a meta-analysis with 77 studies found that self-esteem predicted decreases in depression ($\beta = -.16$) to a greater extent than depression predicted decreases in self-esteem ($\beta = -.08$, Sowislo & Orth, 2013).

Which mechanisms link self-esteem and well-being? According to Beck's cognitive theory of depression (Beck, 1967), negative views of the self predispose one to experience depression. Although few studies have tested mediators of the effect of self-esteem on well-being, one found rumination as a mediator between self-esteem and depression (Kuster, Orth, & Meier, 2012). Alternatively, people with high self-esteem may simply attend to more positive information about themselves. For example, one study used a Stroop task with rejection (e.g., "neglected") and acceptance (e.g. "included") words and found that participants with low self-esteem experienced more interference for (i.e., attended more to) rejection words than acceptance words (Dandeneau & Baldwin, 2004). No such difference was found for participants with high self-esteem. This attentional mechanism may account for another possibility—namely, that self-esteem may lead an individual to have more positive construals of the self overall, boosting well-being. One study found that participants with high self-esteem construed ambiguous attributes of themselves more positively than did those with low self-esteem (Suls, Lemos, & Stewart, 2002). In addition, other studies have found that those with low self-esteem feel like they do not deserve positive events and, thus, experience less positive affect from them (Wood, Heimpel, Manwell, & Whittington, 2009; Wood, Heimpel, & Michela, 2003). In sum, there are many potential avenues by which self-esteem could impact well-being, and future studies can continue to explore the precise mechanisms by which this occurs.

Evaluations of Autonomy/Locus of Control, Competence, and Connectedness: Evaluations of the Self

Self-determination theory posits three needs that are fundamental for the well-being of an in

individual: connectedness, competence, and autonomy (Ryan & Deci, 2000). Connectedness, also called relatedness, indicates the extent to which people feel they are close to others. Thus, a person high in connectedness believes that he or she has meaningful social relationships. Conceptually, the construct of connectedness requires only a perception of social connectedness and not objective connections, such as number of friends. The construct of competence is similarly subjective. Competence is defined by the degree to which people believe they possess mastery and can bring about desired changes in their lives. People low in feelings of competence may lack confidence when trying to learn a new skill, for example. Competence is certainly related to self-esteem and may be a component of it. Indeed, the State Self-Esteem Scale (Heatherton & Polivy, 1991) has a performance subscale that closely resembles competence. Lastly, autonomy indicates the degree to which people believe their actions are a result of their internal motivations rather than pressure from other individuals. Autonomy is closely related to locus of control, which reflects the degree to which people believe they, rather than external factors, control their life. Locus of control, which is similar to the internal/external dimension of attributional style, also varies from internal (i.e., one has great control over one's life) to external (i.e., one has little control over one's life). Due to the heavy degree of overlap between locus of control and autonomy, we will discuss these two constructs together.

According to self-determination theory, autonomy, competence, and connectedness are all necessary for well-being. Thus, all three needs to be satisfied in order for a person to have high well-being. However, research has simply used bivariate correlations between needs and well-being. Autonomy, competence, and connectedness are each positively correlated with well-being (Deci et al., 2001; Kasser & Ryan, 1999; Milyavskaya & Koestner, 2011). If these constructs are indeed needs, then these correlations should hold across cultures and evidence supports this (Chirkov, Ryan, Kim, & Kaplan, 2003; Diener, Ng, Harter, & Arora, 2010; Tay & Diener, 2011). Furthermore, longitudinal research has found significant correlations among these constructs and well-being both between and within individuals (La Guardia, Ryan, Couchman, & Deci, 2000; Reis, Sheldon, Gable, Roscoe, & Ryan, 2000; Sheldon, Ryan, & Reis; 1996). Lastly, people with an internal locus of control tend to have higher levels of well-being than those with an external locus of control (April, Dharani, & Peters, 2012; Cvetanovski & Jex, 1994; Krause & Stryker, 1984).

Clearly, research supports the idea that the needs posited by self-determination theory correlate with well-being. But perhaps a stronger test of whether autonomy/locus of control, competence, and connectedness increase well-being is to test them as causes of well-being. Unfortunately, experimental research examining the effects of autonomy/locus of control, competence, and connectedness on well-being is very limited. However, one study assigned participants to pursue goals related to connectedness, competence, autonomy, or life circumstances (as a control) and tracked well-being over 6 months (Sheldon et al., 2010). The main effect was not significant: Those who pursued the three goals related to self-determination theory did not improve in well-being significantly more than those in the control condition. However, this effect was present for participants who pursued goals with sustained effort and made progress. This study serves as weak evidence for causal effects of autonomy, competence, and connectedness on well-being. Future research can use experimental methods similar to the above study to test for causal effects.

Attributional Style: Evaluations of the Past, Present, Future, and Self

People naturally ascribe causes to events and these are referred to as attributions. According to attributional models of depression, certain patterns of attribution can create a susceptibility to depression (Abramson, Seligman, & Teasdale, 1978). Early attributional models of depression emphasized the importance of attributions of negative events along three dimensions: internal-external (i.e., personal), stable-unstable (i.e., permanent), and global-specific (i.e., pervasive).

Variation on each of these dimensions can be demonstrated by considering the attributions someone can draw. For example, Susan may have failed a midterm exam during her first semester of college. If Susan believed that she failed because she lacked the intelligence and dedication to do well on the exam, she would be drawing an internal (i.e., personal) attribution. However, Susan might make an external attribution by concluding that she failed because the exam was unusually difficult. Thus, the internal-external dimension indicates the degree to which one attributes an event to oneself rather than external forces. Susan may further infer her failing is a stable characteristic of herself—she will continue to fail in similar situations. Thereby, Susan would be using a stable attribution. Alternatively, Susan may believe this instance of failing is not going to be typical for her, thus drawing an unstable attribution. Unstable attributions indicate that future outcomes may be different, whereas stable attributions specify that a negative outcome shows evidence of what the future holds. Lastly, Susan may view her failure as global by reasoning that failing in this one class indicates that she will fall short in other situations. For example,

Susan could believe that her failing an exam indicates that she will fail as a friend and as a mother. However, Susan could also view the event as specific. Perhaps she believes her failure is limited to exams of a certain format. The permanency of attributions indicates the extent to which one believes a negative outcome in one domain indicates that negative outcomes will occur in other life domains.

One study provides evidence that explanatory style is a relatively stable trait. Burns and Seligman (1989) examined the content of written text (e.g., letters, diaries, essays) of 30 participants. Each participant provided text from early adulthood and late adulthood (the average age difference was 52 years). The authors found that the attributional style used by participants in these texts was consistent over time. However, this only demonstrates weak evidence of stability and the study had a small sample size.

Attributional models of depression posit that individuals who consistently draw internal, global, and stable attributions for adverse events and external, specific, and unstable attributions for positive events are at higher risk for depression. This style of attribution is often referred to as a pessimistic or depressive attributional style. An optimistic attribution is the opposite: Drawing external, specific, and unstable attributions for negative events and internal, global, and stable attributions for positive events.

Does evidence support this attributional model of depression? A meta-analysis of over 100 studies found that internal, global, and stable attributions of negative events were each positively related with depression measures, supporting this attributional model of depression (Sweeney, Anderson, & Bailey, 1986). Furthermore, internal, global, and stable attributions of positive events (i.e., an optimistic attributional style) were each negatively related to depression measures. The same pattern of results has also been found in more recent work (Cheng & Furnham, 2001, 2003a; Winefield, Tiggemann, & Smith, 1987). Furthermore, cross-lagged analyses from longitudinal studies demonstrate that attributional style predicts changes in measures of depression (Firth & Brewin, 1982; Golin, Sweeney, & Schaeffer, 1981; Seligman et al., 1984)

Unfortunately, this area of research suffers from a lack of causal studies. This is understandable, as it seems it would be difficult to experimentally manipulate people's habitual attributions. However, clinical therapy may do just that. Indeed, one longitudinal study randomly assigned employees to a cognitive-behavioral training program or waitlist control and assessed whether changes in attributions mediated between condition and well-being outcomes such as job satisfaction, self-esteem, and psychological distress (Proudfoot, Corr, Guest, & Dunn, 2009). Most mediation analyses did not yield significant results. Although this is evidence that attributional styles do not casually impact well-being, one study cannot rule out a causal path. Thus, researchers should conduct more longitudinal experiments to test whether clinical therapy causes changes in attributional styles, which then cause changes in well-being.

Although this area of research lacks experimental longitudinal studies, longitudinal studies without random assignment have been used to suggest a causal effect of attributional style on well-being. One meta-analysis examined whether attributional style could predict subsequent changes in depression among adolescents (Joiner & Wagner, 1995). Across seven studies, a pessimistic attributional style positively predicted increases in depression.

Longitudinal studies in adults also suggest that attributional style has a casual impact on well-being. One study assessed 143 Japanese undergraduates at three time points across 6 months (Sakamoto & Kambara, 1998). In relatively negative environments, participants with a depressive attributional style tended to be more depressed that those without such an attributional style. Another study that did not consider the state of one's environment found that a depressive explanatory style predicted increases in depressive symptoms (Sanjuán & Magallares, 2009).

Interestingly, Sakamoto and Kambara (1998) found that participants with an internal, global, and stable attributional style decreased in depressive symptoms more than those without that attributional style in positive environments. Similarly, Needles and Abramson (1990) found that individuals with depression experienced increases in well-being when they employed an internal, global, and stable attributional style towards positive events. In sum, evidence suggests attributional models of depression are correct. That is, an internal, global, and stable attributional style decreases well-being in negative contexts but increases well-being in positive contexts.

Why are internal, global, and stable attributions maladaptive in negative contexts but adaptive in positive contexts? Internal, global and stable attributions in negative contexts signal learned helplessness, which is the process by which an organism learns that it is helpless when the environment contains threats (Maier & Seligman, 1976). Internal, global, and stable attributions about negative events indicate that this learned helplessness is a result of personal shortcomings, applies to more than the one context, and will persist. This construal creates a grim outlook of one's past, present, and future experiences, thus lowering well-being. However, internal, global, and stable attributions of positive events signal "learned optimism" such that one believes positive events are the result of one's personal capabilities and indicative of positive

events to come both in the situation in question, as well as other domains (Seligman, 2011). Thus, people with learned optimism are thought to be higher in well-being because they are characterized by stronger self-esteem and higher optimism.

Ruminative Style:
Evaluations of the Past, Present, Future, and Self

Drawing internal, global, and stable responses is not the only maladaptive way to respond to negative events. A large body of research has explored the ruminative response style, which involves a tendency to respond to negative events by repeatedly attending to the symptoms, causes, and consequences of distress rather than focusing on possible solutions (Nolen-Hoeksema, 1991). Ruminative thoughts need not contain negative content—their defining feature is their repetitive yet passive approach to negative moods. Although rumination is highly correlated with worry (Fresco, Frankel, Mennin, Turk & Heimberg, 2002), the two are conceptually distinct in several ways (Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008). Rumination typically involves focus on the past, whereas worry involves focus on the future. In addition, ruminative thoughts tend to contain themes of meaning, loss, and self-worth, whereas worried thoughts regard potential threats. Lastly, ruminative thoughts are characterized by certainty, uncontrollability, and insight-seeking, whereas worried thoughts are characterized by uncertainty, controllability, and threat-preparation.

Ruminative style is associated with other cognitive outlooks we have discussed, including maladaptive attributional styles, pessimism, and low self-esteem (Lam, Smith, Checkley, Rijsdijk, & Sham, 2003; Lyubomirsky & Nolen-Hoeksema, 1995; Lyubomirsky, Tucker, Caldwell, & Berg, 1999; Spasojevic & Alloy, 2001). Importantly, rumination predicts depression even after controlling for these cognitive styles (Flett, Madorsky, Hewitt, & Heisel, 2002; Nolen-Hoeksema, Parker, & Larson, 1994; Spasojević & Alloy, 2001). Furthermore, multiple longitudinal studies demonstrate that the more people ruminate, they more likely they are to develop depression and have longer periods of depression (Just & Alloy, 1997; Kuehner & Weber, 1999; Nolan, Roberts, & Gotlib, 1998; Nolen-Hoeksema, 2000; Nolen-Hoeksema, Larson, & Grayson, 1999; Nolen-Hoeksema, Morrow, & Frederickson, 1993; Nolen-Hoeksema, et al., 1994; Sarin, Abela, & Auerbach, 2005; Segerstrom, Tsao, Alden, & Craske, 2000; Spasojević & Alloy, 2001; Wood, Saltzberg, Neale, Stone, & Rachmiel, 1990).

Researchers have sought to establish a causal effect of rumination on well-being—negative affect, in particular—using a rumination induction task developed by Nolen-Hoeksema and Morrow (1993). In this task, participants are told to focus on the meanings, causes, and consequences of their current feelings for 8 minutes. Several studies have demonstrated that this seemingly benign task boosts negative affect among dysphoric or depressed participants (Donaldson & Lam, 2004; Lavender & Watkins, 2004; Lyubomirsky, Caldwell, & Nolen-Hoeksema, 1998; Lyubomirsky & Nolen-Hoeksema, 1993, 1995; Lyubomirsky et al., 1999; Morrow & Nolen-Hoeksema, 1990; Nolen-Hoeksema & Morrow, 1993; Watkins & Baracaia, 2002; Watkins & Moulds, 2005; Watkins & Teasdale, 2001).

Why does rumination exhibit consistent detrimental effects on well-being? Response styles theory (Nolen-Hoeksema, 1991) argues that rumination can lead to depression through several paths. First, rumination is thought to enhance negative thinking while one is in a negative mood. Indeed, dysphoric participants experimentally prompted to ruminate reported more frequent negative life events than did those prompted to distract themselves (Lyubomirsky et al., 1998). Using the same design, other studies have found dysphoric individuals assigned to ruminate (versus to distract themselves) construe hypothetical negative and positive events in a more negatively-biased, pessimistic manner (Lyubomirsky & Nolen-Hoeksema, 1993, 1995). Rumination is also believed to impede problem solving. Dysphoric participants induced to ruminate found problems more overwhelming and developed less effective solutions, compared to participants induced to distract themselves (Lyubomirsky & Nolen-Hoeksema, 1995; Lyubomirsky et al., 1999). Lastly, ruminators engage in less social support. Ruminators seem to avoid social interaction, either to take time to think or write about their feelings or by repelling others with their negativity. In sum, rumination has both behavioral and cognitive adverse consequences, which seem to account for its affective ramifications.

Future Directions

All the cognitive outlooks we reviewed in this chapter have been found to relate to well-being. These findings speak to the value of the top-down approach. Clearly, attention and construal, which are manifested in each of the different outlooks, are both important to well-being. However, despite the relatively sizable research literature on each of these cognitive outlooks, more work is needed in several areas.

Throughout this chapter, we have noted where we believe holes in specific literatures exist.

However, a broad overview of the literature highlights that most researchers tend to focus on a specific cognitive outlook. However, these constructs have considerable overlap. What is the unique effect of each construct on well-being? Furthermore, do any cognitive outlooks interact to predict well-being? For example, self-esteem could moderate the effect of gratitude on well-being because one needs to feel deserving of an act of kindness to appreciate it. Alternatively, a particular cognitive outlook might mediate the association between another cognitive outlook and well-being. For example, a sense of autonomy might boost self-esteem, which then affects well-being. These possibilities can be explored in future studies that focus in concert on several cognitive outlooks and well-being. This type of research could utilize multiple regression and path-analytic techniques to uncover unique, moderation, and mediation effects.

Another hole in the cognitive outlooks literature is the lack of causal evidence. The reasons that little experimental work has been conducted in these areas are likely to vary widely—from relevant researchers' lack of interest or training in experimental methods to some constructs, like self-esteem, being particularly difficult to manipulate experimentally. However, investigators may erroneously believe that some constructs are difficult to manipulate. Thus, we encourage researchers to think creatively to design studies that explore causal effects.

In sum, more research is needed on how to improve people's levels of gratitude, optimism, locus of control/autonomy, connectedness, competence, and optimistic attributional style. We know much more about which cognitive outlooks impact well-being than about how to intervene on these constructs. Determining the most effective ways to shift these cognitive outlooks could have profound implications for individuals' well-being.

Abstract

The human pursuit of well-being occupies space that extends beyond simply seeking pleasure, feeling good, and being satisfied. In philosophy, Aristotle introduced the concept of "eudaimonia" to reflect human flourishing as a reflection of virtue and the development of one's full potential, in contrast to pleasure-centered hedonic well-being. Within psychological science, traditional conceptualizations of subjective well-being have also been expanded to include constructs that capture a more holistic version of well-being. The goal of this chapter is to provide a comprehensive overview of psychological theory and research regarding eudaimonic well-being. I will first briefly review the philosophical underpinnings of eudaimonia. I will then shift focus to the utilization of eudaimonia within modern psychology, first reviewing the ranging definitions and operationalizations of this concept used across the field. Next, I will review theoretical and empirical examinations of eudaimonic well-being in comparison to hedonic conceptualizations of well-being and discussions of limitations to the existing work in this area. In the next section of this chapter, I will provide an overview of the active debate in the field regarding the value vs. costs of maintaining a distinction between eudaimonic and hedonic well-being within psychological science. To end, I will highlight major areas of psychological research falling under the umbrella of eudaimonic well-being, including psychological well-being theory, self-determination theory, and meaning in life. Finally, I will discuss several areas of future research focusing on eudaimonic well-being.

Keywords: well-being, eudaimonia, psychological well-being, self-determination theory, meaning in life

---

While the pursuit of happiness is a near universal, the means to this happiness and the contours of attained happiness can differ widely across people and situations. While happiness can be conceptualized as the presence of positive feelings, the minimization of negative feelings, and a sense of satisfaction with one's circumstances, the three pillars of *subjective well-being*, there seems to be more to it than this (Ryff, 1989). Engagement in important work, making valuable contributions to society, and living in alignment with a set of moral virtues, are a few among many features of a happy life that aren't represented within the realm of positive affect and satisfaction. A holistic view of psychological well-being includes constructs that extend beyond affect and life satisfaction.

A eudaimonic perspective offers a class of constructs to paint an expanded and more complete picture of psychological well-being. In this chapter I will review early philosophical perspectives of eudaimonia before discussing the use of eudaimonia within modern psychological science. Then, I will review the ongoing debate regarding the use of a hedonic vs. eudaimonic distinction in the study of well-being. Finally, I will outline key research areas in psychological science that follow from the eudaimonic perspective including psychological well-being, self-determination theory, and meaning in life.

Philosophy of Eudaimonia, Briefly

The concept of eudaimonia pervades philosophical treatments of ethics, beginning with Aristotle's Nicomachean Ethics (4th century B.C.E./2001), in which he forwarded eudaimonia—"activity expressing virtue"—as an objectivist theory of happiness. Eudaimonia is most traditionally translated as "happiness," though the alternate translation used in much of contemporary philosophy is "flourishing." In modern philosophy many interpretations of, and commentaries on, Aristotle's eudaimonia have been offered (Annas, 1993; Haybron, 2008; Kraut, 1979; Norton, 1976; Tiberius, 2013). Shared among these is the notion that eudaimonia is a reflection of virtue, excellence, and the development of one's full potential (Huta & Waterman, 2014). Rooted in these philosophical origins, eudaimonia refers to that which is worth pursuing in life—an objective standard of goodness (Huta & Waterman, 2014).

Eudaimonia in Modern Psychology

In addition to spurring much philosophical discussion, Aristotle's concept of eudaimonia has also

been deeply impactful in the psychological study of well-being. Similar concepts began emerging in humanistic theories of personality including Maslow's self-actualization (1968) and May's daimon (1969). Such thinking developed over time and eudaimonia has now been adopted widely into the psychological science of well-being. Yet, in this transition, one key aspect of eudaimonia changed; in psychology, eudaimonia is now treated as a subjective state and this subjectivity is a central defining feature of this psychological construct. For example, early psychological treatments of eudaimonia position it as the subjective experiences related to doing what is worth doing and having what is worth having (Norton, 1976; Telfer, 1980).

Defining and operationalizing eudaimonia. Building on philosophical and early psychological thinking about eudaimonia, various conceptual definitions and operationalizations arose to describe the psychological experience of eudaimonic well-being. One definition suggests, "Eudaimonia, as a subjective state, refers to the feelings present when one is moving toward self-realization in terms of the developing one's unique individual potentials and furthering one's purposes in living" (Waterman, Schwartz, & Conti, 2008, p. 42). However, there is little agreement among scholars in this area regarding any one conceptual definition of eudaimonia, nor is there a shared methodological approach for its study (Huta & Waterman, 2014).

Huta and Waterman (2014) outline the basic conceptual and operational definitions of eudaimonia employed by a number of leading scholars in the field. For instance, Waterman (1993) uses self-realization and personal expressiveness as core, defining features of eudaimonia, and suggests that eudaimonia is "activity expressing virtue" (Waterman, 1990). Alternately, Ryff and colleagues conceive of eudaimonia in a broader, trait-like manner, suggesting that eudaimonia is to be fully functioning and successful despite the existential challenges of life (e.g., Ryff & Singer, 2008). Keyes (2002) integrates a component of social well-being into his conceptualization of eudaimonia, while Huta (2015) treats eudaimonia as a motive to develop the best in oneself. Bauer, McAdams and Pals (2008) study eudaimonia from a narrative perspective and consider it in terms of psychosocial integration, ego development, and personal growth. Ryan and Deci (2001) suggest that eudaimonia is living a life in full accord with one's potential, Delle Fave, Brdar, Freire, Vella-Brodrick, and Wissing (2011) consider eudaimonia as flow experiences and long-term meaning-making, and Seligman (2002) claims that eudaimonia is a product of one's characteristic personality traits or strengths.

To accompany these varied conceptualizations of eudaimonia, there are also many operationalizations used in studying these concepts. Eudaimonia can be measured at the trait level. For instance, Ryff's (1989) Scales for Psychological Well-Being have been widely used in this area of study. Additional trait assessments of eudaimonia exist. The Questionnaire for Eudaimonic Well-Being (Waterman et al., 2010) taps six dimensions: self-discovery, perceived development of one's best potentials, sense of purpose and meaning in life, investment of effort in pursuit of excellence, intense involvement in activities, and enjoyment of personally expressive activities. Alternately, Keyes' (2002, 2006) Mental Health Continuum assesses psychological, social, and emotional well-being with a variety of subscales. Eudaimonia has also been measured at the state level using scales such as the Personally Expressive Activities Questionnaire (Waterman, 1993), which assesses engagement in self-defining activities.

These scales also vary in their specificity, each targeting a different theoretical conceptualization of eudaimonic well-being. In recent years, additional scales have been developed with an aim towards capturing the broad range of concepts included in psychological success. First, the Flourishing Scale is an 8-item scale capturing various aspects theorized to be important to eudaimonia, including positive relationships, feelings of competence, and meaning and purpose in life (Diener et al., 2010). An even broader measure of psychological well-being conceptualizations can be found in the Comprehensive Inventory of Thriving (Su, Tay, & Diener, 2014). This scale was developed in a theory-driven manner, first identifying seven core theoretical dimensions of psychological well-being based on prominent theories throughout the literature. These include: subjective-well-being, supporting and enriching relationships, interest and engagement in activities, meaning and purpose in life, mastery and accomplishment, control and autonomy, and optimism (Diener, 1984; Ryan & Deci, 2000; Ryff, 1995; Scheier & Carver, 1985; Seligman, 2011), for a more holistic measurement approach towards well-being.

Comparing eudaimonic and hedonic well-being. One cross-cutting theme inherent in most definitions of eudaimonia is the exclusion of an affective, or hedonic, component (Disabato, Goodman, Kashdan, Short, & Jarden, 2016). Indeed, eudaimonic well-being is often discussed in contrast to hedonic well-being (e.g., Ryan & Deci, 2001; Waterman, 1993). Contrary to eudaimonia, the ideas of hedonic well-being philosophers such as Aristippus, Bentham, and Mill were centered on the notion that pleasure is the highest good (Tatarkiewicz, 1976). Early work examining happiness from a psychological perspective did not discuss a hedonia/eudaimonia distinction (e.g., Brickman & Campbell, 1971; Easterlin, 1974; Wilson,

1967). However, more recently, research in this area has begun to distinguish, and contrast, these two conceptualizations of happiness.

When comparisons are drawn between eudaimonic and hedonic well-being, the concept most frequently used to indicate hedonic well-being is subjective well-being. Subjective well-being consists of high levels of positive affect, low levels of negative affect, and the cognitive appraisal that one is satisfied with the conditions of his or her life (Diener, 1984). Certainly, subjective well-being encompasses a broader range of experiences than simple hedonic pleasure, including values, goals, and need fulfillment (e.g., Ryan & Deci, 2001). Yet, eudaimonia scholars most frequently invoke subjective well-being as the hedonic side of the dual-conceptualizions of well-being. Subjective well-being research has proliferated in recent decades (Diener et al., 2017; Diener, Suh, Lucas, & Smith, 1999). Noting subjective well-being's seeming domination of well-being research, Ryff (1989) countered with an argument for a more inclusive conceptualization of well-being that captured a broader range of what it meant to be well. As these two lines of well-being research have grown, they are often compared and contrasted.

Empirical examinations. The distinction between eudaimonic and hedonic well-being has been the focus of empirical investigation. First, there is a good amount of evidence that eudaimonic and hedonic well-being are strongly related, and experienced simultaneously. For example, Waterman (1993) found that the personal expressiveness reported for activities, an indicator of eudaimonia, related to the hedonic enjoyment of that activity, with correlations ranging from .71 to .86 across activities and studies. In three subsequent studies, similar relationships between feelings of personal expressiveness and hedonic enjoyment have been found, ranging from .83 to .87, indicating that these two state-level measures regarding one's experiences during specific activities share a large variance overlap of about 68% to 76% (Waterman et al., 2008).

While these concepts tend to be very closely related, factor analytic work has demonstrated a statistical separation between hedonic and eudaimonic measures. Most research examining the factor analytic separations of hedonic and eudaimonic constructs have utilized trait measures of each, diverging from the more state-oriented measures utilized in the correlational work noted previously. For instance, in a study including 18 trait-like mental health measures, separate, though correlated, subjective well-being and personal growth factors emerged (Compton, Smith, Cornish, & Qualls, 1996).

Additional studies have utilized factor-analytic techniques to examine hedonia, following Diener's (1984) model of subjective well-being introduced earlier in this chapter, and eudaimonia, following Ryff's model of psychological well-being, which will be examined further in a subsequent section of this chapter. First, Keyes, Shmotkin, & Ryff (2002) examined these relationships among U.S. adults. When forcing the loadings to fit a theoretical two-factor structure with correlated eudaimonic and hedonic well-being, these factors shared a very high correlation of .84. Furthermore, exploratory factor analyses revealed substantial cross-loadings for some subscales meant to indicate eudaimonic well-being, onto a hedonic well-being factor as well. These findings seem to indicate a lack of distinctiveness between these two versions of well-being, though the authors conclude confirmation of their hypotheses for "related but distinct conceptions of well-being" (Keyes et al., 2002, p. 1017). The two-factor structure with high correlations between latent eudaimonic and hedonic factors was also found in a similar U.S. adult sample, r = .78, and was even stronger in an undergraduate sample, r = .92 (Gallagher, Lopez, & Preacher, 2009). In similar analyses utilizing samples from the UK, Linley et al. (2009) found clean two-factor loadings for hedonic and eudaimonic measures of well-being in exploratory factor analyses. Furthermore, in a confirmatory model, they found a correlation of .76 between the two factors (Linley, Maltby, Wood, Osborne, & Hurling, 2009). A similar pattern pointing to the correlated distinction between measures of hedonic and eudaimonic well-being measures has been replicated (e.g., Robitschek & Keyes, 2009) including within a variety of populations including a South African sample (Keyes et al., 2008). Finally, Disabato et al. recently (2016) examined the dimensionality of well-being in an international study with participants spanning over 100 countries, including a number of metrics for both hedonic and eudaimonic well-being. They compared a one-factor model, with all measures indicating a single factor, against a two-factor solution, with the hedonic measures indicating one factor and the eudaimonic measures indicating another. Both solutions fit equally well and furthermore, in the two-factor solution, the factors correlated at r = .96 indicating a shared variance of about 92% (Disabato et al., 2016). Clearly eudaimonia and hedonia are closely linked.

In developing the CIT measure discussed above to capture the breadth of the human experience of thriving, Su et al. (2014) identified 18 facets of psychological well-being, including constructs from both eudaimonic and hedonic traditions. They found excellent fit for a model with correlated latent factors for each well-being facet suggesting correlated, yet distinguishable, psychological well-being constructs. Furthermore, correlations among the facets were typically of moderate size, consistent with the conclusion that these construct scales are relative but distinct. Still the more eudaimonia-oriented facets of the CIT were highly correlated with subjective well-being measures, for instance, the CIT meaning facet shared a

correlation of $r > .80$ with subjective well-being measures.

Using a more sophisticated analytic technique, Chen et al. (2012) utilized a bifactor model to capture the shared variance between measures of eudaimonic and hedonic well-being as well as their unique predictive contributions. They identified a strong general factor shared by the measures as well as two specific factors that each demonstrated predictive power independent of their shared, general factor variance (Chen, Jing, Hayes, & Lee, 2012).

Together, this body of work suggests that eudaimonic and hedonic well-being are strongly related to one another, yet can be potentially differentiated statistically. However, there is certainly substantial overlap between the two, leaving the discussion regarding their independence unresolved and indicating the necessity of additional research to build a more thorough understanding of these concepts themselves and together.

Beyond utilizing factor analytic techniques to examine the structure of happiness, this technique has also been employed to examine the relationships between eudaimonic and hedonic factors and other variables. In a series of studies, feelings of personal expressiveness in an activity, a eudaimonic indicator, were more strongly linked to finding that activity to provide opportunities for the development of one's potential, self-realization, and feelings of being challenged, competent, and assertive, for example, whereas hedonic enjoyment, on the other hand, was more strongly related to feeling relaxed, excited, content, happy, and interested (Waterman, 1993; Waterman et al., 2008). Across a series of daily diary studies, reported engagement in eudaimonic behaviors was more strongly and consistently related to feeling that life is meaningful and satisfying than engagement in hedonic behaviors (Steger, Kashdan, & Oishi, 2008).

In additional cross-sectional and experience sampling studies examining hedonic and eudaimonic pursuits both between and within persons, Huta and Ryan (2010) found hedonic pursuits to relate more strongly to positive affect and carefreeness, while eudaimonic pursuits related more to meaning. Furthermore, an experimental intervention study has been conducted in which participants were randomly assigned to complete hedonic or eudaimonic activities for 10 days. Those in the hedonic activities condition reported more well-being benefits immediately following the intervention, whereas those in the eudaimonic activities condition reported greater well-being in a follow-up assessment 3 months later (Huta & Ryan, 2010). It seems, then, that both hedonic and eudaimonic pursuits are important avenues to well-being, albeit different aspects and with different time frames.

There is also some evidence supporting Telfer's (1980) theoretical notion that eudaimonia is a sufficient, but not a necessary condition for experiencing hedonic enjoyment. Examining events that were rated as very high or very low on personal expressiveness and hedonic enjoyment, 4/5 of activities rated as providing a great sense of personal expressiveness were also rated as very hedonically enjoyable, whereas only about 1/3 of highly hedonically enjoyable activities were also associated with personal expressiveness (Waterman et al., 2008). From this asymmetric finding, which was consistent across three samples, the authors concluded that activities that bring about a sense of eudaimonia are a subset of those that lead to hedonic enjoyment (Waterman et al., 2008). Similarly, Keyes and Annas (2009) found that while 48.5% of individuals in the MIDUS sample reported high levels of hedonic well-being, only 18% were categorized as "flourishing," that is, expressing high levels of both hedonic and eudaimonic well-being. Furthermore, they found that those who were not flourishing, but experiencing high levels of hedonic well-being with only moderate or low levels of eudaimonic well-being, reported much greater rates of mental illness compared with those who were high on both types of well-being (Keyes & Annas, 2009).

Limitations. The inconsistencies within the literature regarding the roles of eudaimonia and hedonia in an individual's well-being stem from a number of different sources. First, as mentioned, the diverse array of conceptualizations of eudaimonia complicates comparisons with hedonic well-being and can account for some differences in findings. Without systematic evaluations of these findings that take into account the conceptualizations of each construct employed, these findings remain muddled. This is especially problematic when comparisons are made between treating hedonia as a way of feeling and eudaimonia as a way of behaving (Huta & Ryan, 2010; Huta & Waterman, 2014). Similarly, as Huta and Waterman (2014) point out, some comparisons treat hedonia as cognitive-affective experiences while treating eudaimonia as mental functioning or trait level orientations (Compton et al., 1996; Gallagher et al., 2009; Keyes et al., 2002; McGregor & Little, 1998) and such asymmetrical treatments can make direct comparisons of their relationships with each other and predictors and outcomes difficult. Finally, the strong correlation between the two conceptualizations of well-being leaves questions regarding the nature of their differential relationships with outside variables as these seem to represent only the extreme ends of both the eudaimonic and hedonic sides of well-being, which seem to be poor representations of the concepts as they are experienced in daily life.

Eudaimonia in Psychology: A Misleading or Valuable Distinction?

The mixed evidence above regarding the divergence of eudaimonic well-being from hedonic well-being and plentiful discussions of the limitations within this area, preview an ongoing debate within the well-being literature regarding the utility of eudaimonia as a concept within the psychology of well-being. The critique of eudaimonia that has generated the most discussion regarding these concerns was published by Kashdan, Biswas-Diener, and King (2008).

In this piece, Kashdan and colleagues (2008) argue that the philosophical distinction between hedonic and eudaimonic well-being does not carry over well into the psychological science of well-being and present a number of critiques to support this argument. I have discussed a few of their criticisms previously in this chapter. Namely, that the field of eudaimonic well-being lacks concise conceptual and operational definitions and, furthermore, that the existing definitions and measurement strategies fail to fully capture the concept of eudaimonia forwarded by Aristotle. In similar critique, Kashdan et al. (2008) argue that the subfield of eudaimonia research suffers from not having a uniting theory to encompass its many arms, and they suggest that such a theory would be problematic anyway given the diversity of the field and the loss of information that would result from a single theory of eudaimonic well-being. This "looseness" or vagueness of definitions and lack of unification has been discussed elsewhere as well (e.g., Huta & Waterman, 2014; Waterman, 2008), yet adequate solutions to these problems remain to be seen.

Kashdan et al. (2008) raise additional concerns regarding the appropriateness of drawing comparisons between hedonic and eudaimonic well-being. First, they argue that this distinction promotes the notion that the two conceptualizations of well-being exist on a moral hierarchy with eudaimonic well-being claiming the superior position (Waterman, 2007). Narrowly, that subjective well-being, the most commonly used conceptualization of hedonic well-being, occupies the lower ranks of this hierarchy is questionable given the plentiful research pointing to the wide benefits of subjective well-being and success in a host of life domains (Lyubomirsky, King, & Diener, 2005). More broadly, this hierarchy is problematic if well-being is to be considered a subjective human experience. This highlights the stark distinction between the psychological study of subjective eudaimonia and its roots in objectivist philosophy. Arguments have been forwarded suggesting that the study of eudaimonic well-being is more about *why* someone is happy rather than an accurate subjective assessment of *whether* someone is happy, which conflates the experience of happiness with the common sources of this experience (Kashdan et al., 2008).

Kashdan et al.'s (2008) critique of eudaimonic well-being's place within psychological science opened a lively discussion about the merits and problems of eudaimonia throughout the well-being field, even eliciting several direct responses (Delle Fave & Bassi, 2009; Keyes & Annas, 2009; Ryan & Huta, 2009; Waterman, 2008). For example, Keyes and Annas (2009) argued, "hedonism logically can't be a *rival* to eudaimonism on its own level. It is one of the *options within* eudaimonism" (p. 198). Even more broadly, Waterman (2008) suggested that it is perhaps too early in the history of the psychological science of eudaimonia to engage in such pointed critiques regarding the shortcomings of this work in the first place.

Eudaimonic Concepts in the Science of Well-Being

Both sides of this debate do share some common ground in finding value in many of the constituent parts of the eudaimonic tradition. The concept of eudaimonia, regardless of its function within the study of well-being in and of itself, provides an umbrella under which to discuss aspects of psychological well-being that aren't included in present psychological definitions of subjective well-being, or happiness, which include only affective feelings and satisfaction with life. Kashdan et al. (2008) recommended referring to specific constructs under this umbrella rather than discussing the broad categories of hedonia and eudaimonia. Here, I will examine three major areas of study that align with a eudaimonic approach to well-being: psychological well-being theory, self-determination theory, and the study of meaning in life. I will also briefly mention several other concepts that also occupy a space within this literature.

Psychological Well-Being Theory. In response to the seeming takeover of well-being field by research focused on the concept of subjective well-being, Carol Ryff (1989) argued that the state of this area of study was suffering from a lack of theoretical grounding and definitional precision regarding the essential features of well-being. To supplant this limitation, Ryff (1989) proposed an alternate, wider, model of psychological well-being driven by diverse theoretical perspectives regarding positive human functioning. Drawing upon some of the most well-known theories from developmental, clinical, existential, and humanistic psychology (e.g., Allport, 1961; Erikson, 1959; Frankl, 1959; Jung, 1933; Maslow, 1968), Ryff's model of psychological well-being includes six central dimensions: self-acceptance, positive relations with others, autonomy, environmental mastery, purpose in life, and personal growth.

To highlight the central features of each factor briefly: (1) self-acceptance refers to the awareness and acceptance of one's personal strengths and weaknesses; (2) positive relationships with others refers to deep connections with significant others; (3) autonomy is living in accordance to one's own convictions; (4) environmental mastery is managing life situations; (5) purpose in life is the extent to which one's life

feels meaningful and purposefully directed; and (6) personal growth is achieved when one is using his or her personal talents and potential (Ryff, 1989, 2014; Ryff & Singer, 2006). Four of these six dimensions of well-being (positive relations, autonomy, purpose, and growth) had not been previously included in other measures of well-being, despite their role in theories of positive functioning, highlighting the novel contributions of this model (Ryff, 1989).

In the decades since the advent of this model of psychological well-being, much research has developed following this widened conceptualization of well-being (Ryff, 2014). First, research regarding its factor structure has been conducted, with numerous papers reporting replications of the theoretical six-factor structure of this model (e.g., Clarke, Marshall, Ryff, & Wheaton, 2001; Gallagher et al., 2009; Ryff & Keyes, 1995). Still, elsewhere, this six-factor model has been challenged and the factor structure has not always replicated (Kafka & Kozma, 2002; Springer & Hauser, 2006). More extensive discussions of the factor-structure replications can be found elsewhere (Ryff, 2014; Ryff & Singer, 2006; Springer & Hauser, 2006).

In addition, work following the psychological well-being tradition has focused on examining age and gender profiles in well-being (Ryff & Keyes, 1995; Springer, Pudrovska, & Hauser, 2011) and additional psychosocial and sociodemographic correlates of eudaimonia (Keyes et al., 2002; Ryff & Singer, 2008). For example, findings suggest that adults with higher psychological well-being than subjective well-being were younger, more educated, and were more open to experience (Keyes et al., 2002). Furthermore, research examining the biological underpinnings of psychological well-being and its importance for health has been growing in recent years (Ryff, 2013). Some initial findings point to connections between eudaimonic well-being and lower salivary cortisol, decreased cardiovascular risk, and better sleep (Ryff, Singer, & Love, 2004). Subsequent work has identified relationships between some factors of eudaimonic well-being and important inflammation indicators (Friedman & Ryff, 2012; Morozink, Friedman, Coe, & Ryff, 2010).

Much of the work highlighting the empirical comparisons of hedonic and eudaimonic well-being utilized Ryff's conceptualization of psychological well-being as an indicator of eudaimonia and note small, yet predictive, differences compared to subjective well-being. Overall, research in this area highlights the advancements made following a well-conceptualized theoretical approach to eudaimonic well-being.

Self-Determination Theory. Another broad theory that embraces a eudaimonic conceptualization of well-being is self-determination theory. Self-determination theory considers self-realization, or eudaimonia, as the key defining feature of well-being and focuses on specifying the processes through which self-actualization can be achieved (Ryan & Deci, 2001). Ryan and Deci (2000) inductively identified three basic psychological needs—autonomy, relatedness, and competence—essential for optimal growth and integration and constructive social development (Ryan & Deci, 2000). As such, the satisfaction of these three needs fosters eudaimonic well-being. Note that unlike psychological well-being theory reviewed previously, which defines eudaimonic well-being in terms of principle factors similar to autonomy, relatedness, and competence, self-determination theory posits that these needs foster, rather than define, well-being (Ryan & Deci, 2001).

The extent to which the basic self-determination needs are satisfied also determines variability in intrinsic motivation (Ryan & Deci, 2000), another concept central to self-determination theory and closely tied to eudaimonic conceptualizations of well-being. Intrinsic motivation reflects positive human potential and represents the inherent tendency to pursue novelty and challenge, explore, learn, develop, and grow (Ryan & Deci, 2000), all central to well-being from a eudaimonic perspective. According to self-determination theory, the satisfaction of the three basic needs and intrinsic motivation across the lifespan are necessary for human thriving (Ryan & Deci, 2000).

Supporting these claims tying needs satisfaction and intrinsic motivation to the fulfillment of human potential, researchers working within the self-determination theory framework have found that the pursuit of some, but not all goals, satisfy these basic needs and, subsequently, enhance eudaimonic well-being (Ryan, Sheldon, Kasser, & Deci, 1996). First, whereas intrinsically driven goals, such as affiliation, growth, and community, satisfy these three basic needs directly, other more extrinsically motivated goals, like wealth, fame, and image do not (Ryan et al., 1996). Additionally, focusing on intrinsic aspirations relates positively to indicators of well-being central to the eudaimonic tradition, such as self-actualization, or the fulfillment of one's potential, while focusing on extrinsic aspirations shares an opposite, negative, relationship (Kasser & Ryan, 1993, 1996; Ryan et al., 1999).

While self-determination theory has always aligned with eudaimonic thinking (Ryan & Deci, 2001), this connection was taken a step further more recently, with the introduction of a formalized model of eudaimonia based in self-determination theory (Ryan, Huta, & Deci, 2008). From a self-determination theory perspective, this model categorizes eudaimonic living into four central motivational concepts: (1)

pursuing intrinsic, rather than extrinsic, goals and values, (2) behaving in an autonomous and volitional, rather than controlled, manner, (3) being mindful and acting with awareness and (4) behaving in need satisfying ways (Ryan et al., 2008).

Much research in the area of self-determination theory has focused on the relationship between goals, needs, and conceptualizations of well-being beyond the eudaimonic tradition, including, as well, more hedonically oriented conceptualizations of well-being (Ryan & Deci, 2001). For instance, the attainment of intrinsic goals was found to enhance hedonic well-being, measured with four items: happy, joyful, pleased, and enjoyment/fun, while succeeding at extrinsically oriented goals does not (Sheldon & Kasser, 1998). Similarly, goals that satisfy the three basic psychological needs, autonomy, competence, and relatedness, contribute to hedonic well-being more than other goals (Sheldon & Elliot, 1999). Furthermore, daily fluctuations in the satisfaction of the basic self-determination needs predicted daily fluctuations in mood (Reis, Sheldon, Gable, Roscoe, & Ryan, 2000; Sheldon, Ryan, & Reis, 1996). This work suggests that psychological needs satisfaction is not only relevant for living a eudaimonic life, but also for concepts within the realm of hedonic well-being. Still, leading self-determination theory scholars maintain the distinction between hedonic and eudaimonic well-being (Ryan and Deci, 2001), noting that there some conditions that foster hedonic well-being that don't promote eudaimonic well-being (Nix, Ryan, Manly, & Deci, 1999).

Meaning in Life. A third large area of research under the umbrella of eudaimonic well-being focuses on the experience of meaning in life. Feeling that one's life is meaningful is a fundamental human motivation (Baumeister, 1991; Frankl, 1984; Klinger, 1977; Maslow, 1968) that has been theorized to be an essential indicator of eudaimonic well-being. While meaning and purpose in life are included as a factor in Ryff's psychological well-being model, an extensive body of work on this topic now exists independent of that framework.

Like other eudaimonic concepts, meaning in life is somewhat difficult to define (e.g., Heintzelman & King, 2013). Yet recent strides have been made in this literature towards a consensus definition of meaning in life. One representative definition of meaning in life states that, "Lives may be experienced as meaningful when they are felt to have a significance beyond the trivial or momentary, to have purpose, or to have a coherence that transcends chaos" (King, Hicks, Krull, & Del Gaiso, 2006, p. 180). This definition highlights three central aspects of the experience of meaning in life: purpose, significance, and coherence (George & Park, 2016a, 2016b; Heintzelman & King, 2013; 2014a, 2014b; Martela & Steger, 2016). Purpose refers to engagement in goal directed pursuits: Striving towards personally significant goals is related to feelings that life is worth living (Battista & Almond, 1973; Emmons, 2003; McGregor & Little, 1998; McKnight & Kashdan, 2009; Vallerand, 2008). Significance is the feeling of mattering or making an impact, and building a legacy that will transcend the self (George & Park, 2016a). Coherence is the degree to which stimuli, events, and one's life make sense and fit with expectations (Antonovsky, 1993; Battista & Almond, 1973; Baumeister & Vohs, 2002; Heine, Proulx, & Vohs, 2006; Heintzelman, Trent, & King, 2013).

Meaning in life research has focused, in large part, on the antecedents and consequences of reporting that one's life is meaningful. Many aspects of life relate to, or causally lead to, feeling like that life is meaningful. These sources of meaning in life include, but are not limited to, social relationships such as family and friends (Lambert, Clark, Durtschi, Fincham, & Graham, 2010; Lambert, Stillman, Kamble, Baumeister, & Fincham, 2013), religion (Hicks & King, 2008; Steger & Frazier, 2005), and regularities (Heintzelman et al., 2013). In terms of consequences, high levels of meaning in life are associated with a number of beneficial outcomes across a host of life domains, for example better physical health (for review, see Roepke, Jayawickreme, & Riffle, 2014), mental health (Heisel & Flett, 2004; Mascaro & Rosen, 2005; Owens, Steger, Whitesell, & Herrera, 2009; Steger & Kashdan, 2009), and social functioning (Stavrova & Luhmann, 2016; Stillman, Lambert, Fincham, & Baumeister, 2011).

Some recent meaning in life research highlights some inconsistencies that emerge when maintaining a traditional hedonic/eudaimonic distinction. First, a strong relationship ($r \approx .65$) between meaning in life and positive affect is consistently replicated across this literature, and furthermore, inducing a positive mood also enhances meaning in life, suggesting positive affect is another source of meaning (King et al., 2006). In addition, eudaimonic well-being is often situated as the morally superior form of well-being, in part, because it is thought to be more difficult to attain than its hedonic counterpart. However, recent research suggests that meaning in life is a very common human experience across populations (Heintzelman & King, 2014a) that responds to momentary experience (Machell, Kashdan, Short, & Nezlek, 2015) and is related to automatic, default, intuitive cognitive processing systems (Heintzelman & King, 2016).

Additional eudaimonic concepts. In addition to growing research following each of the three

traditions elaborated above, there is also an abundance of other psychological concepts following a eudaimonic approach to well-being. I will review four such concepts, selecting those that have comparatively larger surrounding research literatures among the battery of existing eudaimonic concepts.

First, well-being theorizing and research has engaged in efforts to conceptualize "the good life." King and Napa (1998) found that folk concepts of the good life nearly always include both happiness and meaning in life, and additional work demonstrated the necessity of fulfilling personal relationships for a "good life" (Twenge & King, 2005). Finally, effort also seems to play a role in beliefs about the good life as participants rated a meaningful and effortful life as most morally good, while rating a happy and effortful life as most desirable, happy, and meaningful (Scollon & King, 2004).

Another subarea of research within the domain of eudaimonic well-being is Csikszentmihalyi's (1975) concept of "flow" experiences. Namely, flow occurs when one exerts "voluntary effort to accomplish something difficult and worthwhile," typically at the intersection of task challenges and one's skill level (Csikszentmihalyi, 1990). Flow states are characterized by intense focus and a loss of reflective self-consciousness and temporal awareness in which activity engagement is itself rewarding (Nakamura & Csikszentmihalyi, 2014). The concept of flow has even merged into larger areas of study within the eudemonic tradition, namely self-determination theory research (e.g., Schüler, Brandstätter & Sheldon, 2013).

Still another concept within the psychological science of eudaimonia is the human propensity for growth, or ego development (Loevinger, 1976). Growth is often studied by examining the narrative accounts people produce about their own lives and experiences, reconstructing the past and imagining the future (McAdams, 2001). People who have high levels of eudaimonic well-being tend to emphasize personal growth in their narratives and tend to frame difficult experiences as transformative (Bauer et al., 2008). As such, growth seems to be another important aspect of eudaimonia.

Lastly, character strengths also occupy space in the realm of eudaimonic well-being concepts. Character strengths can be defined simply as "positive traits reflected in thoughts, feelings, and behaviors" (Park, Peterson, & Seligman, 2004, p. 603). Peterson and Seligman (2004) identified 24 ubiquitously acknowledged strengths of character by examining core virtues shared by world cultures throughout history. These strengths fit into six categories: wisdom, courage, humanity, justice, temperance, and transcendence. In research regarding positive intervention activities, participants who identified their character strengths and used them in new ways reported improvements in happiness, measured with items tapping the pleasant life, the engaged life, and the meaningful life, that lasted over a six-month period (Seligman, Steen, Park, & Peterson, 2005).

Conclusions & Future Directions

Recent decades of psychological science have certainly contributed much to the centuries-old concept of eudaimonia. This approach has widened the scope of well-being research to include concepts beyond simple pleasure seeking to encompass, as well, those parts of life that are virtuous and meaningful. Still, examining eudaimonic well-being from a psychological science perspective as a subjective experience is a fairly new area of study (Waterman, 2008). As such, many critiques remain yet to be fully overcome (e.g., Huta & Waterman, 2014; Kashdan et al., 2008). Within the study of eudaimonia, more conceptual clarity is needed to move the field forward in a unified manner (Huta & Waterman, 2014).

There remain many doors open for further research following the eudaimonic tradition. Of course, research is currently thriving within subtopic areas in this field, including psychological well-being, self-determination theory, and meaning in life, and the momentum within these areas will continue to propel them forward in their own interesting and informative directions. In addition to research within these subareas, there are also many lingering questions broadly regarding the roles of hedonia and eudaimonia for overall human well-being. There now exists strong support that both hedonic and eudaimonic pursuits lead to well-being (McGregor & Little, 1998; Ryan & Deci, 2001; Seligman, 2002). However, more work is needed to understand how hedonic and eudaimonic variables affect one another (Kashdan et al., 2008). Su et al. (2014, p. 4) stated, "Enrichment of other dimensions of psychological well-being (e.g. mastery or social relations) can, through a dynamic and reciprocal relationship, enhance [subjective well-being]." The question remains, however: Is eudaimonia a means to more hedonic states such as those captured by subjective well-being, or is it, itself, an end? Perhaps this question and others like it are strictly philosophical. However, psychological science now offers insight into a countless number of big questions that were also once deemed too lofty to study empirically. Currently researchers from hedonic and eudaimonic traditions limit their examinations the opposite conceptualization of happiness when trying to distinguish their own ideas as unique (or superior). In order to make forward progress on such deep questions, it will be important, and even necessary, for research to take a balanced approach to these perspectives simultaneously.

Abstract

Ever since the Aristotelian conception of happiness as activity of the soul to modern perspectives on the ever-active biological organism, the doing part of life has been considered essential for survival and wellbeing. Humans must act in order to live—and live well. The basic assumption of activity theories of wellbeing is that doing things in certain ways and for particular reasons constitute a kind of goodness in itself. We can act in ways that are good for us, and we can act in ways that are bad for us. In the current chapter, philosophical, economical and psychological theories are presented and critically analyzed in order to clarify how activities can be regarded as a crucial ingredient of wellbeing. Possible mechanisms accounting for the association between activities and the concept of goodness are introduced, and theoretical disputes and empirical controversies between them are discussed.

Keywords: Happiness, Activities, Aristotle, Welfare, Internal motivation, Flow, Self-determination, Functional wellbeing, Needs

It was Ed Diener, in his now classic 1984 article, who introduced the category of activity theories to the taxonomy of wellbeing theories. In Diener's scheme, the view that happiness is a "by-product" of being active was named as activity theory and contrasted with telic theories of wellbeing. To illustrate the concept, Diener used the example of ascending a mountain: the climbing itself might bring greater happiness than reaching the summit. Telic theories are, according to the Diener classification, not able to explain this kind of goodness, since they are restricted to account only for the pleasure of accomplishing a goal—like reaching the peak of a mountain. Activity theories on the other hand, are able to explain the pre-goal element of wellbeing, and in Diener's article, Aristotle's function argument and Csikszentmihalyi's writings on flow experiences were presented as examples of activity theories of a good life.

Wellbeing [1] typically refers to a life that goes well [2], hence activity theories must clarify *what it is that can go well for a person during an activity*. The critical question is how to categorize something as good even if it does not include goal accomplishment or need fulfilled. The present chapter reviews some of the theories aiming to explain this puzzle and it starts by investigating the notion of activity itself. It proceeds by presenting some historical and philosophical ideas on the issue and moves on to examine the contribution from welfare economics. The final part of the text critically discusses four psychologically activity theories.

Being Active Is The Modus Operandi Of Human Life

To live means to be active and it is activity—not passivity— that is the modus operandi of our lives (Mayr, 1982; Pross, 2016). In stark contrast to what some philosophers have speculated, like Jean-Jacques Rousseau who argued that indolence was the natural condition of human life (see Ciulla, 2000), we must continuously be active in order to keep our biological and psychological structures organized.

The importance of being active was recognized by the psychology pioneers, not at least among those with a biological orientation (e.g., Allport, 1961; Angyal, 1941; deCharms, 1968; Deci & Ryan, 1985; Elkind, 1971; Goldstein, 1939; Hebb, 1955; Henle, 1956; Loevinger, 1976; Rogers, 1963; von Bertalanffy, 1952/2014; White, 1959; Woodworth, 1918). The term organismic was introduced to explain how all living systems are organized as parts of a unified whole, and how this holistic system seems to be continuously active and self-regulated toward a two-folded goal of both preserving and expanding their organic structure. Giants like Piaget and Vygotsky considered activity to be essential not only for basic life regulation, but for all psychological actions, including the formation of cognitive structures (see Fischer & Bidell, 2006). No wonder then, that a scholar such as Brandstätter (2006) argues that action is the center of what people are and how they develop.

Philosophical and Historical Approaches

Aristotle

The significance of activity for human goodness was discussed long before the birth of scientific

psychology, and, not surprisingly, Aristotle had an articulated opinion about it. Activities are important to Aristotle's theory on wellbeing, but he does not start his argument with that concept. He begins with the notion of goals.

Aristotle paid close attention to the world around him and this led him to believe that all creatures were driven by a goal. All forms of life, Aristotle realized, have a purposeful character. Based on this insight he proposed the idea of a 'summum bonum' or ultimate goal. All things, living and non-living, searched towards this goal. The Greek philosopher was wrong, however, in including non-living things in this telic principle, but as far as biological organisms goes, his ideas about their goal-oriented nature was spot on. Modern biologists no longer refer to it as telos, though, they call it 'teleonomy' (Pross, 2016).

Since Aristotle's thinking is essentially telic, Diener's categorization of it as an activity theory in opposition to the telic theories might appear as somewhat misleading. However, the important 'function argument' in Aristotelian theory articulates a close association between goals and activities (e.g., Korsgaard, 2008; Whiting, 1988). The theory is in a sense both a telic and an activity theory and one could say with MacIntyre (2007) that it is "only because human beings have an end towards which they are directed by reason of their specific nature, that practices, traditions, and the like are able to function as they do." Despite its telic grounding, Aristotelian happiness is often defined with reference to an activity, more specifically the kind of activity that takes place "in the rational part of the soul performed well, which is to say, in accordance with virtue." (Korsgaard, 2008, p. 129). Aristotle conceived of virtues as "dispositions not only to act in particular ways, but also to feel in particular ways." (MacIntyre, 2007, p. 149).

MacIntyre has further interpreted Aristotelian happiness as a "state of being well and doing well in being well" (MacIntyre, 2007, p. 148). He thus indicate that the doing well part refers to the practice of actively pursuing the ultimate human goal, which, according to Aristotle, is one and the same for all of us, as dictated by our human nature (e.g., Besser, 2016). Since we cannot escape our nature, including its final goal, only proper activities that direct us toward the true goal will make us flourish.

This conceptualization of a unitary human nature diverges fundamentally from scientific perspectives, which—since Darwin—typically focus on natural differences within each species. The idea of natural variations makes it likely that many different kinds of goals and activities can do the trick of making us happy, depending on the individual's dispositions and environmental peculiarities. After all, Aristotle knew nothing about evolution and it is understandable that he stumbled on the idea of a unitary goal/unitary activity approach to happiness. A critical hand might also be astounded by Aristotle proposal that the only life truly worth living is that of a philosopher, a statement that, according to Thin (2012) sounds "embarrassingly smug." More updated on how and why variations is a natural part of human lives, Lyubomirsky and Layous' writings on the "person-activity fit" suggest that a diversity of goals and activities is exactly what we need to be happy. What is important, is the match between one's dispositions (and these vary across individuals) one the one hand, and the goals held and activities performed on the other. A huge pool of goals and activities are equally potent as sources of happiness, given that the they fit our more or less idiosyncratic dispositions (Lyubomirsky & Layous, 2013). Variations of the perspective presented by Lyubomirsky are mainstream in modern psychology, and can be found in almost every goal-oriented approach in the discipline (e.g., Cantor & Sanderson, 1999; Dweck, 2000; Emmons, 1999; Klinger, 1975; Little, 2016; Sansone & Harackiewicz, 1996; Sheldon, 2014).

A final point about the Aristotelian theory of happiness worth some pondering concerns the meaning of the phrase "by-product." Diener used it to describe activity theories of wellbeing, and other scholars use it in order to explain how an activity can create a feeling state (e.g., Ryan & Martela, 2016). Aristotle seems to have had at least two different opinions on the issue, and experts on interpreting his writings, such as Nussbaum (e.g., Nussbaum, 2008), argue that in Book VII and Book X of the Nicomachean Ethics Aristotle diverge. In Book VII Aristotle identified pleasure with unimpeded activity. As such, pleasure is not a "by-product" of activities, in the sense of a by-product being "a result of making something else, or something unexpected that happens as a result of something: Buttermilk is a by-product of making butter. Illness is one of the *by-products* of overcrowded housing" (Cambridge English Dictionary Online; https://dictionary.cambridge.org/us/dictionary/english/by-product). In Book X of the Nicomachean Ethics, Aristotle speaks of pleasure a bit differently, as something that "supervenes on it, like red check in the youth" (Nussbaum, 2008, p. S84). According to Nussbaum, pleasure in this second meaning is not identified as unimpeded activity, but as a result of such activities. Nevertheless, pleasure as laid out in Book X is "so closely linked to the relevant activities that it cannot be pursued on its own, any more than bloom can be adequately cultivated by cosmetics. To get that bloom you have to pursue health." (Nussbaum, 2008, p. S85). Pleasures such perceived are not simply external rewards, but "achievements and satisfactions available only in the activities of the practice" (Boyle, 1987). Similarly, Katz (2009) has argued that Aristotle held a "Perfection in functioning view", which, in the context of activity theories, means that pleasure arises from being active, from the activity itself. Finally, Lazarus (1991) has pointed

out that Aristotelian happiness is "not goal attainment that generated pleasure but the normal exercise of any function." (p. 92). Irrespective of the interpretations offered on Aristotle's view on the matter, modern emotion theory clearly consider feelings as an integrated part of, and not a by-product of activities. In a later section, the Functional wellbeing approach (FWB) will be offered as a possible explanation as to why activities generates feelings by and in themselves.

The Utilitarian Turn

The Aristotelian idea that humans, by nature, are genuinely social and that our inborn moral dispositions must be actively cultivated in order to develop good societies and lead happy lives was more or less abandoned during the Enlightenment (MacIntyre, 2007). Instead, deontology (Kant), utilitarianism/consequentialism (Bentham) and contractism (Hobbes) came to dominate the ethical debates. Following these views, no connection between (moral) activities and the good life was proposed. Rather, the idea of goodness that started out as utilitarianism and ended up as economic welfarism discarded the distinction between goods internal to and goods external to an activity. Wellbeing, what many scholars hold as the essence of economic welfare (e.g., Hausman, McPherson, & Satz, 2016; Jordan, 2008; Moore & Crisp, 1996; Ringen, 1995; Sumner, 1996), became identical with money, and money was most efficiently generated by the interaction between supply and demand as regulated by competitive markets. The relevance of human activity for wellbeing was reduced to the behavior involved in producing a supply and breeding demands. The logic goes something like this. Since people in a market act on a voluntary basis[3], prices will adjust until supply equals demand (the state of 'market equilibrium'). "The resulting set of prices makes everyone as well-off as possible. In other words, markets produce the best of all possible worlds" (Kwak, 2017, Chapter 2).

Interestingly, the early economists had a much more sophisticated view on human wellbeing that what we are left with in the extreme reductionism of modern versions of the discipline. Adam Smith, for example, was concerned with the nature on human activities, although he, like many of his contemporaries, held a generally negative view of it. To be active was to Smith a hostile necessity. "It is in the inherent interest of every man to live as much at his ease as he can; and if his emoluments are to be precisely the same whether he does or does not perform some very laborious duty, to perform it in as careless and slovenly a manner that authority will permit" (Adam Smith, 1776, cited in Schwartz, 2015). Some years later, Jeremy Bentham talked about "love of labour is a contradiction in terms" (cited in Skidelsky & Skidelsky, 2013, Chapter 1). What is more, Bentham considered the activities involved in paid employment to be so aversive—and poor people to be so lazy and unwilling to take part in it—that in order to motivate them to work "the paupers should be kept in 'wholesome horror'" (Dean, 2008, p. 61).

In contrast to economic welfarism, even a free market apologist like Adam Smith agreed that when it comes to welfare, the negativity of hard work had to be subtracted from the monetary surplus generated by the balancing forces of supply and demand. To Smith, activities like work simply had "negative utility." Not only did he realize that the division of labor meant that the work reduced welfare because it made the life of the workers more boring, Smith also developed a pessimistic outlook on the prospect of capitalism as a provider of welfare in the long run. He believed that the division of work among the assembly line workers eventually would end in material decline and moral decay (Heilbroner, 1973). A person who loses the opportunity to practice the skills of a trade or a craft, becomes, in Smith's own words "as stupid and ignorant as it is possible for a human creature to be" (cited in Schwartz, 2015, Chapter 4). A look at his famous schedule for manufacturing pins illustrates how the division of labor might be good for business, but bad for wellbeing. In order to produce pins efficiently, the task should be divided into more limited tasks, such as drawing the wire, straightening the wire, pointing, cutting heads etc. And not only should the initial craftsmanship involved in the making be chopped up into meaningless chunks of activities, the different part of the process should be delegated to the cheapest possible employees. Women were paid less than males, and girls less than boys. Such a scheme makes the surplus go up, but wellbeing, Smith feared, will go down.

About a hundred years later, reports given to the Children's Employment Commission in England could verify Smith's prophecies about the alienation of factory workers. Here is a mother's testimony on the working conditions for her little son in London in 1863: "When he was seven years old I used to carry him [to work] on my back to and fro through the snow, and he used to work 16 hours a day…. I have often knelt down to feed him, as he stood by the machine, for he could not leave it or stop" (Marx, 1977, cited in Hochschild, 1983, p. 3)

Based, in part, on these and similar observations, Marx developed his view on how capitalism systemically prevents most people from having the requirements of a 'good life'. Marx, who held a PhD in the philosophy of Democritus and Epicurus (see McMahon, 2006) was familiar with the Aristotelian concept of eudaimonia and when Marx wrote about good lives, it was, according to Miller (1992), in

Aristotelian terms. Thus, Marx opposed utilitarianism and accused Bentham for failing to discriminate among the different versions of 'human nature' (R. Miller, 1992, p. 280). As an alternative, Marx was concerned with what he referred to as "species being", his view on human nature and the essence of humanity (Dean, 2016). Being active is an important element of this nature, in fact Marx considered activities to be definitive of human essence and self-realization. A slogan-like summary of this idea is known from his well-known wish "to do one thing today and another tomorrow, to hunt in the morning, fish in the afternoon, rear cattle in the evening, criticize after dinner, just as I have a mind, without becoming hunter, fisherman, cowherd, or critic" (cited in Hurka, 1987, p. 734).

The consequences of not letting people do "one thing today and another tomorrow" had more severe consequences in the nineteenth century than it has today. Nevertheless, ignoring the importance of varied and meaningful activities may still have devastating consequences to many people on the Globe. Not comparable to the exploitation of child workers, though, a recent example from Norway may illuminate the fundamental problem of ignoring the value of being active. A small group of handicapped people has for years been employed to maintain parks in a city at the west coast. The crew show admirable commitment to their job and being thus active helps structuring the lives and secure enjoyment and meaning for these individuals. The chief municipal executive of this city was, however, dissatisfied with the situation: he figured that the world would be a better placed if the handicapped group was fired and replaced by professional gardeners. Expectedly, this arrangement would create a larger monetary surplus. To the chief municipal executive, as to other believers of economic welfarism, what people do, and how they do it, are irrelevant; economic surplus is the only thing that matters. Fortunately, the City Council voted the proposal down (Lexberg & Frafjord, 2017).

Craftsmanship

The shortcomings of economic welfarism is a reminder, not only about the perils of shrinking the complexity of human lives down to an imagined balance of demands and supplies, but also about the dangers of doing science without theoretical guidance. A proper understanding of what it means for humans to lead good lives can never be established without solid knowledge about what human being are like. In order to live, humans must be active. In order to live well, they must be active in the right way. An excellent illustration of this point comes from Sennett (2008) who, from a sociological and philosophical perspective, has contributed a comprehensive analysis of the activities involved in craftsmanship.

Craftsmanship reflects a kind of work engagement characterized as a "desire to do a job well for its own sake." Working towards excellence under the right circumstances, Sennett tells us, creates a deep satisfaction. Not only with regard to what one is doing and its material products, but also for the person's role as a citizen. In a society of functioning guilds and proper craftsmanship, "Learning to work well enables people to govern themselves and so become good citizens" (Sennett, 2008, p. 268). The nourishment of a fine rhythm between problem solving and problem finding is a crucial element of the experience. Since skill development is an enduring process that involves a constant refinement of the craftsman's ability to perceiving crucial details in nuanced ways, solving one problem often points to another. Such a dynamic generates a constant improvement in individual skills and in the knowledge commonly held by a society of craftsmen. But this openness to improvement is, according to Sennett, antagonistic to much of the modern work life, which is enforced upon a growing number of people by the pressures of an impersonal market and an over-bureaucratic state. In contrast to the marked way of thinking, with its focus on getting things done, craftsmanship operates in line with the ideal of getting it right or making it beautiful. Managing complex activities require task-specific rhythms, and sometimes these are slow and repetitive. Acting slowly and repetitively will in turn stimulate professional reflection and self-criticism. These are critical elements of skill development, and if the internally driven struggle for excellence is taken away by a top-down driven management regime, the opportunities for skill-development and professional reflection disappears. This essence of craftsmanship disappears if one push for quick results.

Psychological Approaches

To a psychologist, craftsmanship sounds a bit like intrinsic motivation. For instance, a sense of craft has been described as becoming "engaged in the work in and for itself," and craftsmanship is supposed to occur when "the satisfactions of working are their own reward" (Sennett, 2008, p. 27). These characteristics resembles those typically listed to describe intrinsic motivation, as in Berlyne's (1960) definition of it as "motivation in which the rewards were inherent in the activity," or in Ryan and Deci's terminology as "behavior done for its inherent satisfactions" (2008, p. 655). Moreover, since the term was coined by Harlow (1950), the argument that intrinsically motivated behavior prompts learning and skill-development has been an integrated part of the concept.[4] In other words, both craftsmanship and intrinsic motivation have been presented as prototypical examples of the Aristotelian ideal about "being well and

doing well in being well." Hence, the concept of intrinsic motivation aspires to contribute the best psychological account of the relationship between activities and wellbeing. From a variety of psychological theories with relevance for intrinsic motivation, four will be presented in this section (for more comprehensive reviews, see Deci, 1975; Deci, Koestner, & Ryan, 1999; Eccles & Wigfield, 2002; Eckblad, 1981; Eisenberger, Pierce, & Cameron, 1999; Gerhart & Fang, 2015; Lepper, Henderlong, & Gingras, 1999; Oudeyer & Kaplan, 2007; Renninger & Hidi, 2016; Ryan, 2012; Ryan & Deci, 2017).

Internal Motivation

The concept of internal motivation has clear overlaps with the idea of craftsmanship. For instance, it shares with Sennett the idea that a well performed activity has a structure that associates it with the concept of good. Although it is presented in slight opposition to the mainstream work on intrinsic motivation, the theory of internal motivation is an activity theory, and at an overarching level, it might even be permissible to categorize at as a kind of an intrinsic motivation theory.

The concept of internal motivation has been develop by Schwartz and colleagues, in the spirit of Aristotelian eudaimonism (e.g., Schwartz, 2015; Schwartz & Wrzesniewski, 2016). Its approach to wellbeing is based in the pursuit of excellent activities, and the authors argue that the traditional perspective on intrinsic motivation is too narrow to properly explain the association between activities and wellbeing. To improve this state of affairs, the theory of internal motivation appeals to the Aristotelian concept of telos, and to MacIntyre's (2007) concept of a practice. The theory argues that the Aristotelian ideal of "doing the right thing, at the right time, in the right way, for the right reasons" provides a better framework for analyzing good lives, than does the mainstream idea of intrinsic motivation. The latter is restricted to activities for which a pleasant feeling is the very purpose of the activity—the pleasant experience becomes an end in itself. In such a perspective, the important relationships between motives, actions and their consequences are overlooked. This neglect has serious consequences for the understanding of wellbeing. Here is a brief resume of what Schwartz and colleagues propose as an alternative.

Telos specifies what counts as excellence in an activity. For instance, the telos of a builder is to produce excellent buildings and the telos of a doctor is to cure disease. The telos thus provides an activity with meaning and direction. The theory of internal motivation is also indebted to MacIntyre and his concept of practice. MacIntyre is a neo-Aristotelian who sticks with the idea that it is only because "human beings have an end towards which they are directed by reason of their specific nature, that practices, traditions, and the like are able to function as they do" (MacIntyre, 2007, Prologue). The concept of a practice is further defined as "any coherent and complex form of socially established cooperative human activity through which goods internal to that form of activity are realized in the course of trying to achieve those standards of excellence which are appropriate to, and partially definitive of, that form of activity, with the result that human powers to achieve excellence, and human conceptions of the ends and goods involved, are systematically extended" (MacIntyre, 2007, p. 175).

Surely, this definition is quite a mouthful and it leaves the impression of a very abstract phenomenon. But the concept of practice comprises a very promising and rather concrete idea. It is that the proper value of an activity is only available through the achievements and satisfactions inherent to the practice that defines the framework of the activity. Without goods internal the activity itself, behaviors become little less than technical performances. In liberal democracies, for example, politics cannot be good unless it is motivated by a genuine wish for societal improvement. Without this aim, politics declines to empty rhetoric and cynical fights for power (Boyle, 1987).

Teaching is another example of how excellent activities cannot be guided by just any kind of goals. For a teacher, making a salary can be important, but it will never be the telos of teaching—excellent teaching cannot be measured by the income it produces. It can only be evaluated against the learning it generates; what students learn and how they develop as human beings. Besides, there are many ways to earn money, and teaching is only one among many option (and probably not a very efficient one either). It seems clear to us, Schwartz and Wrzesniewski (2016, p. 130) summarize, "that some goods are only attainable through the particular activity, some are attainable through the activity but also some others (they are internal to success at a practice, but not unique to it), and some are completely arbitrary in their relation to a practice."

Flow Theory

Another theory of intrinsic motivation, broadly defined, is flow theory (Csikszentmihalyi, 1975, 2014). It is the only example of a psychological activity theory of wellbeing mentioned in Diener's 1984 review. According to the description given in that article, a person who is involved in an activity that demands intense concentration will typically experience a pleasurable feeling, a flow experience, as long as the person's skills and the challenge of the task are roughly equal. After more than 40 years of research, this conceptualization has not changed much and Diener's description still reflects the standard understanding

of a flow experience, although the term pleasurable is often replaced with the term enjoyment (e.g., Seligman & Csikszentmihalyi, 2000).

There are some links between Aristotelian eudaimonism and flow theory. For instance, Csikszentmihalyi (1975) explains that flow represents optimal psychological states because when a flow state occurs, people both develop their potentials and feel great at the same time. This idea shares some conceptual territory with the "being well and doing well in being well" kind of eudaimonia defended by MacIntyre (2007). However, Csikszentmihalyi is a bit unclear when it comes to the feeling quality of a flow experience. Sometimes the feeling of flow is presented as intensely positive, like "pleasure, happiness, satisfaction, enjoyment" (Csikszentmihalyi, 1992, p. 24). In other contexts, flow is depictured as a state without any feelings at all: "Strictly speaking, during the experience people are not necessarily happy because they are too involved in the task to have the luxury to reflect on their subjective states. Being happy would be a distraction, an interruption of the flow. But afterward, when the experience is over, people report having been in as positive a state as it is possible to feel." (Csikszentmihalyi, 1999, p. 825). The latter position indicates that the state of flow is thwarting rather than generating good feelings.

Scholars have also questioned the assumption that flow experiences contribute to skill development. Detailed studies of learning in adults suggest that several of the criteria that are necessary for skills to develop are in conflict with the principles of flow (e.g., Ericsson & Charness, 1994). For instance, tedious repetitions and a constant and uncomfortable focus on the errors one makes are essential for skill development but devastating for flow. Studies that compare low performers with high performers show that the latter report fewer occasions of joyful experiences than the lower performers (Ericsson & Charness, 1994). Actually, Ericsson has declared the characteristics of flow to be inconsistent with the process involved in the acquisition of high-level skills (Ericsson, 1996, p. 25).

Another knotty aspect of the flow theory relates to its motivational properties. The problem comes to light in the model typically offered to account for how flow experiences are initiated and maintained (e.g., Csikszentmihalyi, 1975; Rathunde & Csikszentmihalyi, 2006). The model articulates a dynamics between challenges and skills on the one hand, and the feelings of anxiety, boredom and flow on the other. Graphically, this interplay is depicted in a two-dimensional diagram that can be likened to a stairway, leading upwards from left to right. The horizontal dimension reflects a person's skills, which increase as he or she moves to the right. The vertical dimension reflects the challenge afforded by the situation (up means more challenges). Moving horizontally denotes developing skills without increasing the level of challenges. Moving straight up indicates increasing levels of challenges without increasing the level of skills. In terms of feeling qualities, rightward movement creates boredom and upward movement creates anxiety.[5]

A challenges-skills balance implies that a person is properly equipped to cope with the situation at hand—learning, in other words, is not necessary. Consequently, the model suggests that skill improvement only occurs when a person moves into the zone of boredom, and not really during flow. The boredom may, however, motivates a search for higher challenges (an upward move), in which case a flow experience is likely to occur. Note that this is a hedonic escape maneuver (avoiding a negative experience). Approaching flow from a challenging situation imposes avoidance motivation as well. Being in challenges-higher-than-skills position, which really is an opportunity to learn, creates anxiety in the flow model. It is this negative feeling that pushes the individual away from its current position, either as a downward rescue away from the learning opportunity, or rightwards towards skill development. Hence, skills may also be improved during states of anxiety, but once a balance between challenges and skills is established and flow kicks in, the development of skills stops. The only way to continue to learn, is by moving into a state of boredom.

An alternative idea would be that flow results, not from an equilibrium between challenges and skills, but rather when challenges are somewhat higher than skills. Such an "imbalance model" of flow has been proposed by Løvoll and Vittersø (2014). What is gained by an imbalance model is first, the possibility of having a flow state that is motivated by the positive feelings inherent in the flow experience itself (this model assumes that people are actually experiencing intense feeling during the flow state, and not just afterwards). The imbalance model further assumes that it is the slightly higher level of challenges that motivates a person to keep working to overcome the difficulty at hand. When a person is in flow, this urge to cope with a challenge is experienced as something positive, something the person really wants to do. Second, when a challenge is above one's skills, a learning opportunity is immediately available, because one's skills must improve in order to cope with the situation.

A last limitation in flow theory worth mentioning, relates to the nature of activities that are familiar and even repetitious. A series of theories point out that repetitions are not only important for skill development, but also that they sometimes create good feelings and opportunities for reflection (e.g., Eckblad, 1981; Montessori, 1948; Piaget, 1952; Sennett, 2008; Whitehouse, 2004). Csikszentmihalyi claims that "Unless

people get better at what they are doing, they can't enjoy doing it any longer" (Csikszentmihalyi, 1992, p. 262). Several research paradigms have nevertheless convincingly documented how automatized and easy activities are the ones we enjoy most (Hill & Schneider, 2006; Winkielman, Schwarz, Fazendeiro, & Reber, 2003; Zajonc, 1980). For instance, when a grown-up is introduced to a new leisure activity, he or she will typically focus on skill-development for a rather short period of time. Normally, less than 50 hours will be devoted to this phase of effortful exercises. As soon as an acceptable level of proficiency has been established, the person will happily practice this activity without any skill improvement for the rest of his or her life. At this "everyday skills" level, performance has basically become automated and individuals will be satisfied by carrying out the activity with minimal effort, and without further learning (Ericsson, 1996).

Most of the activities we enjoy are automatized and do not facilitate learning. Thus, the interesting question is not whether improvement is a prerequisite for doing something joyfully or not. We know activities can be joyful even if they don't lead to any skill improvements. We also know that skill development typically requires unpleasantly high levels of efforts. The promise of intrinsic motivation, however, is that given the right circumstances, adults can *sometimes* enter a state in which they both feel intensely positive and develop their skills at the same time. Two theories defending this view, although offering different explanations as to why it happens, will be presented next.

Self-Determination Theory

A popular approach that meets the criteria for activity theories of wellbeing is the Self-determination theory (SDT; Deci & Ryan, 1985, 2000; Ryan & Martela, 2016), a wellbeing theory that at least partly draws on Aristotelian eudaimonism (Ryan, Curren, & Deci, 2013). An original idea in the SDT is that humans have an inherent tendency toward organismic growth, and that this growth is regulated by three psychological needs, known as competence, autonomy and relatedness. By organismic Deci and Ryan mean "a fundamental human trajectory toward vitality, integration, and health" (Deci & Ryan, 2000, p. 229), and a need is defined as a psychological entity that "specify the necessary conditions for psychological growth, integrity, and well-being" (Deci & Ryan, 2000, p. 227). The needs are not fulfilled physiologically, but phenomenologically. For example, in order to satisfy the need for competence, a person must *feel* competent. Similarly, feeling autonomy/relatedness is necessary and sufficient to satisfy the need for autonomy/relatedness (Deci & Ryan, 2000; Ryan & Deci, 2008). The theory further suggests that an individual who acts in certain ways toward certain goals will experience feelings of competence/autonomy/relatedness. However, these feelings are not themselves a part of the concept of wellbeing. They are causes of wellbeing. What count as wellbeing in the SDT is a different set of feelings, such as satisfaction/a fuller sense of satisfaction/happiness/happiness in the fullest sense/vitality/fulfillment/thriving/ wellness/integrity/wholeness, which is but a sample of the terms used to describe wellbeing in Ryan and Martela (2016).

Although the SDT is inspired by Aristotle—Deci and Ryan argue that the principle elements of Aristotle's view are modeled in SDT (Ryan et al., 2013)—there are some confusing discrepancies between Aristotelian ideas on wellbeing, and those proposed by the SDT. The next section discusses one of these discrepancies.

In his search for a principal reasoning on the human good, Aristotle came up with the idea that arête, or excellent functioning, could provide a framework for the conceptualization of goodness. An important premise in his functioning argument is that if something functions in accordance with its natural telos, then we can call that functioning good. A sharp knife is a good knife, just as an eye that sees well is a good eye. On this basis it can be inferred that humans also can be categorized as good when they function excellently. Some parts of the writings of Deci, Ryan and their many collaborators are in agreement with this Aristotelian principle. For example, Ryan, Curran and Deci claim that "human potentialities whose fulfillment is essential to well-being and happiness—potentialities whose fulfillment *constitutes* (italics added) the good" (Ryan et al., 2013, p. 57). The authors continue: "the eudaimonist conception of well-being or flourishing rests on the proposition that what is most subjectively satisfying over the course of a life is activity that develops and expresses one's most reflectively valued and well integrated human potentialities. According to this view, pleasure accompanies activities that fulfill human intellectual, social, and productive potentials in good and admirable ways, even though pleasure is not the aim of such activities." (p. 58). Both phrases clearly explain that activities that fulfill human potentials constitutes wellbeing ("the good life").

Somewhat later in the same chapter, however, the authors seem to have changed their minds. Now they argue that eudaimonic activities are not really a part of wellbeing after all. Eudaimonia is just a precursor of wellbeing, an antecedent of the good life. "Central to our considerations is distinguishing between eudaimonia as a way of living and positive affect as a hedonic outcome." (Ryan et al., 2013, p. 60).

Optimal functioning is in other words not good in itself, it is just the cause of goodness. This split between functioning and wellbeing is even more articulated in a more recent chapter by Ryan and Martela: "We argue that eudaimonia should not be understood as referring to any kind of subjective experience or 'richer feeling of happiness' but is rather about a good and valued way of living that can produce happiness, vitality and wellness as its byproducts" (Ryan & Martela, 2016, the abstract). These authors also proclaim that "eudaimonia is rather a depiction of the kinds of pursuits and a manner of living that would most reliably *give rise to* (italics added) a life accompanied by a sense of wellness, vitality and thriving." (p. 111).

In contrast to Aristotelian eudaimonism—in which the most essential argument is that wellbeing is the endpoint or ultimate goal of all human activities—the SDT proposes that eudaimonia isn't that endpoint at all. It is just a mean to reach the endpoint. The endpoint itself, i.e., wellbeing, is, according to the SDT, a broad set of positive feeling states.

Another controversy in the SDT concerns the use psychological needs to account for intrinsically motivated behavior. The authors suggest that the concept of psychological needs is particularly useful when it comes to explain how the introduction of a reward, lack of control or secure attachment seem to undermine intrinsic motivation. However, there is a literature that goes against this position, on several grounds. For example, the category of intrinsically motivated behaviors is much broader than typically discussed by Deci and Ryan. Their focus was initially on relatively simple "free-choice" laboratory tasks or some kind of self-reports behavior. Over the years, other kinds of intrinsically motivated behaviors have been studies from the perspective of SDT (see Ryan & Deci, 2017, for an extended overview), but these activities are still considered as means towards the goal of satisfying a need, and not as an end in themselves. However, many of the most interesting intrinsically motivated behaviors are neither captured by a free-choice laboratory test, nor conducted in order to satisfy a need. Rather, such activities occur spontaneously, can last for long periods of time, and—importantly—they don't seem to be regulated by any kind of need or drive. For instance, in a seminal analysis Koch (1956) insisted that when it comes to intrinsically motivated behavior, the concept of needs would maintain an artificial externality that never could explain the true mechanisms of intrinsic motivation. Similarly, White (1959) showed in his well-known text on effectance motivation that the concept of needs (at least in the sense of states of deficiency) cannot explain intrinsic motivation. White's idea was that inherent feelings of competence came as a result of effective functioning itself, not from the satisfaction of a particular need. Put simply, if an activity is rewarding in and by itself, the concept of needs is redundant.

Actually, needs seem to make the explanation of intrinsic motivation unnecessary complicated, it is as if a wedge has been driven in between activities and wellbeing. Rather than argue, as will be done below, that wellbeing is an integrated part of being active, the concept of need implies a series of complicating steps. First, only activities that are able to fulfill the psychological needs has the power to motivate people intrinsically. Second, the activity will not be intrinsically motivating by the mere presence of positive feelings such as pleasure, satisfaction, interest or curiosity. Actually, pleasant feelings can, according to the SDT, terminate an intrinsically motivated behavior (see Deci, 1975). Finally, the feelings of autonomy, competence, and connectedness are not signs of wellbeing in themselves; they are only triggering something that later on will be experienced as positive affect, fulfillment, life satisfaction, happiness, thriving, wellness, meaning, vitality, depth or any other of the many experiences that SDT holds as indicators of wellbeing. A simpler explanation of intrinsic motivation is offered in the Functional wellbeing approach to be presented next.

The Functional Wellbeing Approach

The functional wellbeing approach (FWA; Vittersø, 2013a, 2013b; Vittersø, 2016a) is an activity theory of wellbeing in the sense that it proposes a set of mechanisms that identify activities with the state of being well. The approach assumes that wellbeing is best conceptualized as an integrated part of human psychology, particularly with regard to the adaptation and regulation of behavior. There are two major processes of adaptation in living organisms; the regulation of stability and the regulation of change. Accordingly, the FWA suggests that the wellbeing associated with these types of adaptation also come in two forms, referred to as hedonic and eudemonic wellbeing respectively. This structure is depicted in Figure 1.

Hedonic wellbeing (HWB) has to do with pleasure, which is a particular kind of subjective good-bad evaluations. There are two important types of hedonic wellbeing felt pleasure and attitudinal pleasure.[6] Attitudinal pleasure is the same as life satisfaction.[7]

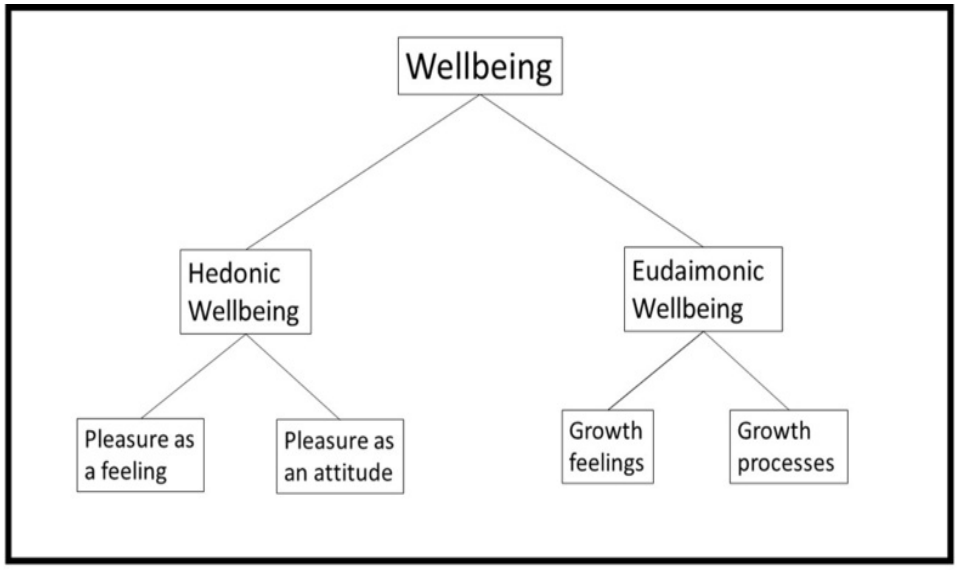

Figure 1. The taxonomy of human wellbeing proposed by the Functional wellbeing approach.

Felt pleasure and attitudinal pleasure have much in common, but they are also different enough to be represented as separate categories at the third level of a wellbeing taxonomy. Felt pleasure is sometimes referred to as being happy **in** your life, whereas attitudinal pleasure is referred to as being happy **with** your life (Vittersø, 2016b). In terms of (optimal) functioning, the major role of HWB is to regulate stability according to the general principles of homeostasis. Briefly, the principle suggests that biological, psychological and social states of disequilibrium will produce feelings of displeasure, which initiate behavior intended to reestablish equilibrium. When the homeostatic balance is regained, we feel pleased. Pleasure is in other words the signal that evolution has developed to communicate to our minds that equilibrium is reestablished and that we currently are well off. A similar mechanism works at the mental level for striving towards, and reaching goals. Hence, HWB covers communication about both need fulfillment and goal achievement. The fulfillment of needs and the accomplishment of goals are both indicating good functioning, thus high HWB reflects a state of well-functioning stability.

The role of eudaimonic wellbeing (EWB) is to regulate change. All complex organisms must be altered in order to survive and according to the FWA, these changes are regulated by a different mechanisms and feelings than those associated with stability. For example, the phenomenology characterizing the process of change can sometimes (but certainly not always) be positive. When that happens, we feel engagement, curiosity, interest and sometimes awe rather than pleasure or satisfaction. The function of eudaimonic experiences is to motivate departures from the comfort zone of pleasant stability, and it operates through a feeling of being absorbed in the task of overcoming a challenge. This allows for biological, psychological and social growth processes and explains why EWB sometimes is described as being happy **fulfilling** your life (Vittersø, 2016b).

Growth processes include certain feeling states, but are not limited to these. Just as life satisfaction reflects a trait element in HWB, there is a trait element in the EWB dimension as well. It facilitates learning and development and is referred to as personal growth. The concept is undeniably a somewhat confusing one (Vittersø & Straume, 2017), but hopefully, more research will make the idea more coherent. In the FWA, personal growth includes some objective element, like moral development. The EWB part of the Functional wellbeing approach thus comprises a combination of subjective and objective criteria, a pattern that has been called a "sobjective" perspective (MacLeod, 2015). This implies that it is not entirely up to the individual to judge whether he or she is growing as a human being. Consequently, self-reports will never be able to fully capture the concept of personal growth. Note also that the growth processes in the FWA include goals and plans for reaching these goals that appear more or less meaningful for a person, which means that the concept of purpose or meaning in life is included in this category.

There are some principal similarities between the FWA and Aristotle's conceptualization of goodness, primarily related to the idea of developing one's potentials *qua* human beings. Although the FWA does not subscribe to the idea that every disposition that appears "natural" is good (e.g., Thin, 2016), it does agree with the description of EWB as "man-as-he-could-be-if-he-realized-his-essential-nature," in contrast to the "man-as-he-happens-to-be" nature of HWB (cf. MacIntyre, 2007).

The influence from Piaget. The FWA builds on Piaget (e.g., 1952, 1971). The influence comes in particular from the connection identified by Piaget between activities and feelings, and from his ideas about needs. General knowledge of biological structures and adaptation enabled Piaget to dissociate the concept of needs from the performance of certain behaviors. It is because the movements involved in an activity already are directed, Piaget pointed out (Piaget, 1952, p. 45), that they are set in motion in the first place. Needs cannot fully account for human behavior because "a need does not explain how the movement necessary for its satisfaction is directed" (Piaget, 1952, p. 44).

To further grasp what Piaget had in mind when he asserted that an activity could be initiated and maintained without reference to the concept of needs, his theory on how activities are organized around a schema is important. When an organism has a structure available, Piaget reasoned, there will be "a basic tendency to exercise the structure, that is, to make it function" (Ginsburg & Opper, 1969, p. 30). The mere acting on these structures had what Piaget referred to as functional meaning, which is to say that the act has "a value for the subject himself. But whence comes this value? From functioning as such" (Piaget, 1952, p. 42). This perspective allows for activities to be reinforced by themselves. Note that Piaget also considered repetition of an acting structure as a necessity for all forms of life, and that some repetitions had functional meaning. Both Sennett's work on craftsmanship (Sennett, 2008) and observations made by Montessori (1948) corroborate Piaget's view on repetitive activities.

A final Piagetian concept worth mentioning is the moderate novelty principle. It suggests that we feel most interested when interacting with stimuli that bears some relevance to what we already know, but at the same time is sufficiently novel to present incongruities and conflicts to the existing structures. Since these new observations do not assimilate easily, they are met with "a resistance which is imposed by the reality of the objects themselves" (Ginsburg & Opper, 1969, p. 59).

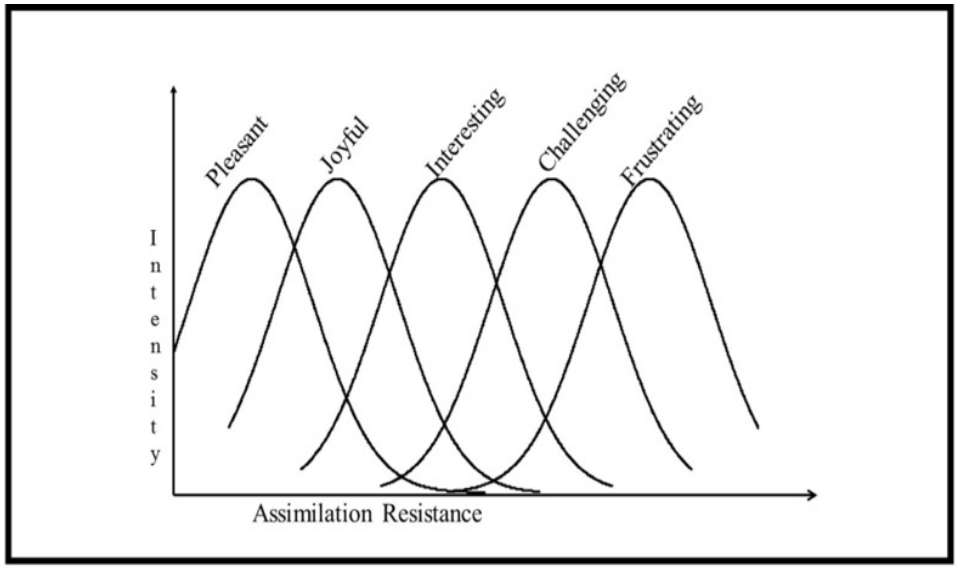

Figure 2. The single-peaked intensity principle in Eckblad's Scheme theory.

The influence from Eckblad. The idea that feelings could be generated directly from an activity that has been initiated by a discrepancy between a cognitive structures and the resistance offered by the circumstances was further developed by Eckblad (1981). By analogy to the Wundt curve—which suggests that pleasure is a curvilinear function of arousal, with maximum pleasure produced at some optimal level of arousal[8]— she developed a multi-curve model in which distinct feelings reached their most intense expressions at increasingly higher levels of assimilation resistance. Thus, each feeling state has "a single-peaked preference function for any given complexity dimension" (Eckblad, 1981, p. 97). The idea is laid out graphically in Figure 2, illustrating for instance how pleasure typically will be experienced at low levels of assimilation resistance. Feelings of joy will kick in at somewhat higher levels, whereas the phenomenological responses to high levels of assimilation resistance are those of interest, curiosity and challenge. The assimilation resistance can also be overwhelmingly high, in which cases feelings like frustration, chaos and perhaps anxiety will be prompted. A more detailed account of these processes is provided by Eckblad (1981, Chapters 2 and 3).

The influence from appraisal theories. Piaget's theory and the additions suggested by Eckblad explains how an activity by itself can generate feelings of different qualities. This account is adopted by

the FWA, into a model that also includes feelings generated according to the principles of appraisal theories of emotions (Lazarus, 1991; Oatley, 1992; Scherer, Schorr, & Johnstone, 2001; C. A. Smith & Ellsworth, 1985).[9] These theories hold the view that emotions are evaluative responses to challenges or opportunities regarding goals that are important to us. As a part of the process, and approaching a novel situation, some kind of a primary appraisal will take place, which is to say that a person will check if the situation is relevant and congruent with his or her goals (Lazarus, 1991, p. 133).

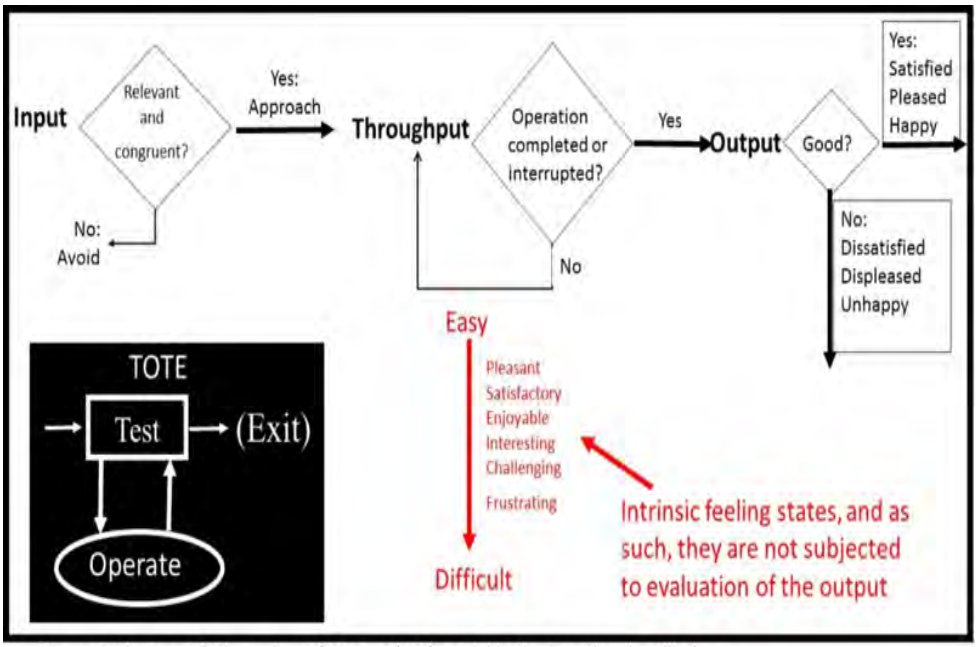

Figure 3. The Input→Throughput→Output (ITO) model in the Functional wellbeing approach. The TOTE model in the lower, left corner is not a part of the ITO model.

Figure 3 illustrates what Piaget and Eckblad refer to as a "totality", which includes both the ongoing activity and the goal of that activity. The mid part of the figure reflects the ongoing activity, the "throughput" in the Input-Throughput-Output (ITO) scheme. The input and output feelings involve evaluations, whereas the throughput feelings do not. They follow the principles of functional assimilation. To illustrate how this may be integrated in a totality, the classical Test-Operate-Test-Exit or TOTE scheme may be of assistance (G. A. Miller, Galanter, & Pribram, 1960). The test procedure involved in TOTE is illustrated in the black frame at the lower left part of Figure 3, and it is regulated by "some criteria established in the organism, to respond if the result of the test is to show incongruity, and to continue to respond until the incongruity vanishes, at which time the reflex is terminated." (G. A. Miller et al., 1960, p. 26).

The idea proposed by the FWA is that as long as one's attention is focused on the operation itself (oval circle in the TOTE box) it is the feelings generated by the functional assimilation process that will be phenomenologically dominant. Intense attentions at the ongoing activity prevents rapid shifts between operation and testing to reach consciousness. Hence, the testing phase will not interfere with the focused attention unless there is a dramatic shift in progress towards, or a retreat away from, the goal of the totality. This lack of interference with the focused activity is the explanation offered for why the feelings of intrinsically motivated behavior and flow can be very intense and lasting. The effect of shutting out disrupting impulses to conscious awareness is referred to as stimulus gating (Elkind, 1971). It is also described by Goffman (1961), who used the term "semipermeable membrane" to explain the phenomenon.

The Future of Activity Theories

The present chapter has discussed strengths and weaknesses of some activity theories of wellbeing. A few possible directions for further research and theorizing are worth mentioning. Chief among these concerns is the development of better concepts.

Some of the major concepts in the activity theories are somewhat outdated. Aristotle's thinking runs thousands of years back. They are difficult to operationalize scientifically and are hardly tested empirically. Still, psychological theories on activity and wellbeing build, at least in part, on some of these ideas. And even if modern activity theories have integrated more recent science into their bodies of knowledge, they

still appear slightly segregated and theoretically old-fashioned. Many of their core concepts were developed more than half a century ago. Hence, conceptual renovations, and in some cases even a theoretical restart, will probably make the approaches more complete and better able to explain the dynamics between the doing parts and the wellbeing parts of human lives. After all, scientific progress consists primarily in refining one's concepts and departing from the outdated ones (e.g., Mayr, 1982).

Economic welfarism is the approach that most urgently needs to change. Research and real life episodes have revealed how this line of though suffers from overly reductionism and surprisingly high levels of errors when making predictions (e.g., Chang, 2012; Ferguson, 2012; Jordan, 2008; Kwak, 2017; Loewenstein, Rick, & Cohen, 2008; Scitovsky, 1992; Skidelsky & Skidelsky, 2013). Using the vocabulary of Kuhn (1970), nothing less than a scientific revolution seems necessary in order to get the mainstream thinking in economic welfarism straight.

Psychological theories need improvements as well. For example, the core concepts of FWA are vague. The notion of a schema has rightfully been criticized for being too broad and imprecise (e.g., Neisser, 1994) and much of the empirical evidence in Piaget's work comes from the study of children. In the years to come, a better integration of general knowledge from cognitive and emotional sciences, including new ways of measuring on-line mental states and feeling qualities will be help strengthening the assumptions made by the FWA and move the approach forward. Another important challenge for future developments on the FWA is to integrate recent attainments in research on the social and moral nature of human beings into the cognitive-emotional framework of the theory.

Self-determination theory has a successful record of assimilating new knowledge into their theoretical framework. It has been less progressive when it comes to accommodating its core concepts. The idea of an organismic nature, or being naturally inclined towards growth, is an example in case. One of the unsolved puzzles here concerns the specific meaning of a "natural inclination towards growth and integration". Another difficult concept is that of psychological needs. At a general level, the notion makes a lot of sense. When needs are not met, we intuitively infer that something negative is about to happen. However, on a more specific footing the notion runs into trouble. For instance, each of the three needs are sweeping very broad, the criteria to have them satisfied are hard to measure with sufficient precision, and the potential conflicts between them are not properly accounted for. The Self-determination theory will gain from further clarifications of these issues.

After 40 years of research, the core concepts of flow theory have hardly changed. Terms like challenges and skills and the balance between them were hard to pin down when the theory was born, and they continue to be so. As a consequence, we still don't know when and even if flow has been validly measured. The proposal that a balance between challenges and skills prompts people to develop their skills is also controversial, and research specifically tailored to back up this idea is needed. More work is also required in order to understand what it really feels like to be in flow. Does it occur in a phenomenological vacuum, or is it filled with intense experiences? Self-reports may not be precise enough to clarify the problem, even when they are collected by the so-called "gold standard" of experience sampling methods. Thus, the development of better methodologies is an important avenue for future research.

Finally, the Internal motivation theory offers important insights on how activities, wellbeing and good societies are interrelated. However, it may fall short of explaining the psychology of intrinsic motivation as classically defined. Occasionally humans act, sometimes even for substantial periods of time, without keeping the aim of that activity in mind. It seems likely that these instances are important to many people, they may even be essential for optimal functioning. These features of human lives call for a theoretical account.

Conclusions

The idea that good living involves good acting is old. This way of thinking was, however, outmaneuvered by the philosophies of deontology and consequentialism/ utilitarianism during the Enlightenment. In the nineteenth century, utilitarianism advanced into economic welfarism, which seems to be the hegemonic wellbeing ideology among politicians and decision makers today. Welfarism defines wellbeing in terms of money and commodities, more specifically as the optimal balance between demand and supply as these are regulated on a marked. In its most radical form, welfarism argues that this equilibrium is all one needs to care about when it comes to wellbeing. As a consequence, human activities are reduced to economic activities and insights into human nature are deflated to beliefs about commodities.

Against this background, the promise of activity theories is two-fold. First, by detailing how good lives by necessity include opportunities to act in accordance with certain aims and rhythms, they contribute general knowledge to the science of wellbeing. Second, by means of this knowledge, activity theories can be precise in predicting how and why wellbeing will be reduced if the doing part of our lives are ignored or reduced to economic performance.

Although much work remains in order to get the details straight, activity theories are well on their way to give reliable descriptions of what states of wellbeing look like, to explain why these states are good for us, and to predict the consequences of changes in the basic structure of these states. That is not a bad accomplishment for a group of scientific theories.

Footnotes

[1]Terms like wellbeing and happiness are used in many different ways, but in compliance with the mainstream literature on subjective wellbeing, I use them as synonyms in this chapter. In psychology, happiness is also frequently use to denote a relatively brief feeling of intense joy or even "satisfaction in the fullest sense". In philosophical literature, the term happiness has a much broader meaning (Badhwar, 2014; Bishop, 2015; Bradley, 2015; Haybron, 2017; Hurka, 2011)

[2]Philosophers sometime add the phrase "for the person who's life it is" to this definition. They do this to clarify that wellbeing is a so-called prudential value—and not a moral or other kind of value (e.g., Griffin, 1986). The prudential perspective might inflict an unnecessarily individualistic constrain on the concept of wellbeing, though, since humans are such ultra-social and morally oriented animals that it is hard to conceive of human goodness as a private property.

[3]Whatever that may imply. For instance, how "voluntarily" is the "demand" for food for a hungry person and the "demand" for medicine for someone seriously ill? Roman law developed a term for this illusionary idea of freedom; 'coactus volui'. The English translation goes something like "Having been forced, I was willing", or more fully "though I would not have been willing had it been freely offered, nevertheless, having been forced, I was willing." *(https://en.m.wikibooks.org/wiki/Annotations_to_James_Joyce%27s_Ulysses/Wandering_Rocks/240)*

[4]Elkind (1971) made a distinction between learning as the outcome of extrinsic motivation and development as the outcome of intrinsic motivation. This distinction is not used in the present text.

[5]Given that the position held before the movement starts is a state of balances between challenges and skills.

[6]Terms like cognitive or evaluative wellbeing are used more frequently than attitudinal pleasure to name this dimension of wellbeing. But evaluations involve both affective and cognitive elements of information processing, and they are also involved in many kinds of psychological processes. Some of these are very brief and state like. Hence, the term attitude is preferred in the FWA to underscore the trait like nature of overall good-bad evaluation. After all, the essential component of an attitude is an evaluation along an affective good-bad dimension (e.g., Eagly & Chaiken, 1993).

[7]Satisfaction can be specified at a lower and more specific level in a taxonomy of wellbeing, typically referred to as domain satisfaction (e.g., Diener, Scollon, & Lucas, 2009)

[8]Note that the Wundt curve is incommensurable with the affect circumplex (Russell, 1980). In Wundt's model, pleasure *depends* on the level of arousal whereas the circumplex model assumes that the two are independent. Both models are consistent with the low correlation typically observed between pleasure and arousal though, because a curvilinear relation between two variable will also comprise a zero correlation.

[9]In Eckblad (1981, p. 34) a dichotomy akin to the one I have proposed is presented as a division between "spontaneous activity of schemes and disequilibrium proper".

The Way is the Goal: The Role of Goal Focus for Successful Goal Pursuit and Subjective Well-Being

By Oliver J. Kaftan, University of Zurich, Dept. of Psychology; Alexandra M. Freund, University of Zurich, Dept. of Psychology and University Research Priority Program Dynamics of Healthy Aging

Abstract

Goals are considered by some theories as essential for subjective well-being (i.e., telic theories, see Diener, 1984). In fact, achieving goals is beneficial for subjective well-being. However, just holding goals does not bring about goal achievement. Therefore, this chapter highlights the importance of goal *pursuit* (autotelic theories) in addition to goal achievement for a more comprehensive understanding of subjective well-being. We address the question of whether goal progress and attainment are differentially related to subjective well-being and examine how people best pursue their goals. Specifically, we posit that focusing more on the means of goal pursuit (i.e., adopting a process focus) is more beneficial for goal progress and subjective well-being than focusing more on its ends (i.e., adopting an outcome focus). There also exists some evidence that suggests that adopting a process focus is adaptive when people face a particular type of difficulty when intending to pursue a goal, namely procrastination. Given that procrastination hinders successful goal pursuit and subjective well-being, this finding again highlights the importance of goal focus for understanding how people best pursue their goals.

Keywords: Subjective Well-Being, Goals, Goal Pursuit, Goal Focus, Procrastination

Albert Einstein reportedly stated: "If you want to live a happy life, tie it to a goal, not to people or things." In fact, research shows that having a goal, even if we do not reach it, provides us with a sense of direction and meaning (e.g., Emmons, 1996; Klinger, 1977; Little, 1989). This might be best illustrated by another quote, this time from actor and martial arts master Bruce Lee: "A goal is not always meant to be reached, it often serves simply as something to aim at." Setting and pursuing long-term goals that go beyond the immediate gratification of needs such as food or shelter seems central to humans: People live by identifying desirable states they want to achieve (or undesirable ones they want to avoid) for themselves and their lives, and ways of achieving (or avoiding) these states (e.g., Carver & Scheier, 1990; Emmons, 1996; Freund, 2007). In this chapter, we will explore some of the mechanisms by which goals affect subjective well-being.

Goals and Subjective Well-Being

A goal can be defined as the cognitive representation encompassing the linking of means to desired outcomes (Kruglanski et al., 2002). For example, the goal to get a college degree entails desired outcomes (e.g., to get a job, to impress others) and means to attain these outcomes (e.g., to study hard, to resist temptation). Because goals are comprised of means and ends, they might act as channels for new knowledge and organize information in terms of means and ends (e.g., Woike, Lavezzary, & Barsky, 2001). As knowledge structures, goals follow similar principles of activation, change, and organization that have been articulated in reference to knowledge representations in general (e.g., Higgins, 1996).

Goals have been described as building blocks for the accomplishment of a variety of developmental tasks and their achievement is likely to foster long-term patterns of successful development (Freund & Riediger, 2006; Heckhausen, 1999; Ryff, 1989). As pointed out above, goals imbue life with meaning and provide structure and direction (e.g., Emmons, 1996; Klinger, 1977; Little, 1989). Against this backdrop, successful goal pursuit can be linked to both cognitive and affective aspects of subjective well-being, which represent distinct lower order constructs, but also load onto a single higher-order factor of subjective well-being (Lucas, Diener, & Suh, 1996). According to Diener, Lucas, and Oishi (2002), subjective well-being denotes "emotional reactions to events as well as cognitive judgments of satisfaction and fulfillment" (p. 63). There is no systematic investigation into a potential dissociation of affective and cognitive aspects of subjective well-being in relation to goal pursuit and goal achievement. Therefore, we will review the literature linking goals and subjective well-being as it is formulated in theories and with regard to the aspects of subjective well-being that were included in the empirical studies. Note, however, that it would be theoretically very interesting to systematically separate affective and cognitive aspects of subjective well-being and their association with goal pursuit and achievement.

Goals are often seen as essential to the cognitive aspect of well-being, as this evaluation entails the judgment of how well one is doing vis-à-vis important goals. In such telic conceptions of cognitive well-being, satisfaction indicates the degree of goal achievement, which, in turn, is crucial for experiencing life satisfaction (Diener, 1984). In other words: when people achieve goals, they experience satisfaction, when they fail to achieve goals, they experience dissatisfaction (e.g., Brunstein, 1993; Emmons, 1986; Klug & Maier, 2015). This is also in line with control theory of goals (Carver & Scheier, 1990) and goal-setting theory (Locke & Latham, 1990), according to which goals are effective because they indicate the level of performance that is acceptable.

With regard to the affective aspect of subjective well-being, prominent models such as the model of goal-directed emotions (Bagozzi, Baumgartner, & Pieters, 1998) consider anticipatory emotions, as well as emotions tied to the actual outcome of goal pursuit. Anticipatory emotions are elicited by the prospects of goal success or failure (e.g., "If I succeed in achieving my goal of getting a degree, I will feel happy"). Depending on their intensity, anticipatory emotions have a smaller or greater potential to motivate goal-directed actions that are necessary for goal attainment. Goal attainment, in turn, elicits outcome-related emotions (e.g. "Because I have now received the degree, I am happy"). Carver and Scheier (e.g., 1990) assume that the velocity with which we approach desired end states (i.e., how fast we close the gap between the actual and the desired state) is associated with positive affect (or, in the case of insufficient speed of progress, negative affect).

Thus, goals have an important function for the regulation and evaluation of behavior and subjective well-being. However, the link between goals and subjective well-being is complex. On the one hand, evidence from longitudinal studies shows that successful goal striving can boost subjective well-being (Sheldon & Houser-Marko, 2001). On the other hand, and according to the hedonic treadmill theory (Brickman & Campbell, 1971), the positive effects of reaching goals are typically short-lived (Frederick & Loewenstein, 1999). That is, people adapt quickly to good or bad outcomes and return to their baseline levels of happiness (e.g., Bonanno et al., 2002; Bonanno, Wortman, & Nesse, 2004; Brickman, Coates, & Janoff-Bulman, 1978; Lucas, Clark, Georgellis, & Diener, 2003; for limitations of the hedonic treadmill theory, see Diener, Lucas, & Scollon, 2006). Goals can even be understood as having an inherent potential for dissatisfaction. This is because setting goals creates a negative discrepancy between the actual and the desired state. In the same vein, McIntosh and Martin (1992) argued that people who see goal attainment as a prerequisite for their happiness might ruminate in the case of failure, which would lead to negative mood and unhappiness.

In addition, some types of goals bring forth more subjective well-being than others. Two important goal characteristics that affect subjective well-being are *goal content* and whether goals are *approach or avoidance* goals (Carver & Baird, 1998; Kasser & Ryan, 1993). Regarding goal content: goals that satisfy basic psychological needs (e.g., to belong) and that converge with underlying motives (e.g., affiliation) are more likely to lead to emotional well-being (Brunstein, Schultheiss, & Grässman, 1998; Deci & Ryan, 2008). However, in the case of failure, they also have a stronger negative effect on subsequent subjective well-being (Sheldon et al., 2010).

Beginning with William James (1890), there is a long and rich tradition of research on approach and avoidance motivation and goals, that was reflected in learning theories (e.g., Hull, Thorndike, Skinner) as well as in motivation theories (e.g., Atkinson, Higgins, Lewin, McClelland). A review of this literature is beyond the scope of this chapter (for an entire handbook on this topic, see Elliot, 2008). Suffice it here to summarize this research very roughly by stating that approach goals are generally related to higher positive emotions and well-being, whereas avoidance goals are related to lower subjective well-being (lower positive mood, less life satisfaction, more anxiety) and performance (e.g., Coats, Janoff-Bulman, & Alpert, 1996; Elliot & Sheldon, 1997; Elliot, Sheldon, & Church, 1997; Emmons, 1996). The lifespan developmental literature has put forth a somewhat different yet related distinction between goals that are oriented towards achieving gains, maintenance, or the avoidance of loss (Freund & Ebner, 2005). This literature shows that adults become more maintenance and loss-avoidant with age, and that this shift seems adaptive when considering the age-differential association of goal-orientation and subjective well-being (for a summary, see Freund, Hennecke, & Mustafić, 2012).

Goal Pursuit and Subjective Well-Being

Despite the evidence for a positive relationship between simply holding goals and subjective well-being, having the right kind of goals is not enough to bring about goal achievement and guarantee well-being (Diener, Suh, Lucas, & Smith, 1999). Thus, important questions in the research on goals are: Are goal progress and attainment differentially related to subjective well-being? How do people best pursue their goals? We will address each of these questions in the next sections.

Differential Effects of Goal Pursuit and Attainment

The idea that goal progress and attainment may be differently related to subjective well-being has its historical roots in the question of whether subjective well-being is brought about by the attainment of desired end states (telic theories) or by the movement toward such end states (autotelic theories). The autotelic perspective has its roots in ancient Greek philosophy as for instance developed by Aristotle, who suggested that positive human experience may lie in the nature of activity itself rather than in any end state toward which such activity might be directed. This thought was seized upon by many classical theorists (for an overview, see Diener, 1984; Omodei & Wearing, 1990) and has led more recent research to explore unique effects of goal pursuit. As mentioned above, Carver and Scheier (1990) drew a direct link between goal progress and emotional well-being by viewing emotions as indicators of distance-reducing processes between actual and desired states. In line with this theory, Hsee and Abelson (1991) found that the *rate of progress* toward one's desired end states, rather than their attainment *per se*, was responsible for differences in affect. Little (2005) posited that positive psychological functioning, which includes subjective well-being, is contingent on the sustainable pursuit of core personal projects. Indeed, a recent meta-analysis (Klug & Maier, 2015) has shown that the association between successful goal striving and subjective well-being was larger when successful goal pursuit was defined as goal progress instead of goal attainment. However, Wiese and Freund (2005) found that subjective progress in the pursuit of personal goals was not (or only weakly) related to subjective well-being (positive and negative affect, satisfaction) but that the degree to which people were involved in pursuing their goals was associated with an increase in subjective well-being over the course of three years.

There is empirical evidence for qualitatively different subjective well-being experiences between goal progress and attainment. Austin and Vancouver (1996) suggested that progressing toward a goal might be associated with a unique "flow"-like (Csikszentmihalyi, 1990) type of affect that is not related to outcome valence. Support for such distinct emotional experiences during goal pursuit and following goal attainment is provided by brain research. For example, Davidson (1994) posited that approach-related affect (e.g., enthusiasm) is usually generated when moving toward a desired goal and associated with an activation of a specific brain region (i.e., the dorsolateral prefrontal cortex). In contrast, positive affect experienced after goal attainment is phenomenologically experienced as contentment and not associated with this brain region. In sum, then, goal pursuit and progress are beneficial to subjective well-being and separate from goal attainment effects (see Wiese, 2007, for an overview). We will next elaborate more on the issue of goal pursuit.

Successful Goal Pursuit

The question how people best pursue their goals concerns the factors that promote successful goal pursuit. Different social psychological models such as the theory of reasoned action (Fishbein, 1980; Fishbein & Ajzen, 1975), the theory of planned behavior (Ajzen, 1985, 1991), and protection motivation theory (Rogers, 1975, 1983) propose that intentions to perform a behavior are the most immediate and important predictor of actual behavior. However, although intentions (e.g., "I intend to get a degree") can predict actual behavior, the intention-behavior consistency is far from perfect (see Sheeran, 2002). This so called 'intention-behavior gap' can be the result of people not having the necessary resources, skills, or cooperation needed to turn commitment into action (Sheeran, Trafimow, & Armitage, 2003).

Often, people fail to cope effectively with problems during goal striving. That is, they may have problems detecting opportunities to act (Kruglanski et al., 2002), shielding goals from distractions (Fishbach, Friedman, & Kruglanski, 2003) or competing goals (Shah, Friedman, & Kruglanski, 2002), and monitoring progress toward goals (Liberman & Dar, 2009). Such difficulties in goal pursuit can be seen as a function of both which goal is selected (i.e., a goal's content) as well as strategies and plans associated with how to pursue and achieve the goal (i.e., goal process). Important dimensions are the concreteness of the goal (both, concerning the means and the ends) and the difficulty of goal pursuit and attainment. Locke and Latham (2002) have summarized the core finding of more than three decades of research on goal-setting theory as showing that specific and challenging goals are best suited to promote goal success as well as subjective satisfaction. However, as Ordóñez, Schweitzer, Galinsky, and Bazerman (2009) have pointed out, setting appropriate goals in this way may be a challenge itself: People may set goals that are too specific or too challenging. Inappropriate goal setting, in turn, may have harmful effects on subjective well-being. For instance, goals can focus attention so narrowly that people neglect other important dimensions in life, or they might set goals that are so difficult that the likelihood of failure is very high.

Problems during goal pursuit might also be due to the use of inefficient means such as a poor strategy to pursue a goal or to a poor implementation of the strategy. When goals are personally highly important, such difficulties in goal pursuit are associated with lower subjective well-being (e.g., Diener, 1984; Emmons, 1986; Little, 1983; Omodei & Wearing, 1990; Palys & Little, 1983; Ruehlman & Wolchik, 1988; Snyder et al., 1996). The obvious question, then, is: What are effective strategies of goal pursuit?

Effective strategies. Different strategies have proven effective to tackle problems during goal pursuit and to positively influence subjective well-being. One of the strategies is mental contrasting of vague positive fantasies of outcomes with the less positive actual state, thereby producing commitment to a more reachable goal and the related involvement in goal pursuit (Oettingen et al., 2009). The actual involvement in goal pursuit is related to the specification and concreteness of the representation of the behavioral steps that have to be undertaken (i.e., implementation intentions; Gollwitzer, Fujita, & Oettingen, 2004). In implementation intentions, people plan the when, where, and how of striving for a goal in the format of "*If* I encounter situation Y, *then* I will perform goal-directed response Z." A wealth of evidence supports the effectiveness of implementation intentions (e.g., Gollwitzer, 1999; Gollwitzer & Brandstätter, 1997; Parks–Stamm, Gollwitzer, & Oettingen, 2007). Combined with mental contrasting, the formation of implementation intentions is even more effective than either of the strategies alone (Adriaanse et al., 2010). Further factors that support goal progress and attainment that have been shown to increase subjective well-being include persistence, self-efficacy, and optimism (e.g., Bandura, 1997; Carver et al., 1993; Emmons, 1996; Freund & Baltes, 1998; Freund & Riediger, 2006; Scheier et al., 1989; Seligman, 1991).

Although goal progress enhances subjective well-being, being able to disengage from goals is also important for the maintenance of subjective well-being (e.g., Brandtstädter & Greve, 1994; Heckhausen & Schulz, 1995): When goals are beyond reach and cannot be attained, people are at risk of compromising their subjective well-being if they do not protect emotional and motivational resources by disengaging from these goals and reengaging in new meaningful goals (Brandtstädter & Renner, 1990; Heckhausen, Wrosch, & Schulz, 2010; Wrosch & Miller, 2009; Wrosch, Miller, Scheier, & de Pontet, 2007; Wrosch, Scheier, Miller, Schulz, & Carver, 2003).

As pointed out above, the representation of goals in terms of concrete goal-relevant actions in a specific context (i.e., implementation intentions) as well as the specificity of outcomes (in contrast to vague fantasies) is important for successful goal pursuit and subjective well-being. However, this research does not address the consequences of focusing more on the process or the outcome of goal pursuit for successful goal pursuit and subjective well-being. We will do so in the remainder of this chapter.

Goal Focus

At the beginning of this chapter, we defined goals as cognitive representations linking means to outcomes of goal pursuit. The concept of goal focus denotes the salience of the means or the process (i.e., *process focus*) and the salience of the ends of goal pursuit (i.e., *outcome focus*) in the representation of a given goal. In other words, process focus is the degree to which a person attends to the aspects of the goal that are related to the means, whereas outcome focus is the degree to which a person attends to the desired outcomes and consequences of goal pursuit (Freund et al., 2012).

As elaborated by Freund and Hennecke (2015), relative to outcomes, means (e.g., running) are typically more proximal and concrete than their more distal and abstract outcomes (e.g., an increased endurance; Carver & Scheier, 1998; Trope & Liberman, 2003; Vallacher & Wegner, 1989). Similarly, the process of goal pursuit takes place in specific situational contexts, whereas outcomes tend to be more decontextualized. For example, a runner must run in specific contexts (e.g., in the woods), while the desired gain in endurance is not context-bound but hopefully generalizes to diverse situations. Another feature distinguishing outcome and process focus is that outcome focus more likely provides a clear standard of comparison between actual and desired states and therefore also for goal achievement: The appropriateness of the means is measured according to the standard set by the outcome—the runner, for instance, is successful only if the running results in the desired gain in endurance; the number of miles he or she is able to run without a break reveals the discrepancy between the desired and the current state. However, different to a focus on the process, outcomes do not offer guidelines for goal-relevant actions (e.g., Emmons, 1996; Klinger, 1977; Little, 1989): Focusing on better endurance does not bring about this outcome (Oettingen, 1996), but focusing on *how* to achieve better endurance is more likely to lead to the necessary running exercises (Gollwitzer, 1999).

Similarities and Differences Between Goal Focus and Related Constructs

In order to introduce the concept of goal focus more fully, the following sections place it in the context of related psychological constructs.

Construal level and psychological distance. Construal level theory posits that the same event, object, or goal can be represented at different levels of abstractness or generality (Trope & Liberman, 2003, 2010). A low-level construal conveys specific features of a stimulus, the implications of which are often context-specific, whereas a high-level construal conveys a more global, de-contextualized representation of the stimulus (e.g., Fujita, Trope, Liberman, & Levin-Sagi, 2006). Moreover, construal level theory assumes that people use increasingly high levels of construal to represent an object as their

psychological (i.e., temporal, social, spatial, or probabilistic) distance from the object increases. However, whereas construal levels denote general mind-sets representing events or goals in more concrete/immediate or abstract/delayed terms, goal focus refers to means-ends relations (Freund & Hennecke, 2015). For example, when a dieter chooses between an apple and a candy bar as a snack, lower level construals would lead the person to focus on the immediate hedonic value and concrete features of the choice (e.g., differences in taste). Therefore, a concrete construal of the two options likely leads to a choice of the candy bar. In contrast, higher levels of construals would lead the dieter to consider the more abstract and delayed health-related implications of each food option. Therefore, an abstract construal of the two options likely leads to the choice of the apple (Fujita & Sasota, 2011). In contrast, goal focus refers to the salience of means and ends *within a given goal*. Whereas the candy bar would likely be judged a good means if the goal is to increase the hedonic enjoyment of food, it would not be considered a good means for a health goal. For a health goal, an apple would likely be represented as a better means than a candy bar (Freund & Hennecke, 2015).

Evidence for the idea that goal focus and concreteness are related but not redundant is also provided by Freund and Hennecke (2012). Although there was a weak to moderate positive association between goal focus and concreteness, goal focus explained unique variance over and above concreteness in a health-related outcome. Moreover, according to construal level theory, people construe goals along a unidimensional continuum from concrete to abstract. In contrast, process and outcome focus are conceptualized as two dimensions. Empirical evidence supports this view: We investigated how process and outcome focus change with an approaching deadline when pursuing an important goal (Kaftan & Freund, 2017a), and found that they evolve asymmetrically over time. In addition, process and outcome focus show a weak positive association, implying that outcome and process focus are two dimensions rather than two opposite poles on one dimension.

Intrinsic and extrinsic motivation. When intrinsically motivated, people engage in activities because they derive satisfaction from the engagement in the activity itself, without concern for its further instrumentality. According to self-determination theory (SDT; Deci & Ryan, 2000), intrinsic motivation is content-based because an intrinsically motivated action serves at least one of three end goals that are essential for achieving and maintaining well-being: autonomy, competence, or relatedness. When extrinsically motivated, people do not act out of interest but because they perceive them as being instrumental to bring about more tangible and separable consequences like a material reward. When extrinsic goals dominate over intrinsic goals, according to SDT, they can distract people from intrinsic endeavors that support their subjective well-being (e.g., Deci & Ryan, 2008).

In contrast, goal focus is mute regarding the underlying reasons for engaging in goal pursuit as both process and outcome focus can be associated with intrinsic or extrinsic motivation (Freund et al., 2012). For example, while reading a paper, a student may focus on highlighting important passages (i.e., process focus) or focus on acquiring new knowledge (i.e., outcome focus). When focusing on highlighting important passages, the student might do so because he or she loves to structure texts with different colors (i.e., intrinsic motivation) or because he or she is positively reinforced for doing so by being paid by another student for highlighting the most important passages of the text (i.e., extrinsic motivation). Similarly, when focusing on acquiring new knowledge, the student might do so because he or she is autonomously interested in understanding new scientific discoveries (i.e., intrinsic motivation) or to impress a teacher with his or her knowledge (i.e., extrinsic motivation).

Intrinsic motivation involves enjoyment of the activity – Rheinberg (1989) describes this as the incentive that lies solely in engaging in the task – and is positively related to positive affect (e.g., Bye, Pushkar, & Conway, 2007). Goal focus, in contrast, is affectively neutral in the sense that it takes on the affective valence that people experience or anticipate when they focus on the process or outcome, respectively. For instance, when a person focuses on highlighting important passages in a paper and experiences this activity as fun, this would likely positively influence her affect, but if she experienced this activity as boring, this would likely negatively impact her affect.

The meaning of the concept of goal focus dissolves in the structure-perspective on intrinsic motivation by Shah and Kruglanski (2000). The authors maintain that intrinsic motivation occurs when an activity (means) and the outcome of this activity (goal) are closely associated such that there is a sense of inseparability between the two (i.e., a *means-end fusion;* Kruglanski et al., 2013). A case in point is the goal to have a good time with friends where the means – doing something fun with friends – cannot be separated from the ends. If the activity itself constitutes the desirable end state, as is the case in all enjoyment goals (e.g., enjoying music, a good meal, or somebody's company), the concept of goal focus becomes vacuous as it presupposes separable means and ends.

In sum, the concept of goal focus has some overlap with other motivational constructs such as

construal level as well as intrinsic and extrinsic motivation, but it also carries unique meaning that is not covered by these constructs (for links between goal focus and mastery/performance goal orientation, see Freund et al., 2012). Let us now turn to the adaptiveness of goal focus. Specifically, we first give an overview of empirical evidence suggesting that a process focus (i.e., a "the way is the goal" attitude) is related to a higher likelihood of achieving difficult goals and to affective well-being. Then, we will address the underlying mechanisms that explain why focusing on the process is adaptive, and also consider situations in which an outcome focus might be more adaptive.

Adaptiveness of Process Focus for Successful Goal Pursuit and Subjective Well-Being

There is growing evidence that adopting a process focus is more beneficial to successful goal pursuit and achievement than adopting an outcome focus – particularly when goal pursuit is difficult. In a longitudinal study with overweight women, Freund and Hennecke (2012) found that focusing on the process (dietary behaviors) rather than on the outcome of dieting (weight loss) is associated with more successful goal pursuit and achievement. Similarly, Hennecke and Freund (2014) examined how goal progress during a diet (i.e., weight loss) impacts subsequent weight loss depending on whether success is identified on the process level or the outcome level of dieting. They found that successful weight loss in one week predicted less weight loss (or even weight gain) in the subsequent week – a well-known effect from the literature on "self-licensing" (e.g., De Witt Huberts, Evers, & De Ridder, 2012). However, identifying success on the process level (vs. the outcome level) attenuated this negative effect.

In the academic context, Pham and Taylor (1999) found that students who mentally simulate the process of studying for an exam study more hours and obtain higher exam scores than students who mentally simulate the feeling of receiving a good grade or that do not mentally stimulate anything at all (i.e., a control group). In the same context, focusing on the process has also been found to be adaptive when learning a new task such as acquiring writing revision skill (Zimmerman & Kitsantas, 1997, 1999). Houser-Marko and Sheldon (2008) found that students who self-reported lack of goal progress framed in terms of the outcome (which they termed "primary goal level") reported lower levels of perceived performance than students who framed lack of goal progress in terms of the process (which they termed "sub-goal level").

In other studies, a process rather than an outcome focus was positively related to dental flossing (Fishbach & Choi, 2012) and exercising adherence (Fishbach & Choi, 2012; Freund, Hennecke, & Riediger, 2010; Kaftan & Freund, 2017b). For example, Fishbach and Choi (2012) found that asking participants to describe why (i.e., outcome focus) they were engaging in a particular activity (e.g., yoga) resulted in a lower level of persistence than was observed when asking participants to describe their experience of the activity (i.e., process focus). Goal persistence, in turn, is associated with subjective well-being and good health (e.g., Bandura, 1986).

Similarly, in the study of Freund et al. (2010), participants with the goal to exercise regularly reported greater persistence, a higher goal satisfaction, and higher affective well-being (i.e., positive affect) over a period of 3 months when they focused on the means (vs. the outcomes) of achieving a goal. Further evidence regarding links to subjective well-being suggests that goal focus might be indirectly related to affective well-being through the ability to regulate one's behaviors and thoughts (Freund & Hennecke, 2012). Thus, outcome focus might indirectly affect negative emotions through failures of self-control. This is also supported by results from Houser-Marko and Sheldon (2008), who found that failure feedback had stronger negative effects on mood when it pertained to the outcome compared to the process. When goal pursuit is difficult, people who focus on the process are also more satisfied with their performance (Vallacher, Wegner, & Somoza, 1989).

Underlying mechanisms. Why is adopting a process focus more adaptive than adopting an outcome focus? As mentioned before, a process focus likely provides guidelines for goal-relevant actions (e.g., Emmons, 1996; Klinger, 1977; Little, 1989). In their study, Pham and Taylor (1999) investigated the mechanisms by which process simulation exerts its positive effect on exam performance. They found that the effect was mediated by enhanced planning and reduced anxiety. In a similar vein, Fishbach and Choi (2012) explained their findings by arguing that experience weighs more than the outcome as soon as people actually pursue an activity. In their study, an outcome focus not only negatively affected the positive experience of pursuing a goal but also reduced participants' motivation and adherence to goal-relevant routines. Thus, when people adopt an outcome focus, they might be more likely to pursue an activity only as a means to an end, which causes a devaluation of the intrinsic appeal of the activity. In contrast, focusing on the process may counteract the tendency for complacency and to "slack" when making progress towards goal achievement (Amir & Ariely, 2008; De Witt Huberts, Evers, & De Ridder, 2014). For example, when people focus on the process, success and failure are followed by less intense affective reactions (Houser-Marko & Sheldon, 2008). That is, focusing on the process of successful goal pursuit less

likely generates a sense of achievement that can be followed by a period of decreased goal-related effort than focusing on the outcome (Amir & Ariely, 2008). In contrast, a failure in goal pursuit less strongly impairs mood, subsequent motivation, and expectancy for future goal performance when focusing on the means instead of the outcome (Freund & Hennecke, 2012; Houser-Marko & Sheldon, 2008).

There are several reasons why focusing on the process may be particularly beneficial when people learn a new task (Zimmerman & Kitsantas, 1997, 1999), a task is difficult (Vallacher et al., 1989), or the goal demanding with respect to self-regulation (Freund et al., 2010). In these cases, a process focus helps people to acquire the necessary goal-relevant means and make fewer errors. In the dieting study of Hennecke and Freund (2014), process focus (but not outcome focus) predicted increases in self-efficacy from baseline to after the diet. Self-efficacy, in turn, is known to adaptively influence the goal challenges people set for themselves, the effort they invest in the endeavor, and how perseverant they are when facing difficulties and setbacks (Bandura, 2013). In this line, several studies have documented that people who are confident to achieve what they want (i.e., are high in self-efficacy) also experience higher subjective well-being than people who are not (i.e., are low in self-efficacy; e.g., Caprara & Steca, 2005; Lent et al., 2005; Luszczynska, Scholz, & Schwarzer, 2005). Similarly, it is likely that a higher process focus leads to higher perceived behavior control, which entails both self-efficacy (dealing largely with the ease or difficulty of performing a behavior) and controllability (the extent to which performance is up to the actor; Ajzen, 2002).

Moreover, when adopting a process focus, people more likely persist in a given activity (e.g., studying) if they experience this activity as rewarding (Freund & Hennecke, 2015). The reward might lie in the intrinsic value of the means (e.g., an increased interest in the activity) or in their instrumentality for achieving the desired outcome. When people perceive the means as particularly instrumental, this not only positively influences their motivation to pursue a given goal but also how much effort they invest in goal pursuit, and their performance (Bandura, 1997; Labroo & Kim, 2009). In turn, when people feel that they invest effort in the process of goal pursuit, they also come to view the means as more valuable and instrumental (Labroo & Kim, 2009). In contrast, an outcome focus may distract from practicing and acquiring the goal-relevant means and thereby hinder successful goal pursuit.

A related reason for the adaptiveness of process focus is that people use effort as a heuristic: the more effort they invest in goal pursuit, the more valuable they deem the outcome to be (Kruger, Wirtz, Van Boven, & Altermatt, 2004). Higher value beliefs, in turn, are linked to a higher persistence (e.g., Eccles & Wigfield, 2002; Wigfield & Eccles, 2000). Thus, when a person focuses on the means of goal pursuit, the effort he or she has invested in goal pursuit as well as the value and instrumentality of the means should be more salient compared to when the person focuses on the outcome. A process focus should therefore intensify the described effects and contribute to greater persistence and better performance. A quote that nicely encapsulates these effort-related benefits of a process focus comes from former supreme court justice Benjamin Cardozo, who stated that: “In the end the great truth will have been learned that the quest is greater than what is sought, the effort finer that the prize (or rather, that the effort is the prize), the victory cheap and hollow were it not for the rigor of the game.”

Adaptiveness of Outcome Focus

At first sight, the reviewed evidence supporting the adaptiveness of process focus for successful goal pursuit contradicts findings from other studies in the field. A first important contradiction seems to exist between the work on goal focus and research on construal level. Research on goal focus favors the adaptiveness of adopting a process focus, whereas research on construal level has shown that higher-level, more abstract construals increase the adoption of both immediate (e.g., Magen & Gross, 2007; Schmeichel & Vohs, 2009) and prospective (e.g., Fujita & Roberts, 2010) self-control strategies.

For example, Fujita et al. (2006) found that higher-level construals can improve self-control by reminding people of the reasons why (i.e., their superordinate goals) they are engaging in a difficult behavior (e.g., studying for an exam). Self-control, in turn, is related to positive affect as part of subjective well-being (e.g., Hamama, Ronen, Shachar, & Rosenbaum, 2013). However, note that goal focus denotes the salience of means and ends within a given goal, whereas the operationalization of construal level by Fujita and colleagues induces a *general cognitive mind-set* of a more high-level (i.e., abstract) and a more low-level (i.e., concrete) representation of events. This mind-set is induced using events that are unrelated to the goals and self-reported self-control judgments that are subsequently assessed. This kind of procedural priming does not target the relative salience of the means and ends within a given goal. For instance, in Study 1, Fujita et al. (2006) asked participants to generate responses to “why” or “how” to maintain good physical health. They subsequently assessed a variant of the delay of gratification scenarios that are unrelated to physical health as a measure of self-control for various items (e.g., a DVD player), indicating a preference for immediate versus delayed rewards. In fact, Fujita and colleagues (2006, p. 355)

state that "preferences for immediate versus delayed outcomes do not capture a conflict between means and ends but rather a conflict between what is primary and what is secondary."

Another potential issue that challenges the supremacy of process focus over outcome focus is that outcome focus may be adaptive in specific phases of goal pursuit. There are no studies that systematically compare the adaptiveness of outcome focus and process focus in different phases of goal pursuit, however, Freund et al. (2012; see also Krause & Freund, 2014b) suggested that process and outcome focus as well as their adaptiveness may change over the course of goal pursuit. For instance, when a deadline is still far away, a focus on the outcome may distract people from the implementation of goal-relevant actions. In contrast, once the deadline is looming, an outcome focus might revive the importance of a goal and give a final "boost" to motivation even if the means are unpleasant. If research were to show that the adaptiveness of process and outcome focus dynamically varies over time, this would also have implications for subjective well-being. One particular challenge that would have to be addressed in this research is the separation of changes in subjective well-being tied to goal focus and goal pursuit from fluctuations of subjective well-being due to independent factors such as diurnal rhythm (Chow, Ram, Boker, Fujita, & Clore, 2005; Larsen, 2000; Luhmann, Schimmack, & Eid, 2011). Solving this issue necessitates the assessment of both goal focus and indicators of subjective well-being repeatedly over time (see Diener, Pressman, Hunter, & Delgadillo-Chase, 2017).

Similarly, Carver and Scheier (1998) argue that focusing on the outcome and comparing the current with the desired state could motivate a person to move towards the goal. Especially when a task is perceived negatively, being reminded of its importance (the abstract framing) may aid goal-pursuit and achievement (Ferguson & Sheldon, 2010; McCrea, Liberman, Trope, & Sherman, 2008). Shah and Kruglanski (2003) found that priming attainment means increases the cognitive accessibility of desired goal states, which has a positive effect on persistence and performance during goal pursuit. However, the activation of goals (i.e., outcomes) by their attendant means was moderated by the perceived effectiveness of the means and it remains unclear to what extent participants consciously focused on means and outcomes during actual goal-directed striving.

If a task at hand is relatively easy to master, an outcome focus might be more adaptive than a process focus because people can better appreciate and consolidate their own motivations for striving, which may then re-energize them towards the goal (Ferguson & Sheldon, 2010; Houser-Marko & Sheldon, 2008; Vallacher & Wegner, 1989; Vallacher et al., 1989). A person who focuses on the outcome or keeps her "eyes on the prize" (Houser-Marko & Sheldon, 2008) might also be less distracted by alternative activities. In contrast, a person who focuses on task details, could feel overwhelmed (Dewitte & Lens, 2000). Further evidence suggests that people can benefit from shifting from a process to an outcome focus when they have acquired the necessary skills to master a task (Zimmerman & Kitsantas, 1997, 1999).

In summary, the existing research suggests that adopting a process focus (vs. outcome focus) promotes successful goal-pursuit and subjective well-being. More research is needed to identify boundary conditions and potential moderators and mediators of the relationship between goal focus, successful goal pursuit, and subjective well-being. This includes the investigation of additive or synergistic effects of process and outcome focus. A simultaneous focus on both process and outcome may lead to a recognition of trade-offs between the desirability of a goal on the outcome level and its feasibility on the means level, hence be beneficial for goal pursuit. For example, in their mental simulation study, Pham and Taylor (1999) found that mentally simulating both the process and the outcome was more beneficial for motivation than mentally simulating the process alone. Conversely, focusing on process and outcome may lead to decision difficulty, that is, a greater willingness to postpone making a choice, and a lower commitment to the chosen option (Escalas & Luce, 2004; Thompson, Hamilton, & Petrova, 2009).

The evidence reviewed above shows that goal focus predicts successful goal pursuit and subjective well-being. Exploring the boundaries of the usefulness of this construct, the next section elaborates more on the role of goal focus in the context of one of the highly prevalent failures in goal pursuit: procrastination.

Goal Focus, Procrastination, and Subjective Well-Being

People typically do not pursue one goal in isolation but instead have multiple goals that compete for goal-relevant resources such as time and energy. For instance, wanting to pass an exam might conflict with the goal to make new friends. The presence of multiple goals thus poses challenges to goal pursuit. For example, to the extent that alternative goals are accessible, they may interfere with the commitment to a given goal. Accordingly, goals and means have to be defended or shielded by inhibiting alternative goals (e.g., Shah et al., 2002; Shah & Kruglanski, 2008). In this sense, alternative goals represent temptations. A temptation can be understood as an alternative goal, the pursuit of which hinders attainment of the focal goal, and provides less important (though often more psychologically immediate) rewards than the focal

goal (Trope & Fishbach, 2000; Trope & Liberman, 2003).

Procrastination denotes the difficulty in protecting a given focal goal against alternative goals (Dewitte & Schouwenburg, 2002; Dietz, Hofer, & Fries, 2007) and is defined as "the voluntary delay of an intended and necessary and/or personally important activity, despite expecting potential negative consequences that outweigh the positive consequences of the delay" (Klingsieck, 2013, p. 26). In other words, a person has the intention to act but delays doing so to the point of discomfort (e.g., Howell & Watson, 2007; Krause & Freund, 2014a; Solomon & Rothblum, 1984).

Procrastination and Subjective Well-Being

Over the past three decades, extensive research has provided a wealth of insights into the correlates and consequences of procrastination for subjective well-being. This research has shown that procrastination is associated with negative mood states such as depression and anxiety (e.g., Ferrari, 1991; Martin, Flett, Hewitt, Krames, & Szanto, 1996; Senécal, Koestner, & Vallerand, 1995), shame and guilt (e.g., Blunt & Pychyl, 2005; Fee & Tangney, 2000; Giguère, Sirois, & Vaswani, 2016), negative self-blame (Sirois & Kitner, 2015), negative self-evaluations in general (Flett, Stainton, Hewitt, Sherry, & Lay, 2012; McCown, Blake, & Keiser, 2012), low self-esteem (Ferrari, 1994, 2000), low levels of self-compassion (Sirois, 2014), distress (e.g., Flett et al., 2012; Richardson, Abraham, & Bond, 2012), and poor overall mental health (Stead, Shanahan, & Neufeld, 2010). At first glance, the many ties of procrastination to subjective well-being may seem surprising because waiting to the last minute to get tasks done is often only immediately stressful and seems to save the time of longer goal pursuit. In fact, when we give talks on procrastination there is typically at least one person in the audience who proudly claims that he or she saves time by procrastinating and gets the task done nevertheless. Obviously, the attribution we are to make is: The person is simply a genius and gets everything done perfectly well at the very last minute. However, even if this prototypical audience member is in fact a genius and an exception to the rule, the rule is that procrastination leads to lower levels of subjective well-being and task performance (Steel, 2007). In fact, it is likely that procrastination as a more enduring tendency leads to chronic stress, which is associated with an increased risk for chronic illness that can create additional vulnerabilities and compromise subjective well-being (for an overview and the *procrastination-health model*, see Sirois, 2016a, 2016b).

Linking Goal Focus to Procrastination

Procrastination research has predominantly focused on explaining procrastination as a *dispositional* trait (Milgram, Mey-Tal, & Levison, 1998) and only little research has conceptualized and investigated procrastination as a behavioral phenomenon that depends on situational or action-oriented factors (Klingsieck, Grund, Schmid, & Fries, 2013).

We assume that the general mechanisms underlying the adaptiveness of process focus discussed above also apply to procrastination. However, some additional mechanisms are helpful for understanding procrastination. People who represent a goal more concretely (vs. abstractly) perceive goals as more urgent and, thereby, are more likely to engage in goal pursuit and to procrastinate less (McCrea et al., 2008). In contrast, a higher-level, distant construal of a task (i.e., outcome focus) might lead to the conclusion that the task only needs to be completed in the distant future, thereby matching levels of construal.

Krause and Freund (2014b) argued that focusing on the means of goal pursuit might reduce procrastination by directing one's attention to the specific actions required during goal pursuit (e.g., exam preparation) rather than to the – temporally more distant – outcome (e.g., good grade in an exam) that, in addition, might be associated with fear of failure. Testing this hypothesis, Krause and Freund (2016) found that process focus is negatively related to procrastination. In addition, a higher process focus reduced fear of failure and task aversiveness that also contributed to procrastination. In a workout study (Kaftan & Freund, 2017b), we found that people with a higher average process focus skip less workout sessions (i.e., procrastinate less), report a higher workout satisfaction, and improve more over time as measured by objective fitness indicators (i.e., number of push-ups). Additionally, average process focus was positively related to mood.

Similarly, research on implementation intentions has found that, compared to the consideration of *why* one should pursue a given goal (i.e., outcome focus), the consideration of *how* to go about pursuing a goal (i.e., process focus) leads people to faster identify opportunities to act (Parks–Stamm et al., 2007; Webb & Sheeran, 2004), to initiate goal-relevant activities (Orbell & Sheeran, 2000; Parks–Stamm et al., 2007), to anticipate action earlier (Gollwitzer, Heckhausen, & Ratajczak, 1990), and to engage in as well as complete assigned tasks prior to a deadline (i.e., to procrastinate less; Bamberg, 2002; Gollwitzer & Brandstätter, 1997).

Moreover, when people focus on small, manageable units of action, a process focus may not only provide concrete guidelines for action (Carver & Scheier, 1998; Freund et al., 2010), but also circumvent

the problem of delay of gratification as it directs attention to the small, immediate steps toward goal achievement (Steel & König, 2006), and thus reduces procrastination.

Goal Focus and the Immediate Experience of Activities

Goal focus may also have very immediate effects on how people experience or perceive activities during goal pursuit. Particularly in the case of procrastination, reports of immediate experience are important because they may differ from retrospective reports due to rationalization processes. For example, students may not experience much guilt when procrastinating because they suddenly perceive cleaning as very important, only to regret afterwards that they cleaned instead of studying for an exam. In line with this reasoning, Krause and Freund (2014a) found a negative association between self-reported procrastination and affective well-being (but see Pychyl, Lee, Thibodeau, & Blunt, 2000).

In our own experience sampling study (Kaftan & Freund, 2017c), we sent questionnaires to participants at times they had planned to engage in goal pursuit (writing a thesis) and asked them to indicate how they perceived the alternative activities they were currently engaged in when procrastinating. One of the results was that a higher outcome focus on alternative activities was associated with a higher perceived importance, lower pleasantness, and less guilt. These changes in the perception of activities were also found in a second experience sampling study (Kaftan & Freund, 2017b) conducted in a different context (i.e., the sports domain) and may have important consequences for further goal pursuit. On the one hand, perceiving alternative activities as more important and less guilt-evoking can be maladaptive because it may sustain procrastination. On the other hand, the lower pleasantness may serve as a stop signal to procrastination. By affecting further goal pursuit, goal focus, then, might also affect subjective well-being. Overall, these studies suggest that the relationship between goal focus and procrastination is complex and that more research is needed to better understand the dynamics underlying procrastination.

Conclusion

Whether goal attainment leads to subjective well-being depends on different factors, such as what goals are selected (e.g. approach or avoidance goals) and whether they meet basic needs (e.g., competence). Although people usually experience a form of contentment when they attain their goals, they are trapped in a hedonic treadmill running in vain for greater happiness as the effects of goal achievement are more short-lived than they might wish. Given that we typically spend much longer on pursuing our goals than experiencing their attainment, it seems crucial to investigate processes linking goal pursuit to subjective well-being. We maintain that goal focus is a promising construct for understanding the mechanisms of how goal pursuit may increase (or decrease) subjective well-being. Growing evidence supports the view that adopting a process focus (i.e., focusing on the way of goal pursuit) is associated with positive affect and subjective well-being, and leads to a higher persistence and goal attainment, even when encountering difficulties or setbacks during goal pursuit.

Abstract

Classical theories of hedonic adaptation assume that lasting changes in subjective well-being (SWB) are not possible because one's SWB inevitably returns to its baseline level, a phenomenon known as the hedonic treadmill. This baseline level is sometimes referred to as the set point for SWB and is assumed to be primarily determined by heritable factors. In this chapter, we review classical theories on hedonic adaptation: adaptation-level theory, range-frequency theory, hedonic relativism and the hedonic treadmill, opponent-process theory, the concept of the genetically determined set point, the distinction between desensitization and shifts in adaptation levels, and dynamic equilibrium theory. We then review the empirical evidence on these theories, with a focus on longitudinal studies on the heritability and stability of SWB, on changes in SWB after life events, and on the effectiveness of SWB interventions. Together, the empirical evidence suggests that although SWB is stable for most people, lasting changes are nevertheless possible. Recent theoretical developments such as the revised set-point theory, SWB homeostasis theory, and the hedonic adaptation prevention model offer different explanations for these findings. The chapter concludes with a discussion of four central questions that need to be addressed in future research.

Keywords: Hedonic Adaptation, Hedonic Treadmill, Set Point Theory, Dynamic Equilibrium Theory

A quick stroll through the self-help section of any average bookstore conveys a clear message: Happiness is attainable anytime and for anyone, if one only chooses the right lifestyle. Although there is considerable disagreement on which lifestyles are particularly good for happiness, with options ranging from meditating to finding fulfilling relationships to achieving material success, the common theme of this industry is that happiness and well-being can be changed.

For decades, scholars of happiness and well-being begged to differ. The science of happiness and well-being was for a long time dominated by the notion that our individual level of well-being is primarily determined by our genes, that we adapt to any changes in life circumstances rapidly and completely, and that any attempts to improve our happiness are futile. This notion has been proposed under various labels, including adaptation level (Helson, 1948, 1964), hedonic treadmill (Brickman & Campbell, 1971), dynamic equilibrium (Headey & Wearing, 1989, 1992; Solomon & Corbit, 1974), set point (Lykken & Tellegen, 1996), and hedonic adaptation (Frederick & Loewenstein, 1999), and became such a fundamental part of this field of research that some likened it to a research paradigm (Headey, 2008b).

In the 2000's, however, a series of longitudinal studies examining changes in life satisfaction after major life events such as widowhood, marriage, divorce, or unemployment (summarized in Lucas, 2007a) challenged the assumption that people can adapt to any circumstances and initiated a paradigm shift (Headey, 2008b). It is now widely accepted that while most people experience stable levels of happiness and well-being, significant and lasting changes can, and do, occur (Sheldon & Lucas, 2014).

The present chapter recounts this paradigm shift and provides an overview of past and current theories and empirical research. It begins with a review of historical and philosophical accounts, followed by a presentation of the main classical theories. We then review empirical evidence for these theories, focusing on longitudinal studies, and discuss recent and current theoretical developments that have been prompted by the empirical evidence. The chapter concludes with a discussion of open questions and directions for future research.

Early Historical and Philosophical Accounts

In many cultures and languages, the word "happiness" appears as a synonym for luck and fortune. This reflects an ancient view of the world as a place governed by an external power where there was little human beings could do to improve their conditions (McMahon, this volume). The pursuit of happiness consequently was a worthless task for humans. Since they are subject to the change of fate and fortune, humans should not even strive for happiness. In accordance with this idea, the pursuit of happiness has often been compared to Sisyphus' task: No matter how hard we try to be happier, we will always go back

to our previous level of happiness. Sisyphus, a figure in Greek mythology, was condemned to rolling an immense stone up a hill, only to watch it roll down again and again for eternity.

Whether this notion is true has been a point of debate since the days of the religions traditions and the Ancient Greece (McMahon, this volume). In contrast to the very early idea of happiness as merely governed by luck, most Hellenistic philosophers believed that happiness and well-being can change but differed in what causes these changes. For example, Democritus suggested that happiness does not depend on fortune and external circumstances, but resides in people's cast of mind. Epicurus was the first to propose that the best way to improve our human lives is to have pleasure and to avoid pain. In contrast, Seneca, as a Stoic, believed that virtue alone was sufficient for happiness. Aristotle thought that happiness is achievable by anyone living a virtuous life but admitted that fortune and external circumstances play a big role in human happiness. In sum, even if they differed on what happiness is and how it can be achieved, all the great ancient school of philosophy agreed that the possession of certain material goods, such as money, cannot guarantee that one's well-being increases beyond a certain threshold. Most importantly, they also agreed that the determinants of happiness lay within individuals, in that only one's moral and rational behaviors lead to happiness (Haybron, 2008a; McMahon, 2006; Tatarkiewicz, 1976).

Similar to Greek philosophers, Christian philosophers of the Middle Ages believed that virtue was indispensable for happiness, but in contrast to Greek philosophers, they believed that happiness lays in the hands of God and could only be attained by leading a life inspired by faith in God (McMahon, 2006).

The idea of happiness as something that humans have the power to achieve spread again in the Age of Enlightment. The concept of happiness assumed a subjective connotation, and pleasure was all that mattered for a happy life. At the beginning of 18th century, John Locke declared that happiness is the utmost pleasure of which we are capable, thereby implying that we are able to change our happiness. In this spirit, the United States Declaration of Independence of 1776 granted the pursuit of happiness as an unalienable right. The notion that happiness (in terms of pleasure) was achievable was also unquestioned by the Classical Utilitarians, Jeremy Bentham and John Stuart Mill, who argued that we ought to maximize the total amount of happiness, that is, bring about 'the greatest amount of happiness for the greatest number'.

In sum, most of these philosophers agreed that lasting happiness is at least in principle attainable. The concept of adaptation is, however, discussed in contemporary treatises on happiness and well-being which usually integrate philosophical thinking with empirical research findings. A common notion in contemporary philosophy is that even if there is a set level of happiness, there are still opportunities for us to improve our level of happiness (e.g., Haybron, 2008b).

Classical Psychological Theories

Most psychological theories relate to aspects of happiness and well-being that can be counted as components of subjective well-being (SWB), and we therefore focus on this construct for the remainder of the chapter. According to Diener (1984), SWB comprises cognitive components such as life satisfaction and satisfaction with specific life domains (also referred to as cognitive well-being) as well as affective components such as the frequency of positive affect (PA) and negative affect (NA) (also referred to as affective or emotional well-being and comprising both mood and specific emotions).

Adaptation-Level Theory

In general, *adaptation* describes a process through which systems change their sensitivity to external stimuli. For example, our eyes are able to adapt to varying lighting conditions. When we enter a dark room, we are almost blind at first, but within minutes, our eyes adapt to darkness and we are able to perceive more and more details.

In his adaptation-level theory, Helson (1948, 1964) proposed a mathematical model of adaptation. The main concept in this theory is the *adaptation level*, which is defined as the level at which a stimulus evokes a neutral response. The adaptation level determines whether stimuli are experienced as positive (above the adaptation level), neutral (at the adaptation level), or negative (below the adaptation level). For example, an object is experienced as heavy if its weight is above a person's adaptation level, and as light if its weight is below a person's adaptation level.

According to Helson (1948), the adaptation level is a function of the weighted geometric mean of all past stimuli. A person who lifted primarily light objects in the past would therefore have a lower adaptation level than a person who lifted primarily heavy objects in the past. Each new stimulus is factored into this equation, which means that the adaptation level is not fixed but can change. A shift in the adaptation level then influences how future stimuli are evaluated. For example, if a person with a low adaptation level for perceiving weights is required to lift a number of heavy weights, his or her adaptation level should move upwards. This shift affects how objects lifted in the future are evaluated. Objects that

were initially above the adaptation level and therefore had been perceived as relatively heavy might then be below the adaptation level and be perceived as relatively light.

Although adaptation-level theory was originally developed and tested with respect to perception, Helson (1964) explicitly argued that his theory is generalizable to other psychological experiences. With respect to SWB, the main implication of adaptation-level theory is that changes in stimuli lead to changes in what is perceived as neutral (i.e., adaptation level) such that despite changing stimuli (i.e., circumstances), people inevitably revert to a point of neutrality over time. On average, people should therefore experience SWB that is neither positive nor negative.

Range-Frequency Theory

Similar to adaptation-level theory, range-frequency theory (Parducci, 1968, 1995) offers a mathematical formulation of how people evaluate hedonic and non-hedonic stimuli. Just like adaptation-level theory, range-frequency theory assumes that novel stimuli are compared to past stimuli. In contrast to adaptation-level theory, however, range-frequency theory predicts that a novel stimulus is not evaluated against the *mean* of the value of past stimuli but with respect to two parameters of the *distribution* of the value of past stimuli: range and frequency. The *range principle* posits that a stimulus is compared to the minimum and maximum of the distribution of previous stimuli. The closer a novel stimulus lies to the maximum of the range (i.e., to the most positive past stimulus), the more positively it is evaluated. The *frequency principle* posits that a novel stimulus is evaluated with respect to the frequency of previous stimuli below the novel stimulus. The more stimuli lie below the novel stimulus, the more positively the novel stimulus is evaluated.

To illustrate these principles and to highlight the difference between adaptation-level theory and range-frequency theory, consider an example where the value of past stimuli follows the positively skewed distribution shown in Figure 1 and the value of a novel stimulus corresponds exactly to the mean of previous stimuli. According to adaptation-level theory, this stimulus would be evaluated as neutral because its value is equal to the adaptation level. According to the range principle, this stimulus would be evaluated negatively because it lies in the bottom half of the range. According to the frequency principle, in contrast, this stimulus would be evaluated positively because more than half of the previous stimuli were even more negative. Hence, the range principle and the frequency principle can lead to divergent evaluations and therefore have to be weighed against each other when evaluating new stimuli. In sum, range-frequency theory differs from adaptation-level theory (Helson, 1948, 1964) in that it explicitly assumes that not all past stimuli are equally important in predicting how people react to new stimuli.

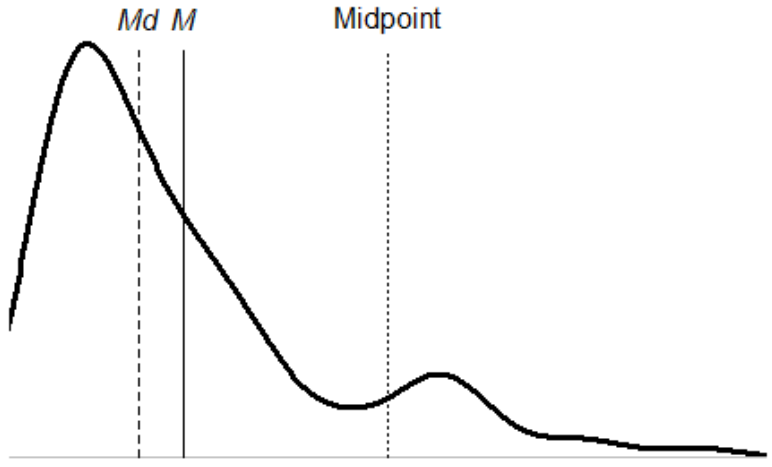

Figure 1. Illustration of adaptation-level theory and range-frequency theory. The figure shows the distribution of past stimuli which in this example is positively skewed. The solid vertical line indicates the geometric mean (*M*) of past stimuli, i.e. the adaptation level as defined in adaptation-level theory. The dashed vertical line indicates the median (*Md*), i.e. the value that splits the distribution into two equally-sized halves. The dotted vertical line indicates the midpoint of the entire range of past stimuli. A novel stimulus with a value corresponding exactly to the mean (M) would be evaluated as neutral according to adaptation-level theory because it is identical with the adaptation level. According to the frequency principle, it would be evaluated positively because it is more

positive than the median. According to the range principle, it would be evaluated negatively because it is more negative than the range midpoint.

The Hedonic Treadmill

Brickman and Campbell (1971) were among the first to systematically apply adaptation-level theory to hedonic experiences. They proposed that people experience pleasure and satisfaction when they are confronted with stimuli that are more positive than their *hedonic adaptation level*, and they experience pain and dissatisfaction when they are confronted with stimuli that are more negative than their hedonic adaptation level. These stimuli are then integrated into the hedonic adaptation level, leading either to an upward or a downward shift in what people experience as hedonically neutral. The satisfaction or dissatisfaction elicited by a particular stimulus therefore fades over time, and people inevitably revert to a level of hedonic neutrality. Permanent happiness or satisfaction can thus only be achieved through a constant stream of novel positive stimuli – an endeavor that Brickman and Campbell described as a *hedonic treadmill*.

Expanding Helson's (1948, 1964) original ideas, Brickman and Campbell (1971) further proposed that a new stimulus is not only compared to one's past experiences (*temporal comparisons*), but also to one's experiences in other life domains (*spatial comparisons*) and to experiences made by other people in one's social network (*social comparisons*). Social comparisons are assumed to be particular powerful. For example, whether receiving one's monthly salary is experienced as hedonically positive, negative, or neutral depends not only on one's previous salaries (the salary would be experienced as positive if it were higher than before) but also on the salary of similar people (e.g., the salary would be experienced as negative if it were still lower than the salary of one's co-workers).

Brickman and Campbell realized that the hedonic treadmill has serious individual and societal implications. On the individual level, it implies that "subjective pleasure is, as a state, by its very nature transient and, as a goal, an ever-receding illusion" (Brickman & Campbell, 1971, p. 289) unless one manages to get off the hedonic treadmill by "abandoning all evaluative judgments" (Brickman & Campbell, 1971, p. 300). They also infer that high SWB would be easiest to attain for those with particularly low hedonic adaptation levels because almost all stimuli would be experienced as positive. Thus, they conclude, "the happiest adult is one who had a moderately unhappy childhood" (Brickman & Campbell, 1971, p. 293) and who remembers these unhappy moments occasionally in order to maintain a permanently low hedonic adaptation level.

On the societal level, the hedonic treadmill implies that any policy interventions aimed at improving a population's SWB are doomed to fail because people adapt to any changes in their life circumstances. This conclusion was backed up by the *Easterlin Paradox* which describes the observation that national happiness levels remain constant across time despite rising income levels (Easterlin, 1974).

Opponent-Process Theory

Similar to the theories discussed thus far, opponent-process theory (Solomon & Corbit, 1974) assumes that the hedonic impact of any stimulus on SWB is brief and that people eventually return to a state of hedonic neutrality. The most important contribution of opponent-process theory lies in spelling out how this return to baseline unfolds over time.

Solomon and Corbit (1974) propose that the standard hedonic response to a stimulus can be split into five stages (Figure 2). (1) Stimulus onset is associated with an immediate pleasant or unpleasant *primary reaction*, which peaks shortly after stimulus onset. (2) Over time, the intensity of the hedonic reaction declines through *adaptation*, even if the stimulus remains present. (3) The hedonic reaction then stabilizes on a non-neutral level as long as the stimulus remains present. (4) Once the stimulus is terminated, an *opponent process* kicks in. This so-called affective after-reaction is opposite to the primary reaction (e.g., negative if the primary reaction was positive) and peaks shortly after the stimulus is terminated. This pattern is sometimes referred to as the *overshoot effect*. The opponent process is activated automatically and indirectly through the primary reaction and constitutes a physiological response to the primary reaction. (5) The opponent process weakens over time and the affective state returns to its initial neutral level (*hedonic equilibrium*).

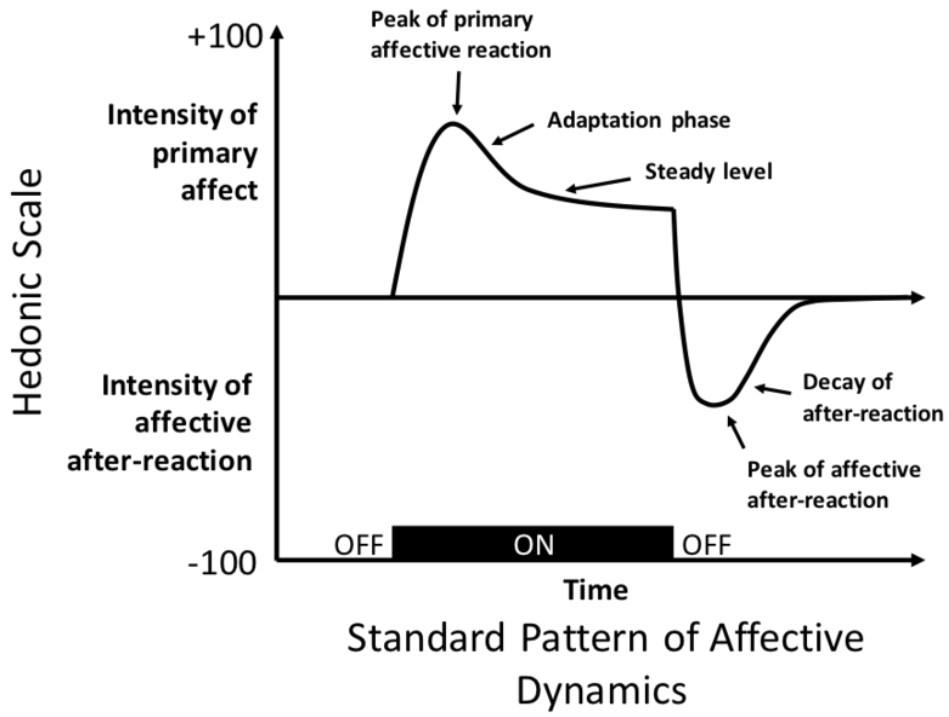

Figure 2. Five stages of the hedonic response to a stimulus according to opponent-process theory (Solomon & Corbit, 1974). Figure adapted from Solomon and Corbit (1974, p. 120, Figure 1).

To illustrate this pattern, imagine a young couple on one of their first dates. When they first see each other, they experience intense joy and excitement (primary reaction). Over the next hours, the intensity of these emotions declines (adaptation) but they remain in a generally positive hedonic state. However, when they part ways, the automatic opponent process takes over, leaving them sad and longing for each other's company. These negative emotions are most intense immediately after the separation and decline again over time until both return to their initial state of hedonic equilibrium.

The existence of opponent processes has several important implications. First, this theory is unique among all classical theories discussed here in its emphasis of the role of time. Because the affective reaction to a stimulus unfolds in a highly complex and dynamic pattern over time, its trajectory can only be described adequately if multiple repeated measures that cover each of the five stages are available. Cross-sectional studies and longitudinal studies using inappropriate time points and intervals between measurement occasions may lead to wrong conclusions because they may confound primary and opponent processes. A study of the affective impact of a romantic date would come to vastly different conclusions if the affective reactions of the couple were measured shortly after the date began, shortly after it ended, or a few days later when both had returned to hedonic neutrality. Second, this theory implies that any stimulus can cause both positive and negative reactions, either as the primary process or as the opponent process. Although opponent-process theory has been developed to describe the short-term dynamics of affect, this implication may also apply to more long-term dynamics of SWB, for example in the context of major life events.

We conclude this section with highlighting additional differences between opponent-process theory on one hand and adaptation-level theory and its spin-offs on the other. All of these theories assume that stimuli are evaluated relative to the baseline level, which they refer to as adaptation level (adaptation-level theory) or hedonic equilibrium (opponent-process theory). However, adaptation-level theory and related accounts propose that this level can change as a function of previous related stimuli whereas opponent-process theory implies that this level remains unchanged (cf. Bowling, Beehr, Wagner, & Libkuman, 2005). Furthermore, only opponent-process theory explicitly assumes that the underlying processes are automatic and physiological. Hence, while all theories assume that people experience, on average, hedonic neutrality, they differ fundamentally in their assumptions about the underlying processes through which hedonic neutrality is maintained.

Dynamic Equilibrium

Headey and Wearing (1989, 1992) expanded previous theoretical accounts by adding personality to the equation. According to their dynamic-equilibrium theory, each person has two types of equilibriums: a SWB equilibrium and a life-events equilibrium. The term equilibrium is used in a similar sense as by Solomon and Corbit (1974) and indicates that people's levels of SWB as well as the frequency of positive and negative life events fluctuate over time, but they do so around a stable baseline – the equilibrium.

Both equilibriums differ between individuals and are at least partly predicted by stable personality traits. Specifically, Headey and Wearing (1989, 1992) predict that high levels of SWB are predicted by high levels of extraversion and low levels of neuroticism—which is indeed one of the most robust findings in SWB research (DeNeve & Cooper, 1998; Steel, Schmidt, & Shultz, 2008). Dynamic-equilibrium theory therefore deviates from previous theoretical accounts in that it does not assume that all people experience, on average, hedonic neutrality but posits that (a) the average level of SWB is positive and (b) there are individual differences in SWB.

Dynamic-equilibrium theory further assumes that people differ in their typical patterns of life events because life events are not completely random (i.e., exogenous), but at least partly driven by personality characteristics (i.e., endogenous). Specifically, Headey and Wearing propose that high extraversion is associated with experiencing more positive events, high neuroticism is associated with experiencing more negative events, and high openness to experiences is associated with experiencing both more positive and more negative events, relative to low levels on these three traits.

Personality therefore stabilizes levels of SWB through two pathways: through its direct impact on people's disposition to experience low or high SWB and through its indirect impact on what kind of life events people experience. Headey and Wearing further predict that life events do not change people's levels of SWB per se but only if they deviate from the normal equilibrium of life events. For example, a positive event should not have much impact on a person's SWB who experiences positive events all the time, but it should lead to a temporary improvement in SWB in a person who rarely experiences positive events. Over time, however, people adapt even to these kinds of changes because their personality pulls both their SWB and the frequency of events back to their respective equilibrium levels (Headey & Wearing, 1992).

Dynamic-equilibrium theory differs from previous theories in three important aspects. First, this theory allows and explains individual differences in both SWB and stimuli (here: life events). Second, it drops the notion of a neutral baseline to which people revert. Finally, it includes personality as a major driver of individual differences and adaptation. Headey and Wearing (1989) provided preliminary support for their theory in a longitudinal study, but as we will see below, Headey (2008) later revised this theory substantially to account for divergent empirical findings.

The Happiness Set Point

Despite their differences, the common notion of the theories discussed up to this point is that one's level of SWB always returns to some kind of baseline or equilibrium. To date, this baseline is usually referred to as *set point*, a term suggested by Lykken and Tellegen (1996). Using twin data, Lykken and Tellegen (1996) estimated that the stable component of SWB is 80% heritable. Although this seems like a strikingly high estimate, it is important to keep in mind that this estimate refers to the heritability of the *stable* component of SWB only. Lykken and Tellegen (1996) do in fact acknowledge that SWB can be and should be expected to be highly volatile across time. Nevertheless, their conclusions centered on the high heritability of SWB, and this paper was typically cited in this context.

In the same study, Lykken and Tellegen (1996) also found that the individual level of SWB was better predicted by the twin's level of SWB than by the individual's sociodemographic characteristics, leading them to the conclusion that the effects of life circumstances on SWB are negligible and that individual differences in SWB are primarily determined by genetic factors. Although they were not able to test this assumption in their study, Lykken and Tellegen (1996) assumed that how happy one can be depends on one's *happiness set point,* which they assumed to be heritable and stable across time. This term was quickly adopted by others to describe theories of SWB that assumed that people adapt to any changes in life circumstances.

Shifts in Adaptation Level versus Desensitization

Frederick and Loewenstein (1999) defined *hedonic adaptation* as "processes that attenuate the long-term emotional or hedonic impact of favorable and unfavorable circumstances" (Frederick & Loewenstein, 1999, p. 302). To describe and explain hedonic adaptation, they revived the mathematical definition of the adaptation level (Helson, 1948, 1964) and extended it in two critical ways. Similar to adaptation-level theory, they maintained that how a stimulus is perceived depends on past stimuli. For example, a stimulus is perceived as positive if its valence is above the current adaptation level, which is

defined as a function of past stimuli. However, unlike to Helson, they acknowledged that the intensity and valence of these past stimuli can fade over time through adaptation. The adaptation level AL at time t is then defined as

$AL_t = \text{a}\ X_{t-1} + (1 - \text{a})\ AL_{t-1}$ (equation 16.3, p. 306)

where X_{t-1} is the valence of the previous stimulus, AL_{t-1} is the adaptation level at the previous occasion, and a is the rate of adaptation. If there is no adaptation (a = 0), the current stimulus is compared to the mean of all previous stimuli, as originally proposed by Helson (1948). Conversely, if the rate of adaptation is maximal (a = 1), the current stimulus is compared to the previous stimulus only and past stimuli are irrelevant. In addition, Frederick and Loewenstein (1999) proposed that the hedonic experience does not just depend on the contrast between the current stimulus and the adaptation level, but that some stimuli are inherently good or bad and therefore always trigger a positive or negative hedonic response, regardless of past experiences. For example, starting a new romantic relationship with someone always feels good, regardless of how many romantic relationships one might have had before. Formally, the hedonic response (or, in their terms, experienced utility) u to a stimulus X at time t is defined as a function of the contrast between the current stimulus X_t and the adaptation level AL_t and a constant c that reflects the inherent valence of the stimulus:

$u_t = c + f(X_t - AL_t)$ (p. 307)

This function follows an S-shaped curve (Kahneman & Tversky, 1979) (see solid blue curve in Figure 3A). The valence of the stimulus is depicted on the x-axis, with $X = 0$ corresponding to the adaptation level, and the hedonic response is depicted on the y-axis. As the curve illustrates, the hedonic response is particularly sensitive to differences in stimuli that are close to the adaptation level (steep slope in the middle of the plot) and less sensitive to differences in stimuli that are far from the adaptation level (flat slope at both ends of the plot). This phenomenon is known as *declining marginal utility* in economics (Kahneman & Thaler, 2006; Kahneman & Tversky, 1979). The constant c is reflected in the intercept of the curve (i.e., the hedonic response at $X = 0$): An inherently good stimulus with a positive value for c will elicit a positive response even if its valence is exactly at the adaptation level.

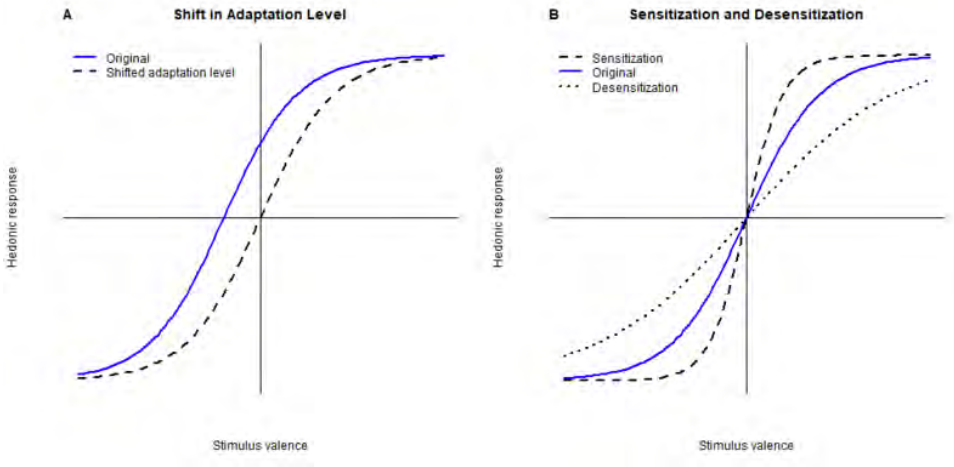

Figure 3. Illustrations of the S-shaped hedonic response curve according and changes in the hedonic response due to shifting adaptation levels (Panel A), and desensitization and sensitization (Panel B), as proposed by Frederick and Loewenstein (1999).

This formalization of the relationship between a stimulus and the hedonic response allowed Frederick and Loewenstein (1999) to distinguish two different processes of hedonic adaptation. First, the hedonic response to a stimulus may become weaker because of *shifting adaptation levels*, as proposed by Helson (1948), Parducci (1968, 1995), and Brickman and Campbell (1971). The shift in adaptation level would result in an upward or downward shift of the hedonic response curve. For example, a downward shift of the hedonic response curve would imply that a stimulus that once elicited a positive hedonic response now elicits a neutral or even negative response (see black dashed line in Figure 3A). Second, the sensitivity towards differences between stimuli may weaken. This *desensitization* would result in a flatter slope of the hedonic response curve, and positive stimuli would elicit an attenuated hedonic response (dotted line in Figure 3B). The slope of the hedonic response curve could also change in the opposite direction, leading to

sensitization towards stimuli (dashed line in Figure 3B).

Note that there is some disagreement in the literature on whether both of these processes reflect hedonic adaptation. Frederick and Loewenstein (1999) clearly think so, as they define hedonic adaptation as "anything that reduces the subjective intensity of a given stimulus" (p. 303). Others, however, explicitly draw a line between adaptation (i.e., shifts in adaptation levels) and desensitization (Armenta, Bao, Lyubomirsky, & Sheldon, 2014; Cummins, 2014).

Summary

Classical theories on adaptation converge on the assumption that external factors do not have lasting effects on SWB because people adapt to any changes in external factors. Hence, although observed SWB can fluctuate, the average long-term level of SWB is stable. This long-term level of SWB has been termed adaptation level (Brickman & Campbell, 1971; Helson, 1948, 1964), dynamic equilibrium (Headey & Wearing, 1989, 1992; Solomon & Corbit, 1974), and set point (Lykken & Tellegen, 1996), which is the term that we will use for the remainder of the chapter.

These basic assumptions lead to the following testable hypotheses. (1) Because the set point is genetically determined, SWB should be highly heritable and be correlated more strongly with other heritable factors such as personality than with presumably non-heritable external factors such as life circumstances. (2) Because the set point cannot change, SWB should be highly stable across time both in terms of rank-order stability and in terms of mean-level stability. (3) Because people always return to their set points, external stimuli such as major life events or interventions should have only short-term effects on SWB. In the following section, we review the empirical evidence for these hypotheses.

Empirical Evidence

Early studies of hedonic adaptation often relied on non-experimental cross-sectional data from small samples. In this section, we first explain why hypotheses about adaptation cannot be tested adequately with these kinds of studies, but only with studies using longitudinal studies. We then review studies examining (a) the stability and heritability of SWB, (b) the association between changes in life circumstances (e.g., life events) and changes in SWB, and (c) the effectiveness of interventions aimed at improving individual SWB (for a similar comprehensive review, see Tay & Kuykendall, 2013).

Why Adaptation Should Be Studied Longitudinally

Before longitudinal data became widely available, researchers of hedonic adaptation usually relied on two types of indirect evidence. The first type of evidence came from cross-sectional correlational studies that tried to explain individual differences in SWB with various correlates. Such studies usually found that personality accounted for a substantially higher proportion of the variance in SWB than life circumstances such as marital status, employment status, or income, leading many to conclude that one's level of SWB is primarily determined by one's personality and that the effects of life circumstances are negligible (for reviews, see Argyle, 1999; Diener, Suh, Lucas, & Smith, 1999; Myers & Diener, 1995). Such a conclusion, however, is problematic for several reasons. First, cross-sectional correlations only refer to *momentary* rank-order differences *between* individuals. It is impossible to infer whether these differences are stable across time and whether changes in the predictors (e.g., changes in life circumstances) are associated with changes in SWB *within* individuals. Second, weak correlation coefficients may conceal practically significant effects. For example, the correlation between individual income and individual SWB is typically around .30 (Howell & Howell, 2008), which means that income explains about 9 % of individual differences in SWB. This seemingly low figure conceals that the SWB differences between poor and rich individuals can be substantial (Lucas & Schimmack, 2009). Finally, equating personality influences with stability is misleading because personality can change across the entire life span (Roberts, Walton, & Viechtbauer, 2006; Specht et al., 2014).

The second type of evidence came from studies that compared the average level of SWB among groups that differed in whether they had recently experienced major changes in their lives. A citation classic in this category is the study by Brickman, Coates, and Janoff-Bulman (1978). In this study, a group of lottery winners and a group of paraplegic accident victims were compared to a control group that had not recently gone through any major life changes. Lottery winners were not significantly happier than participants in a control group. Accident victims were unhappier than both lottery winners and control participants, but happier than "might have been expected" (Brickman et al., 1978, p. 921) because their average happiness level was above the neutral midpoint of the scale. Together, these findings seemed to suggest that major life events do not have any lasting effects on SWB, presumably because people adapt quickly and completely. However, this interpretation is false: (a) The sample size was rather small ($N = 22$ for lottery winners, $N = 29$ for accident victims, and $N = 22$ for controls), so weak effects were unlikely to be detected. (b) Despite these relatively small sample sizes, the mean-level difference between accident

victims and controls was statistically significant and quite strong in terms of effect size (d = 0.75; Diener, Lucas, & Scollon, 2006). (c) The study was cross-sectional, making it impossible to judge whether these differences were caused by the event or had existed before.

The latter point reveals a more general problem with these types of cross-sectional studies. Mean-level differences in SWB after life events only allow conclusions about the impact of a life event if there were no differences in SWB before the events. Without data on SWB collected before the event, this assumption cannot be tested. In fact, multiple studies suggest that life events are not completely random but at least partially associated with person characteristics such as personality (Headey & Wearing, 1989; Kandler, Bleidorn, Riemann, Angleitner, & Spinath, 2012; Lüdtke, Roberts, Trautwein, & Nagy, 2011; Magnus, Diener, Fujita, & Pavot, 1993) and even the previous level of SWB (Luhmann, Lucas, Eid, & Diener, 2013).

In conclusion, non-experimental cross-sectional studies are inconclusive with respect to whether, when, how fast, and for whom hedonic adaptation occurs. For this reason, the following review of the empirical evidence focuses on longitudinal studies.

Heritability and Stability of SWB

A central hypothesis in set-point theory is that SWB fluctuates around a stable, genetically determined set point (Headey & Wearing, 1992; Lykken & Tellegen, 1996). This hypothesis implies that long-term levels of SWB should be highly heritable and stable across time. To probe to what extent these predictions are confirmed in empirical studies, we first review the current state of research on the heritability and then discuss studies on the rank-order and mean-level stability of SWB.

Heritability of SWB. Heritability refers to the proportion of the total variance of a variable (i.e., phenotype) that is accounted for by genetic factors and is usually estimated using behavioral genetic designs such as twin studies (Plomin, DeFries, Craig, & McGuffin, 2003). Across studies, the average heritability of SWB is between .30 and .40 (Bartels, 2015; Nes & Røysamb, 2016; Røysamb & Nes, this volume), which is slightly below the heritability of personality which is estimated to be between .40 and .50 (Bleidorn, Kandler, & Caspi, 2014).

However, some studies also found much lower and much higher heritability estimates. Specifically, heritability estimates of momentary affect are typically lower (between .00 and .35; Eid, Riemann, Angleitner, & Borkenau, 2003; Riemann, Angleitner, Borkenau, & Eid, 1998) and heritability estimates of the long-term SWB are typically considerably higher (between .70 and .95; Lykken & Tellegen, 1996; Nes et al., 2013; Nes, Røysamb, Tambs, Harris, & Reichborn-Kjennerud, 2006). Hence, fluctuations in day-to-day affect appear to be mainly driven by environmental factors whereas long-term SWB appears to be mainly influenced by genetic factors. The latter conclusion is consistent with set-point theory (Lykken & Tellegen, 1996).

Several caveats of these studies need to be considered when interpreting these findings (Røysamb, Nes, & Vittersø, 2014). First, estimates of heritability depend on a number of assumptions which are often not met in reality. One of these assumptions is that the parents of twins are matched randomly. However, several studies found evidence for assortative mating with regard to SWB such that spouses often have similar levels of SWB (e.g., Hoppmann, Gerstorf, Willis, & Schaie, 2011; Schimmack & Lucas, 2010). Moreover, estimates of heritability depend not only on the amount of genetic variance, but also on the amount of environmental variance in a population. Estimates of heritability are higher in environmentally homogeneous populations (e.g., populations with similar sociodemographic background) than in environmentally heterogeneous populations (e.g., different cultures), even if the effect of the genetic factors is identical (Røysamb et al., 2014).

Second, even if one accepts that the heritability of long-term SWB is as high as suggested by some of the studies mentioned above, this figure does not automatically imply that we have genetically fixed set points to which we return no matter the circumstances. As Røysamb et al. (2014) discuss in more detail, even monozygotic twin pairs tend to differ from one another in their levels of SWB, suggesting that it may be more appropriate to think of the set point in terms of a range of values rather than a single fixed value. Life events or interventions may cause individuals to experience permanent levels of SWB that are above or below the middle of the set point range. Adaptation, defined as a return to baseline, is therefore not inevitable. Furthermore, gene expression changes over the life course, which means that different genes might be effective in different circumstances and different life stages (Nes, 2010; Røysamb et al., 2014). Even if the set point is genetically determined, it is not necessarily fixed to a specific value that remains the same across the entire life span (Røysamb et al., 2014).

In sum, behavioral genetics studies suggest that SWB is at least partly influenced by genetic factors, particularly if long-term SWB is considered, but these findings do not imply that hedonic

adaptation is quick and inevitable.

Rank-order stability of SWB. Under the assumption that individual differences in SWB exist (Headey & Wearing, 1989, 1992; Lykken & Tellegen, 1996), a further implication of the classical adaptation theories is that the rank order of individuals should be stable across time. If Person A has a higher set-point for SWB than Person B, then Person A should have higher observed levels of SWB than Person B at any given point in time. This rank-order stability is estimated by the retest correlation between observed SWB scores measured at Time 1 and observed SWB scores measured at Time 2. For most psychological variables, the retest correlation is highest when the time lag between the two time points is minimal and decays with increasing time lags until it reaches an asymptote that is typically above 0 (Fraley & Roberts, 2005). The decay reflects the cumulative effect of changing environmental factors and the asymptote reflects the effect of the stable component of the variable. Thus, the higher the asymptote, the stronger is the influence of stable factors such as a genetically determined set point.

The rank order of SWB has been examined in multiple studies, with retest intervals ranging from a few days to 10+ years. Meta-analyses of these studies found that both life satisfaction and affect follow the pattern described above, with retest correlations decreasing over time until they reach an asymptote of about $r = .30$ (Anusic & Schimmack, 2015; Schimmack & Oishi, 2005). For comparison, the asymptote for retest correlations of personality is about $r = .60$ (Anusic & Schimmack, 2015), indicating that SWB is substantially less stable than personality.

If more than two waves of data are available, the relative contribution of stable and changing factors can also be estimated with structural equation models for longitudinal data (Cole, Martin, & Steiger, 2005; Kenny & Zautra, 1995). Such models allow decomposing the total variance into components that are due to stable influences, occasion-specific (momentary) influences, and in some models, autoregressive influences (i.e., effect of the SWB at the previous occasion on SWB at the following occasion). Using data from representative panel studies, Lucas and Schimmack (2009) estimated that stable, autoregressive, and occasion-specific influences each account for roughly one third of the total variance in life satisfaction. In their meta-analysis, Anusic and Schimmack (2015) estimated that stable influences account for 42 % of the variance in affect and 52 % of the variance in life satisfaction (see also Eid & Diener, 2004, for similar estimates), compared to 83 % for personality.

In sum, these findings suggest that while a substantial proportion of the variance of SWB is due to stable factors, which is consistent with the existence of a set point, SWB is also at least as much influenced by changing environmental factors. Similar to the findings on heritability, these studies do not provide any information on whether hedonic adaptation is indeed quick and inevitable. To examine whether people return to a stable baseline regardless of the external circumstances, stability and change in mean levels of SWB must be examined.

Mean-level stability of SWB. If the assumption that people always return to their stable set points is correct, mean levels of SWB should be stable over longer time spans both on the population level and within persons. With regard to the population level, a frequent finding is that national levels of SWB change very little across long time spans, despite changes in sociodemographic circumstances such as national income levels (Easterlin, 1974). However, this pattern has primarily been replicated in countries that experienced relative stability in the past decades. By contrast, both upward and downward changes in national levels of SWB can be found in countries that experienced significant economic and political changes (e.g. Russia, Greece) (Veenhoven, 2014), indicating that stable population levels of SWB are not universal.

Furthermore, classical theories of adaptation imply that SWB does not change across the life span. Again, however, the empirical evidence does not fully support this assumption. Both affective well-being (Charles, Reynolds, & Gatz, 2001; Lachman, Teshale, & Agrigoroaei, 2015) and life satisfaction (Baird, Lucas, & Donnellan, 2010; Mroczek & Spiro, 2005; Steptoe, Deaton, & Stone, 2015; Stone, Schwartz, Broderick, & Deaton, 2010) change over the life span (for a recent review on the development of SWB across the life span, see Luhmann, 2017) and decline in the last years of life, suggesting that people do not adapt fully to the cognitive and health-related decline that characterizes this period in life (Gerstorf et al., 2008; Kunzmann, Richter, & Schmukle, 2013).

Together, these studies show that average levels of SWB can change over time, which is hard to reconcile with the classical theories of adaptation. Note, however, that studies on average mean-level change offer only limited insights into changes occurring within persons. In fact, moderately changing mean levels of SWB can reflect (a) that most people experience moderate changes in their individual SWB or (b) that most people do not experience any changes in their individual SWB but a significant minority experience strong changes. Similarly, stable mean levels of SWB can reflect (a) that individuals do not experience any changes in SWB or (b) that the number of individuals experiencing increases and decreases

are roughly similar. Empirical studies considering interindividual differences in intraindividual change suggest that both explanations are somewhat true. Using longitudinal data on life satisfaction spanning up to several decades, several authors found that while most people experience stable levels of life satisfaction, a substantial minority of about 20 % experience significant and lasting increases or decreases over the multi-year period (Fujita & Diener, 2005; Headey, 2008b; Headey, Muffels, & Wagner, 2014).

Changes in SWB after Life Events

If hedonic adaptation is indeed inevitable, even major life events should not have any lasting impact on SWB. Two general methodological approaches to study the relationship between life events and SWB can be distinguished. In the first approach, the *frequency of life events* experienced over a specified time frame is measured, often with life events checklists such as the Social Readjustment Scale (Holmes & Rahe, 1967). For example, Headey and Wearing (1989) measured the frequency of positive and negative events experienced over a period of two years and found that these frequency measures predicted life satisfaction and positive affect over and above extraversion, neuroticism, and openness to experiences. In addition, the frequency of negative events, but not the frequency of positive events, predicted negative affect over and above extraversion, neuroticism, and openness to experiences.

In another study using the frequency approach, Suh, Diener, and Fujita (1996) regressed momentary SWB on the number of positive and negative self-reported life events experienced in specific time periods over the past four years. They found that positive affect was significantly predicted by the number positive life events, negative affect was significantly predicted by the number of negative life events, and life satisfaction was significantly predicted by both positive and negative life events. Crucially, they also found that when the time point of the occurrence of these events was considered, only events experienced in the past three months, but not more temporally distal events, were significantly associated with SWB. Suh et al. saw their findings as consistent with Headey and Wearing's (1992) dynamic equilibrium theory and concluded that "it seems to be the case that SWB does react to external changes in life but returns to a stable individual baseline rather quickly. More specifically, the results of our study indicate that the impact of most life events on SWB diminishes in less than 3 months" (Suh et al., 1996, p. 1098). This conclusion, however, is unwarranted given the study design. In fact, this study did not provide any evidence on whether people return to the set point at all nor on how quickly they do because the intraindividual trajectories of SWB were not examined. Instead, this study merely shows that individual differences in SWB cannot be predicted by the frequency of life events that occurred more than three months ago. An additional limitation of the frequency approach is that life events that differ quantitatively (in terms of their hedonic impact) and qualitatively (in terms of, for example, life domain or subjectivity) are lumped together in one single score, which means that the impact of specific events on SWB cannot be examined.

This limitation is resolved in the second methodological approach that focuses on *single specific events.* Many studies focusing on single specific events compared individuals having experienced the event with individuals not having experienced the event (e.g., Brickman et al., 1978, for more examples, see the comprehensive review by Frederick & Loewenstein, 1999). However, as discussed above, these types of cross-sectional group comparisons do not allow conclusions about the impact of life events nor about the process of adaptation.

The strongest approach to testing whether and how adaptation to external stimuli unfolds over time is therefore to examine intraindividual changes in SWB after life events using prospective longitudinal data. Data are prospective if SWB is measured both before and after the event. Only prospective data permit testing whether and how quickly people return to their pre-event (i.e., baseline) levels of SWB after the event. Prospective studies on life events are hard to conduct because they require repeated measures of SWB (to allow examining intraindividual change) from large samples (to ensure that a significant number of people experienced the event of interest) tracked over long time periods (to ensure that both pre-event and post-event data on SWB are available). Fortunately, such studies have increasingly become available. For example, the German Socioeconomic Panel Study (SOEP) provides longitudinal data on life satisfaction collected annually since 1984 in a large sample representative of the German population (Wagner, Frick, & Schupp, 2007). This study and similar ones from other countries have been used extensively to study changes in SWB in the context of family-related events such as marriage (Lucas, Clark, Georgellis, & Diener, 2003), childbirth (Dyrdal & Lucas, 2013; Galatzer-Levy, Mazursky, Mancini, & Bonanno, 2011), divorce (Lucas, 2005), widowhood (Lucas et al., 2003; Specht, Egloff, & Schmukle, 2011); work-related events such as unemployment (Galatzer-Levy, Bonanno, & Mancini, 2010; Lucas, Clark, Georgellis, & Diener, 2004; Luhmann & Eid, 2009), job transitions (Lindfors, Hultell, Rudman, & Gustavsson, 2014), and retirement (Pinquart & Schindler, 2007); and health-related events such as the onset of disability (Lucas, 2007b; Pagán-Rodríguez, 2012). Reviews (Lucas, 2007a; Yap, Anusic, & Lucas, 2014) and meta-analyses (Luhmann, Hofmann, Eid, & Lucas, 2012) of this literature indicate that whether

and how fast people adapt to life events depends on the specific event. On average, people appear to adapt within a few years to marriage, childbirth, and divorce. Adaptation can also be found for widowhood and bereavement, although the rate of adaptation is slower than for divorce. For some events, however, changes in SWB are more permanent, for example after unemployment and disability. These results suggest that while adaptation is common, it is neither automatic nor inevitable, particularly after negative life events.

Despite their many strengths, a number of limitations of these studies need to be considered. First, most studies only included individuals who had experienced a particular event but did not include a control group comprised of individuals who had not experienced this event. A control group is necessary to (a) examine selection effects (e.g., people high in SWB are more likely to get married; Mastekaasa, 1992) and (b) to disentangle event-induced changes from age-related normative changes. Ideally, individuals would be randomly assigned to the event group and the control group, but with few exceptions (e.g., Galiani, Gertler, & Undurraga, 2015), such a random assignment is ethically impossible. An alternative is propensity score matching (Thoemmes & Kim, 2011), a statistical procedure that can be used to a create control group that is matched with the event group. A study by Yap, Anusic, and Lucas (2012) demonstrates how the conclusions can change by including a control group: While they replicated previous findings that people return to their pre-event levels after marriage, they also observed similar declining levels of life satisfaction in a matched control group, suggesting that while marriage did not change people's general downward trajectory of life satisfaction normal in this age period, it did give people a boost that kept them permanently above the life satisfaction level of the unmarried control group.

Second, SWB was measured annually in most studies, which limits the possibility to detect short-term variations in SWB. As the meta-analysis on life events and SWB (Luhmann, Hofmann, et al., 2012) shows, variability in SWB is particularly high in the first months after a significant event, suggesting that the first weeks and months after an event may be particularly volatile. We return to this issue below when we discuss open questions and future directions.

Third, most studies focused on life satisfaction. Only few longitudinal studies on changes in affective well-being are available. Distinguishing between these components is important because life satisfaction and affective well-being are differentially affected by life events (e.g., Knabe, Rätzel, Schöb, & Weimann, 2010) and change at different rates and, for childbirth, even in different directions (Luhmann, Hofmann, et al., 2012).

Finally, both the reaction to life events and the rate of adaptation to life events vary substantially among individuals experiencing the same events and among different kinds of events. An active field of research is to identify the person-related and event-related moderators that account for this variability. We return to this issue below.

In sum, studies on life events and SWB paint a complicated picture: adaptation seems to occur frequently for most events and most individuals, but not for everyone.

Effectiveness of SWB Interventions

Lykken and Tellegen (1996) famously stated that "it may be that trying to be happier is as futile as trying to be taller" (Lykken & Tellegen, 1996, p. 189). Unfazed by this quote, a number of researchers and practitioners have developed interventions that attempt just that: to improve people's levels of SWB. This volume includes several chapters reviewing these interventions (Layous; Ehlers, Salerno, Aguiñaga, & McAuley; Stone & Parks; Chow; Holman, Johnson, & O'Conner, this volume), so we will not reiterate them here. For our purposes, it suffices to say that the empirical evidence available to date suggests that SWB can be improved through interventions (Bolier et al., 2013; Davis et al., 2016; Sin & Lyubomirsky, 2009) and through intentional activities (Layous, this volume), a finding that is inconsistent with classical theories of adaptation.

Summary

In this section, we reviewed studies on heritability and stability of SWB as well as studies on the impact of external stimuli (life events and interventions) on SWB. Together, these studies indicate that SWB is relatively stable but nonetheless changeable. For most people, their SWB fluctuates around a stable baseline that is partly heritable, which is consistent with classical theories of adaptation. However, a significant minority experiences major increases or decreases in their SWB. In sum, adaptation is a real phenomenon, but it may not be as pervasive and inevitable as classical theories suggest.

Recent Theoretical Developments and Current Debates

In reaction to the empirical evidence, Headey (2008b) announced a paradigm shift in this field of research and called for a revision of the classical set-point theories. A comprehensive theory of SWB, he states, needs to be able to explain both stability (which classical theories do) and change (which classical

theories fail to do) (Headey, 2010). In this section, we review current theoretical developments that attempt to achieve this goal.

Revisions to Set-Point Theory

Diener et al. (2006) and Headey (Headey, 2008b, 2010) independently argued that the classical theories of adaptation need to be fundamentally revised. Diener and colleagues (2006) proposed five major revisions. (1) Set points are not neutral, as assumed in some classical theories (Brickman & Campbell, 1971; Helson, 1948, 1964; Solomon & Corbit, 1974), but are, on average, positive (Diener & Diener, 1996; Diener, Kanazawa, Suh, & Oishi, 2015). (2) People differ in their individual set points, and these differences can partly be explained by heritable factors such as personality. (3) People may have multiple set points for different components of SWB. (4) SWB can change, for example through the experience of major life events. (5) People differ in the degree to which they adapt, and these individual differences can partly be explained by differences in personality and coping strategies.

Headey was compelled to substantially revise his dynamic equilibrium theory (Headey & Wearing, 1989, 1992) which, in its original form, was able to explain stability but not lasting changes in SWB. Recall that a central proposition of the original dynamic equilibrium theory was that people's levels of extraversion, neuroticism, and openness to experience predispose them to a characteristic pattern of life events. SWB changes not when particular life events occur, but when the pattern of life events deviates from the characteristic pattern of life events. For example, one would experience significant increases in SWB not by experiencing positive events per se, but by experiencing more positive events than normal.

In his revision of this theory, Headey (2008b) suggests that such positive and negative deviations from the normal pattern of life events are more likely for individuals with certain combinations of personality traits. Specifically, he proposes that people who are at the same time high in extraversion and low in neuroticism have an 'upside risk' of experiencing more positive events than normal and thereby have a greater chance of experiencing lasting increases in SWB. Conversely, he proposes that people who are at the same time low in extraversion and high in neuroticism have a 'downside risk' of experiencing more negative events than normal and thereby have a greater risk of experiencing lasting decreases in SWB (for preliminary empirical support, see Headey, 2008b). Moving even further away from the original theory, Headey later proposed that lasting changes in SWB can also be due to people's behavioral choices, for example, who they choose as a partner, how they balance work and leisure, their degree of social participation and volunteering, how physically active and healthy they live, and other life goals (Headey, 2008a; Headey, Muffels, & Wagner, 2010; Headey et al., 2014). This notion presents quite a dramatic shift away from the classical theories that all converged on the idea that people cannot influence their SWB because it is mainly determined by personality and by automatic adaptation processes.

Subjective Well-Being Homeostasis

In a stark contrast to Headey's revised set-point theory, Cummins (2010, 2014) continues to emphasize the role of automatic processes. In his theory of SWB homeostasis, Cummins posits that SWB, particularly mood, can be described as a homeostatic system. He specifically focuses on what he calls *homeostatically protected mood* (HPMood), a biologically determined and normally distributed predisposition for certain positive mood states that influences people's personality (not vice versa), cognitive processes, and other aspects of SWB such as life satisfaction. HPMood is controlled by homeostatic processes that keep HPMood within a narrow range, the so-called *set point range*. These processes comprise internal processes such as automatic habituation and cognitive mechanisms such as reframing and meaning making, and external resources such as wealth and social relationships.

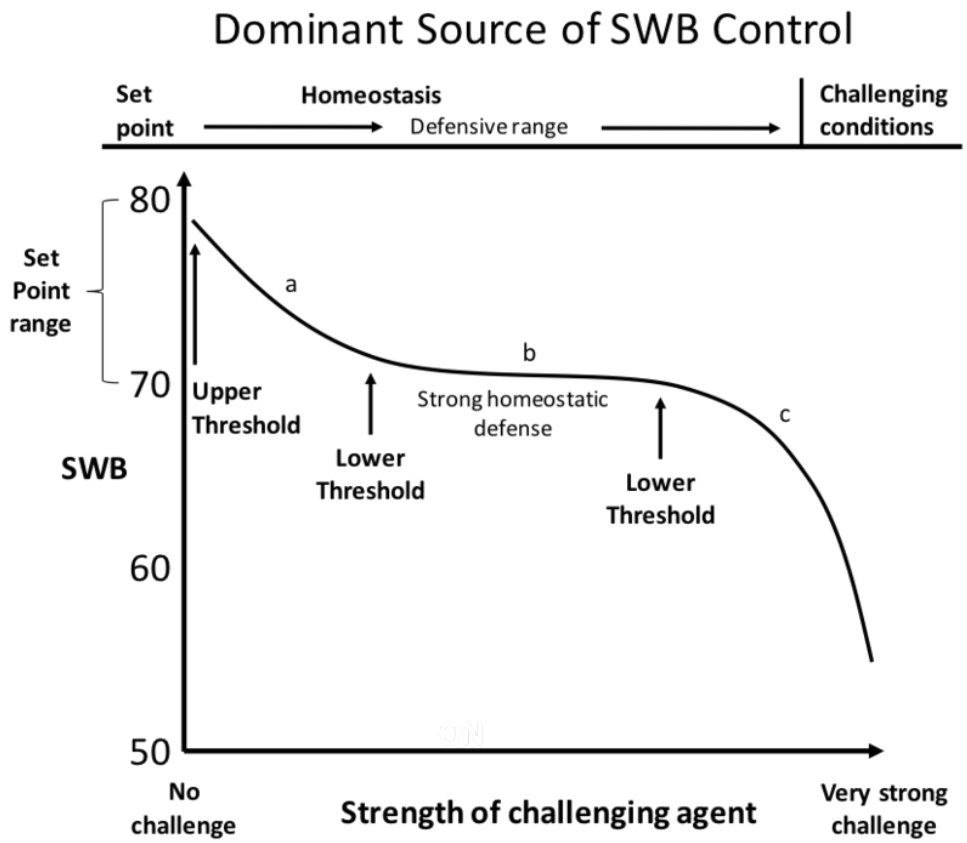

Figure 4. The SWB homeostasis system. The plot illustrates the association between HPMood (y-axis) and the strength of challenges to the homeostatic system (x-axis). HPMood normally (a) fluctuates within the set point range (here: between 70 and 80). For moderate challenges (b), HPMood moves to the thresholds of this range, but a strong homeostatic defense keeps it within the set point range. Only for very strong challenges (c) can the threshold be passed (homeostasis failure). Figure adapted from Cummins (2010, p. 5).

The homeostatic system is illustrated in Figure 4. The more the current level of HPMood approaches the thresholds of the set-point range, the harder the system works to keep HPMood within this range. Under ordinary circumstances, the system will therefore ensure that people's fluctuating HPMood stays within their individual set point range, which explains why most people experience stable levels of SWB over long time spans. Under extraordinary circumstances, however, homeostasis may fail and the threshold may be exceeded, leading to significant changes in HPMood and, consequently, other aspects of SWB. Cummins attributes findings on long-term changes in SWB after life events to this kind of homeostasis failure. Over time, however, the homeostatic system regains control and HPMood returns to the set point range. Importantly, the assumption that the set point is biologically determined does not imply that it is fixed to a specific value or a specific range across the entire life span. Rather, just like other physiological parameters, the biological foundations of the set point for HPMood can change with age.

In their attempts to reconcile the empirical evidence with a theory of SWB, Headey and Cummins appear to come to widely divergent conclusions. At a second glance, however, it becomes clear that these theories explain different phenomena. Although Headey typically refers to SWB, his empirical studies focus on the cognitive component of SWB, that is, life satisfaction. Cummins, by contrast, explicitly focuses on the affective component of SWB, that is, HPMood. Although correlated, cognitive and affective well-being are structurally and functionally distinct (Lucas, Diener, & Suh, 1996; Luhmann, Hawkley, Eid, & Cacioppo, 2012; Luhmann & Hennecke, 2017), and show divergent change trajectories over the life span (Stone et al., 2010) and after life events (Luhmann, Hofmann, et al., 2012). It is therefore plausible to assume that the mechanisms that account for stability and change are not the same for affective and cognitive well-being, and that distinct theories might be necessary to explain stability and change in these components of SWB.

Hedonic Adaptation Prevention Model

Anyone invested in improving people's SWB inevitably wonders how adaptation to negative events can be expedited and how adaptation to positive events can be prevented or at least slowed down. These questions can only be answered if the mechanisms and moderators of adaptation are well understood. This is the goal of the Hedonic Adaptation Prevention Model (Lyubomirsky, 2011; Sheldon, Boehm, & Lyubomirsky, 2013), a comprehensive model that distinguishes two central paths to adaptation and identifies several moderators that affect the rate of adaptation. Similar to other presentations of this model, we focus on adaptation to positive changes, but it should be noted that the model applies to adaptation to negative changes as well.

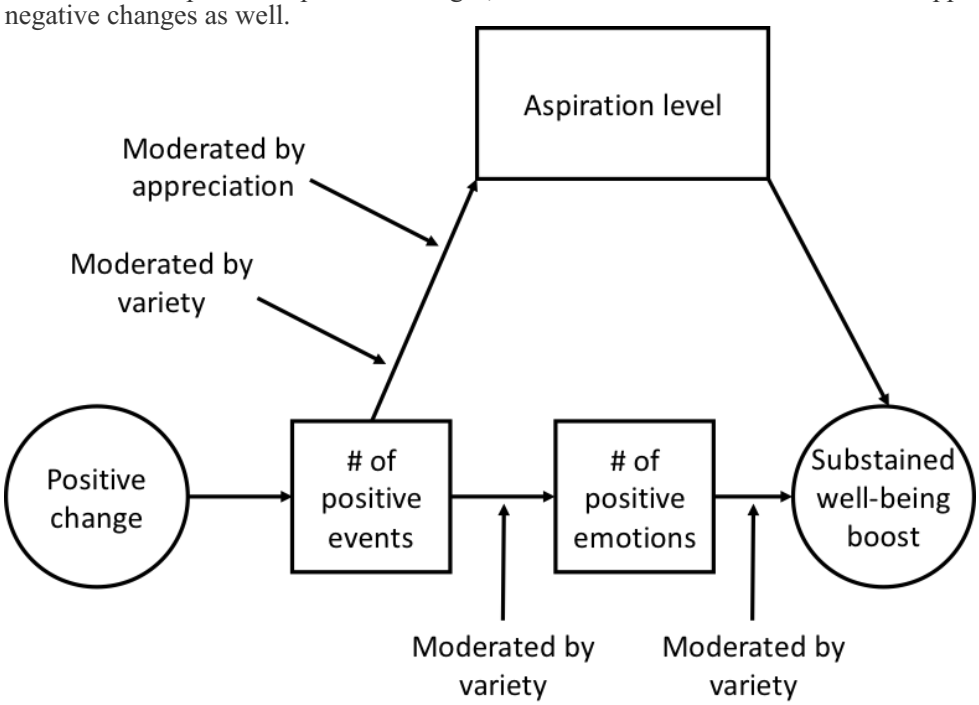

Figure 5. The Hedonic Adaptation Prevention Model. The effect of positive changes on SWB is attenuated by two separate processes. First, the emotional reaction to positive events associated with the positive change becomes weaker over time. Second, aspiration levels increase. Variety and appreciation of the positive events may moderate these pathways. Figure adapted from Armenta et al. (2014, p. 64).

The full model is shown in Figure 5. A first basic assumption in this model is that major positive changes (e.g., getting a pay raise) are associated with a number of positive events (e.g., dinner in a fancy restaurant, an extended shopping spree, or simply being able to pay a bill on time). These positive events have a positive effect on SWB, but this effect can wear off over time (hedonic adaptation). Two separate pathways account for adaptation. First, positive events elicit positive emotions which in turn improve SWB, but both the link between events and emotions and between emotions and SWB become weaker over time. For example, a dinner in a fancy restaurant feels less and less special over time and is therefore associated with less joy and pleasure the more often one experiences it. Furthermore, even if one continues to experience positive emotions at the dinner, these positive emotions are less likely to have a lasting effect on SWB because they become part of the normal pattern. This pathway resembles what Headey and Wearing (1989, 1992) described as a dynamic equilibrium for events and SWB and what Frederick and Loewenstein (1999) described as desensitiziation.

Second, experiencing a large number of positive events may raise people's aspiration levels. The higher the aspiration level, the more likely people experience a discrepancy between their current and their desired state, which is experienced as negative affect and low life satisfaction (Carver & Scheier, 1990; Michalos, 1985). For example, the quality of food and service experienced in the fancy restaurant might soon feel normal, and restaurants that do not meet the new high standard are more likely to give cause for negative affect and dissatisfaction. This pathway is similar to a shift in hedonic adaptation levels proposed in some classical theories (Brickman & Campbell, 1971; Frederick & Loewenstein, 1999; Helson, 1948, 1964).

In addition to describing the main processes of adaptation, the Hedonic Adaptation Prevention Model identifies two central moderators of these processes. The first, *variety*, relates to how similar or variable the positive events are. Specifically, the more variable the positive events, the slower the aspiration level rises and the longer these events elicit positive emotions which in turn improve SWB. A person who spends the new disposable income only on restaurant dinners will adapt to the pay raise more quickly than a person who spends the disposable income on a variety of different things and experiences. The second moderator, *appreciation*, relates to how much people appreciate the positive events. The more one is able to savor a nice dinner at a fancy restaurant, the slower one's aspiration level rises. A short-term longitudinal study found initial support for the two pathways and the moderating effects of variety and appreciation (Sheldon & Lyubomirsky, 2012).

The identification of these moderators has important practical implications. While changing aspiration levels and dampening emotional reactions may be automatic, both variety and appreciation can be controlled and might therefore be effective tools to speed up adaptation to negative events and slow down adaptation to positive events.

Open Questions and Future Directions

We conclude this chapter by addressing four main open questions that need to be addressed in future research: (1) How should we study adaptation? (2) How does adaptation work? (3) Why is adaptation faster after some events than after others? (4) Why do some people adapt more quickly than others?

How Should We Study Adaptation?

As we discussed repeatedly in this chapter, studies on adaptation are subject to a number of methodological challenges. Here, we outline how an ideal study would deal with these challenges (for an in-depth discussion, see Luhmann, Orth, Specht, Kandler, & Lucas, 2014).

The ideal study on adaptation should be longitudinal and focus on some discrete stimulus or event that affects people's SWB. SWB should be measured multiple times both before and after the event to be able to determine whether and when people's SWB returns to baseline after the event. Multiple measurement occasions are necessary to model nonlinear change trajectories. The intervals between measurement occasions are neither too short nor too long. If the intervals between occasions are too long, short-term changes may be overlooked (Uglanova & Staudinger, 2013). Conversely, if the intervals between occasions are too short and the study therefore ends too soon, it may not be possible to determine whether adaptation continues beyond the last occasion. The ideal study furthermore includes a matched control groups to disentangle changes caused by adaptation from normative changes and regression-to-the-mean effects. Finally, the ideal study includes different generations, age groups, time periods, and cultures to evaluate to what extent the observed adaptation patterns are influenced by age, cohort, period, and cultural effects. Of course, no single study can meet all of these requirements. This field of research therefore exemplifies the importance of cumulative research where multiple imperfect studies eventually lead to a comprehensive picture of the frequency and time course of adaptation.

How Does Adaptation Work?

The theories discussed in this chapter propose a great variety of mechanisms of adaptation, ranging from automatic, physiologically driven processes (Brickman & Campbell, 1971; Cummins, 2010, 2014; Lykken & Tellegen, 1996; Solomon & Corbit, 1974) to stable personality differences pulling people back to a set point (Headey & Wearing, 1992) to cognitive changes (Frederick & Loewenstein, 1999; Helson, 1948, 1964; Lyubomirsky, 2011; Sheldon et al., 2013) to behavioral choices (Headey et al., 2014). As mentioned above, empirical studies suggest that the processes underlying adaptation may be distinct for affective and cognitive well-being, with automatic, homeostatic processes more likely underlying adaptation of affective well-being and cognitive processes more likely underlying adaptation of cognitive well-being.

One frequently mentioned cognitive process is that the exposure to external stimuli leads to a change in the standard of reference against which new stimuli are judged (Brickman & Campbell, 1971; Frederick & Loewenstein, 1999; Helson, 1948, 1964; Lyubomirsky, 2011; Parducci, 1995; Sheldon et al., 2013). How exactly this standard of reference is formed in the first place and changes over time is still poorly understood. In particular, it is an open question to what extent the standard of reference used for SWB judgments is determined by past experiences (temporal comparison; Helson, 1948, 1964; Parducci, 1995), by comparisons with other people (social comparison; Diener & Fujita, 1997; Festinger, 1954), or by our ideal and/or ought selves (self-discrepancy; Higgins, 1987). A better understanding of how people judge their SWB is necessary to fully understand how and why these judgments change over time.

Another cognitive mechanism is proposed in the AREA model by Wilson and Gilbert (2008).

Wilson and Gilbert assume that events only impact SWB if people focus their attention on the event (Attend), which is a prerequisite for an emotional reaction to the event (React). Attention to an event dissipates over time and thereby reduces the emotional reactions to the event. Furthermore, as a consequence of attending and reacting to the event, people may be able to make sense of and assign meaning to the event (Explain). Once an event is completely explained, no further attention is paid to the event and the event cannot further impact SWB (Adapt). In their review of the literature, Wilson and Gilbert (2008) provide empirical evidence for each link in this cognitive process, but to our knowledge, this model has not yet been tested in its entirety.

Tasks for future research include (a) conducting rigorous tests of specific mechanisms of adaptation, (b) distinguishing between affective and cognitive well-being when studying mechanisms of adaptation, and (c) integrating these empirical findings into a comprehensive theory of hedonic adaptation.

Why is Adaptation Faster After Some Events Than Others?

The average reaction and rate of adaptation vary substantially across different life events. Based on the notion that negative stimuli often have stronger effects than positive stimuli (Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001; Cacioppo, Gardner, & Berntson, 1999), a common assumption is that people adapt faster to positive events than to negative events (Cummins, 2010; Larsen & Prizmic, 2008). Indeed, those events that appear to have lasting effects on SWB (e.g., unemployment, widowhood, disability) would be considered undesirable by most people. It is easy, however, to come up with counterexamples. Adaptation is quick after divorce (Luhmann, Hofmann, et al., 2012), another rather undesirable life event. Moreover, some studies find lasting positive changes in SWB after events such as cosmetic surgery (Margraf, Meyer, & Lavallee, 2015) and moving to a greener urban area (Alcock, White, Wheeler, Fleming, & Depledge, 2014). Furthermore, people might differ in how they evaluate the valence of a particular event. For example, the death of the spouse might have some positive connotations if it marks the end of enduring suffering. Finally, as suggested by opponent-process theory (Solomon & Corbit, 1974), even events with a clear positive or negative valence may lead to opposite hedonic reactions due to opponent processes. Thus, valence alone cannot explain the differences among life events.

Obviously, events differ on many other aspects besides valence. Easterlin (2005) speculated that people only adapt to changes in economic factors such as income, but not to changes in non-economic factors such as relationships. Wilson and Gilbert (2008) suggested that event characteristics such as novelty, surprise, variability, and certainty about the nature of the event might account for differences among events because they affect how well people can make sense of the event. A one-week laboratory study on chocolate consumptions found that people savored eating chocolate more if they abstained from eating chocolate for an entire week than if they did not abstain (Quoidbach & Dunn, 2013), suggesting that adaptation to positive stimuli may be slowed down by deliberately reducing the exposure to these stimuli. Some events may also be associated with specific consequences that mediate the impact of the event on SWB. For example, the transition to parenthood is associated with a host of positive and negative changes which jointly determine how people react and adapt to this event (Nelson, Kushlev, English, Dunn, & Lyubomirsky, 2013). Exposure to a missile attack has been associated with increased avoidance motivation which in turn was associated with lowered levels of SWB (Van Dijk, Seger-Guttmann, & Heller, 2013). In sum, an open question for future research is which characteristics of events influence the rate of adaptation and why.

Why Do Some People Adapt More Quickly Than Others?

The rate of adaptation does not just differ across different events, but also among individuals experiencing the same event (Bonanno, 2004; Diener et al., 2006; Lucas, 2007a). Two general approaches to explore these individual differences can be distinguished. The first approach focuses on specific variables that are theoretically derived and examines whether these variables affect the reaction and rate of adaptation to life events. Most studies in this domain have focused on the Big Five personality traits, particularly extraversion and neuroticism. Results are mixed. Some studies found positive results. For example, adaptation to unemployment appears to be more negative for people high in conscientiousness (Boyce, Wood, & Brown, 2010; Hahn, Specht, Gottschling, & Spinath, 2015) and low in extraversion (Hahn et al., 2015); the reaction to spousal bereavement was found to be stronger for people low in extraversion and openness (Pai & Carr, 2010), adaptation to disability was found to be faster for people high in agreeableness (Boyce & Wood, 2011), and fluctuations in income were more strongly associated with life satisfaction among people high in neuroticism (Soto & Luhmann, 2013). However, these effects cannot be consistently replicated in independent samples (Anusic, Yap, & Lucas, 2014; Yap et al., 2012) and can vary even within samples, for instance between men and women (Boyce, Wood, & Ferguson, 2016). Other studies focused on more narrow personality variables and found protective effects of sense of mastery (Marum, Clench-Aas, Nes, & Raanaas, 2014), humility (Krause, Pargament, Hill, & Ironson,

2016), perceived control (Infurna et al., 2016), and external locus of control (Specht et al., 2011), but no significant moderating effects for perceived social support (Anusic & Lucas, 2014; Marum et al., 2014).

The second approach is more exploratory and descriptive and aims at identifying different patterns of adaptation using latent growth mixture modeling (Muthén, 2006). This statistical procedure allows identifying and describing different latent classes that differ in their average SWB trajectories. Latent growth mixture models have been applied to various life events, including marriage (Mancini, Bonanno, & Clark, 2011), childbirth (Galatzer-Levy et al., 2011), divorce (Mancini et al., 2011; Perrig-Chiello, Hutchison, & Morselli, 2015), bereavement (Infurna & Luthar, 2017b; Mancini et al., 2011; Spahni, Morselli, Perrig-Chiello, & Bennett, 2015), unemployment (Galatzer-Levy et al., 2010), and retirement (Pinquart & Schindler, 2007). A typical result of these kinds of studies is that three to four latent classes can be distinguished, one of which is characterized by a relatively flat trajectory. This so-called resilient trajectory is often (but not always, e.g., Infurna & Luthar, 2017a) found to be the most common trajectory; however, latent growth mixture models are highly complex methods with strict assumptions that are often not met and, if violated, can lead to an overestimation of the prevalence of the resilient trajectory (Infurna & Luthar, 2016).

In sum, more research is needed to identify variables that explain individual differences in reaction and adaptation consistently across samples and methods.

Conclusion

After assuming for decades that SWB is highly stable, the field has recently made a significant turn towards recognizing that lasting changes in SWB are possible. This turn was at first entirely data-driven, ignited by the availability of large-scale longitudinal studies that track people's SWB over long periods of time. Theory is catching up, as several promising models that explain both stability and change have been proposed in the past years. These models provide useful directions for future research, which is necessary to arrive at a complete understanding of the mechanisms and boundary conditions of hedonic adaptation.

Acknowledgments

Preparation of this chapter was supported by grant #57313 awarded to Maike Luhmann by the Happiness & Well-Being Project, a joint program by the St. Louis University and the Templeton Foundation. We thank Nick Augustat and Vincent Beermann for their assistance in the literature search and formatting of this manuscript.

Well-Being, Self-Actualization, and Fundamental Motives: An Evolutionary Perspective

By Douglas T. Kenrick & Jaimie Arona Krems, Arizona State University

Abstract

From an evolutionary perspective, feelings of subjective well-being signal progress toward adaptive goals. We discuss life history theory and fundamental motives—integrating ideas from social psychology and evolutionary biology that offer a potentially useful perspective on subjective well-being. We discuss some preliminary research from this perspective, and outline implications for future research. In doing so, we suggest that different people may have very different notions of which behavior evokes feelings of subjective well-being, linked to their particular life history features (e.g., age, sex, relationship status). This perspective also suggests predictable variations in what evokes subjective well-being across geography and cultures. We end by addressing avenues for future work taking an evolutionary perspective to understanding happiness and satisfaction—as well as the positive side of unhappiness and dissatisfaction.

Keywords: Fundamental motives, Evolutionary psychology, Well-being, Self-actualization, Life-history.

At first blush, the pursuit of happiness and well-being sounds like a good thing. Indeed it accounts, in good part, not only for the popular appeal of positive psychology, but also for a multi-million dollar industry of personal fulfillment workshops, books, and magazines. It could be argued that goods and experiences designed to enhance feelings of well-being account for the major portion of non-essential consumer goods, as well as a large part of how people spend their leisure time.

From an evolutionary perspective, though, natural selection has not shaped human beings to feel a blissful sense of well-being (Buss, 2000; Keltner, Haidt, & Shiota, 2006; Nesse, 2004; Nesse & Ellsworth, 2009). Although psychologists and laypeople may lament the hedonic treadmill (Brickman & Campbell, 1971; Diener, Lucas, & Scollon, 2006), which implies that achieving any form of emotional satisfaction is soon followed by boredom and dissatisfaction, this treadmill might not be such a bad thing on an ultimate, functional view. Once one of our ancestors had achieved an important goal, such as catching several fish, or building a hut, redirecting his or her attention to other unmet goals, such as the annoying leak in the hut's roof or a potential threat to a romantic relationship, would have made more sense than smugly resting content.

This is not to say that people are designed to *desire* unhappiness and agitated dissatisfaction rather than happiness and contentment (or vice versa). It is also not to say that people *consciously* wish to hop back on the hedonic treadmill as soon as they finish the next lap. However, we would argue that unhappiness and dissatisfaction serve purposes equally as important as those served by happiness and satisfaction. Without those negative affective states, our ancestors would not have survived, or, more importantly from the perspective of their descendants (i.e., us), reproduced.

In this chapter, we consider subjective well-being in light of two related sets of ideas at the interface of evolutionary biology and social psychology: Life history theory and fundamental motives. From an evolutionary life history perspective, what constitutes "subjective well-being" would be expected to vary in predictable ways across people and across contexts. Those variations would have made adaptive sense in ancestral environments (though not always in modern society). After laying out some of the theoretical rationale for our particular evolutionary life-history approach to well-being, we describe our own previous work examining how evolved fundamental motives are connected in somewhat different ways to subjective well-being (versus eudaimonic and hedonic wellbeing, or self-actualization), and present some unanswered questions generated by an evolutionary approach to subjective well-being. We suggest that: (1) feelings of subjective well-being may signal progress toward adaptive goals; (2) there is no monolithic, one-size-fits-all path to achieving subjective well-being; rather, what evokes a sense of well-being may differ sensibly for different people, and for the same person at different times, such that (3) life history features (e.g., age, sex, relationship status, presence of children) may be able to predict what behavior people believe will give rise to their feelings of subjective well-being; (4) ecological and cultural factors might also affect what goal pursuits give rise to subjective well-being, such that there may be

predictable and sensible variations in what causes subjective well-being across geographical and national boundaries; and, finally, (5) because unhappiness and dissatisfaction are also of adaptive importance for humans, it is important to understand the positive side of negative affect as well.

Fundamental Motives and Life-History Theory

A number of classical approaches to human motivation have attempted to explain human choices, goals, and motivations in "domain general" terms. One example of a domain-general theory is the idea that organisms are programmed to "seek reward," another is that people are designed to "maximize benefits and minimize costs." These approaches aggregate all positive outcomes into a single coin, as in economic approaches that ask how many dollars a given good or service is worth. Such domain-general approaches have the advantage of parsimony. A domain-specific approach, however, assumes that different rules apply to some categories of reward or benefit than to others (for example, that the cognitive and affective systems dealing with costs and benefits for friendship are different from those dealing with amorous affairs or relationships between parents and children; Kenrick & Griskevicius, 2013).

Domain-specific approaches have arisen partly because domain-general models have faced a number of problems in accounting for human behavior. Harlow's (1953) classic work, for example, demonstrated that attachment in primates could not be explained through secondary association with food rewards, but seemed to be associated instead with physical contact, and that attachment might be linked to a separate desire for what he called "contact comfort." In a related vein, Garcia and Koelling (1967) demonstrated that the simple rules of classical conditioning did not apply cleanly to learning to avoid nausea-inducing foods (which occurred after a single trial, and despite several hours passing between the presentation of the taste and the consequence of nausea). Wilcoxon, Dragoin, and Kral (1972) suggested that the mechanisms for conditioning nausea were even more complex, differing in species-specific ways that made evolutionary sense. They found that rats, which use taste and smell cues to find food in their natural environments, easily condition nausea to taste, whereas quail, which typically eat seeds that they locate by vision rather than smell or taste, more easily condition nausea to visual cues than to taste cues. Furthermore, neuroscientific findings, such as Sperry and Gazzaniga's work with split brain patients (e.g., Gazzaniga, 2005), further suggested that the brain is not one monolithic processing unit, but consists of multiple systems processing different types of information in parallel. In a review of diverse bodies of evidence from comparative psychology, neuroscience, and learning, Sherry and Schacter (1987) built a strong case that animals, including humans, required multiple distinct memory systems for different, and sometimes incompatible types of learning (a bird learns its species single song at a critical early age, and then never modifies it, but it may learn hundreds of places where it has stored food, which need to be selectively remembered and forgotten depending on whether they have been used up, and it learns to avoid poisonous foods throughout life, without ever forgetting them). All of these lines of evidence have led many behavioral scientists to adopt a modular, or domain-specific, approach, which presumes that affective and cognitive processes are not monolithic, but composed of multiple parallel sub-systems that function in ways that are often specific to the particular types of threats and opportunities that each species confronts in its typical social and physical environment.

Abraham Maslow (1943), a student of Harry Harlow, suggested an influential early model of multiple human motivations. He postulated that motivations could be arranged into a "hierarchy of prepotency," and the hierarchical pyramid of human motivations has remained a highly appealing and robust cultural meme (Ackerman, Nocera, & Bargh, 2010; Diener, 2000; Kenrick, Griskevicius, Neuberg, & Schaller, 2010; Krems, Kenrick, & Neel, 2017; Peterson, Park, & Seligman, 2005). Maslow postulated that distinct motivational systems unfold developmentally. Maslow also assumed that only once people had achieved lower-tier physiological and social goals, such as affiliation, and esteem, they could they move on to individual pursuits of self-actualization, or fully realizing one's own unique potential. Maslow (1943) used the term "self-actualization" to refer to: "the desire to become more and more what one is, to become everything that one is capable of becoming" (p. 382). He wrote:

Even if all these *[physiological, safety, and social]* needs are satisfied, we may still often (if not always) expect that a new discontent and restlessness will soon develop, unless the individual is doing what he is fitted for. A musician must make music, an artist must paint, a poet must write, if he is to be ultimately happy. What a man can be, he must be. This need we may call self-actualization. (1943, pp. 382-383).

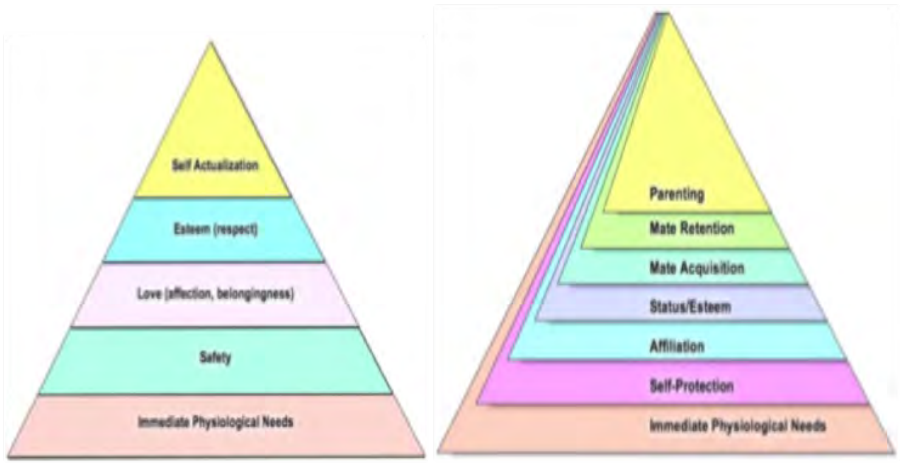
Maslow's (1943) model of motivation was a precursor of modern evolutionary perspectives on domain specificity. However, modern developments have suggested a number of renovations to his pyramid (Kenrick et al., 2010). For example, Maslow paid very little attention to reproductive motivations, sweeping sexual desire in with basic physiological needs such as hunger and thirst.

Figure 1 presents a graphic illustration of a "renovated" hierarchy of needs (Kenrick et al., 2010). Our model begins with the premise that, over the course of evolutionary time, humans have faced recurrent,

distinct challenges. Successfully surviving, reproducing, and rearing reproductively viable offspring required humans to meet these wide-ranging problems. Furthermore, because humans are a highly social species, many of these challenges were social in nature, such as competing for and acquiring friends as well as mates. We thus suggested a hierarchy of "fundamental human motives" that distinguishes between basic physiological needs, self-protection, disease avoidance, affiliation, status, mate acquisition, mate retention, and parenting (Kenrick, et al., 2010). Each of these motivational systems evolved in response to distinct selection pressures. The particular decision-rules that would make adaptive sense when interacting with one's offspring would not be the same as those that make adaptive sense when dealing with friends, and still different sets of decision-rules would be adaptive in dealing with romantic partners, strangers, and so on (Kenrick & Griskevicius, 2013). Once a given motivational system is activated, it would direct attention to different stimuli, weight those different stimuli in different ways, and produce distinct outputs, in ways that would be likely to best avoid particular threats and approach particular opportunities.

One notable feature of the revised pyramid is that, unlike Maslow's model, self-actualization is not conceptualized as the pinnacle human motivation. From an evolutionary perspective, it is unlikely that our ancestors would have evolved to solve the problems of protecting themselves from harm, acquiring friends, and winning respect, only to go off on one's own to play music and contemplate philosophical questions, *per se*. It makes sense that such noble pursuits are easier for those who do not have to grapple with hunger and physical danger, but from an evolutionary perspective, it seems likely that artistic and intellectual creativity are not end in themselves but actually ways of winning respect and acquiring mates (Griskevicius, Cialdini, & Kenrick, 2006; Miller, 2000; Krems et al., 2017). On this view, seeking a sense of self-actualization is not a separate adaptive pursuit in and of itself, then, but a means of achieving other adaptive goals. Likewise, subjective well-being would, on this view, be viewed not as a separate goal in itself, but as a signal of adaptive progress toward functional goals.

Figure 1. Maslow's (1943) pyramid of human motivation (left) and Kenrick et al.'s (2010) revised pyramid of human motivation (right).



This renovation—and the general approach to thinking about happiness, self-actualization, and well-being—is based on ideas from evolutionary life history theory (e.g., Stearns, 1992). Life history theory is based on the general premise that all animals, including humans, must continually make decisions involving economic trade-offs (e.g., Stearns, 1992). All living organisms, even the healthiest, wealthiest, and most resourceful human beings, have limited resources of time and energy. At any moment, those resources need to be allocated to one of several mutually exclusive tasks: developing and maintaining one's own body (including developing one's brain), attracting mates, or parenting. Biologists refer to these tasks as somatic effort, mating effort, and parenting effort. Whereas some animals invest very little effort in parenting (e.g., many amphibians and fish lay hundreds of eggs, and do not care for them afterwards), other species invest a great deal in parenting effort (e.g., elephants do not reach sexual maturity for well over a decade, and then produce a very small number of offspring in which they invest a great deal of energy for years). Compared to most other mammalian species -- and indeed most other living species -- humans are very slow-developing, not reaching sexual maturity for well over a decade after birth and investing heavily in very few offspring.

This typical human life history trajectory has implications for how and when we pursue the various

fundamental motives over the lifespan. On this view, a calorie devoted to pursuing one of these goals (e.g., seeking mates) is a calorie that cannot be invested in pursuing another (e.g., caring for one's children). Moreover, we must invest in growing our bodies before we can invest in finding a mate, and we must, of course, successfully find a mate before we can invest in our own offspring. Allocating these finite resources over the life span—and doing so in ways that make sense given one's environmental surroundings—can enhance one's fitness. Whereas all humans are relatively slow developing—compared to many other mammals, which can become sexually mature in several months and begin having large litters of offspring early in life—there are individual differences within any species, humans included. We consider some of these differences below.

Sex differences. One important difference in life history is linked to biological sex. Humans are like other mammals in that females have a very high obligatory investment (gestation and lactation for several years; Trivers, 1972). This, in turn, leads to a sex difference in desires for number of mates (males benefit more from additional mates), as well as other myriad other features—not all of which are directly linked to mating. For example, men have relatively high standards for long-term relationships, as do women. However, when compared to women, men have relatively lower standards for short-term, low-commitment relationships (Kenrick, Sadalla, Groth, & Trost, 1990). Men and women also select mates using somewhat different criteria (Li & Kenrick, 2006). Females prefer high-status males, and often choose older males who have had a chance to gain social position, whereas males prefer women with features indicating high fertility (e.g., Kenrick & Keefe, 1992). Humans are also *unlike* most other mammals in that the male often does make a very high indirect investment (provision of resources for developing offspring; Geary, 2000; Trivers, 1972). As a consequence, men are, compared to other mammalian males, more selective in choosing longer-term mates.

Ecological influences. Different ecological factors—such as the availability and predictability of resources, the prevalence of external mortality threats (e.g., violence), pathogen prevalence, and sex ratios —are known to affect how an organism allocates its finite resources across the lifespan (Durante, Griskevicius, Simpson, Cantu, & Tybur, 2012; Ellis, Figueredo, Brumbach, & Schlomer, 2009; Griskevicius et al., 2011). For example, a number of researchers have found evidence that harsh and unpredictable environments are associated with relatively "fast" strategies in human beings: earlier puberty, earlier reproduction, emphasis on immediate rewards, more children, and less investment in any particular child (e.g., Griskevicius, Tybur, Delton, & Robertson, 2011; Pollet, Nelissen, & Nettle, 2007). Although people often moralize about such "fast" behavior, this calibration to the environment may have been adaptive, allowing humans to reap all-important fitness rewards in harsh and unpredictable environments (e.g., Ellis et al., 2009; Griskevicius et al., 2011; Williams, Sng, & Neuberg, 2016).

Implications of an Evolutionary Life History Perspective for the Subjective Well-being

Subjective well-being(s). Taking an evolutionary perspective means asking what functional, fitness-relevant outcomes feelings of subjective well-being might generate. On our view, feelings of subjective well-being might signal progress toward adaptive goals. Thus, from a general evolutionary perspective, feelings of subjective well-being ought to be systematically calibrated to one's fitness. That is, I should feel subjective well-being when I am generally experiencing success in enhancing my fitness, and not when I am experiencing failure.

However, humans are unlikely to have a general, all-purpose fitness calibration mechanism in our brains (e.g., Barrett & Kurzban, 2006). Instead, we are likely to have a number of separate "systems" that gauge success in particular domains that correspond to the recurrent challenges and opportunities our ancestors faced. Considering the set of fundamental motives we discussed earlier, this might mean that we gauge success separately for satisfying nonsocial physiological needs, protecting ourselves from physical attacks, making and keeping friends, winning respect in our social groups, acquiring mates, keeping mates, and successfully caring for our offspring and other relatives (Kenrick & Griskevicius, 2013; Kenrick, Sundie, & Kurzban, 2008).

One implication of this is that people might have domain-specific subjective well-being *s*. For example, a hedge fund wunderkind who achieved riches by working day and night during his 20s might, once he reached his early thirties, lament not having a wife and kids. His financial successes might have garnered him status and esteem, which might have evoked feelings of subjective well-being at the time, but perhaps only in the status domain. By continuing to focus all of his finite time and energy on achieving financial success, he would be unable to spend the necessary time and energy to acquire a mate and start a family. Hence, his sense of subjective well-being regarding status achievements might be overshadowed by his deficits in the mating and kin care domains. Getting back on the hedonic treadmill to erase these deficits via pursuing a wife and having children would serve his reproductive fitness more than continuing to relish his wealth and status achievements.

Thus, the very same behavior (i.e., working overtime to achieve financial success) could constitute success in one fundamental motive domain, but failure in another. As a consequence, at any one time, a person might feel subjective well-being in one domain, but not in others. This notion of multiple, domain-specific subjective well-beings is somewhat consistent with Diener's (2000) assertion that subjective well-being is composed of several separable components, including satisfactions with various important domains (e.g., work, family life). This raises questions about how humans might aggregate across different types of well-being in various functional domains when reporting their general, global sense of subjective well-being. We return to this question later in the chapter.

Different outcomes evoke feelings of subjective well-being as a function of life history features. In a related vein, we would also expect well-being to be differently linked to each of the goal systems at different ages, and in different contexts, depending on which evolved fundamental motives are currently salient. That is, we would expect that there are important individual differences in which fundamental goals (e.g., seeking status, pursuing mates, caring for kin) are chronically active. Different goals are likely to be differentially weighted depending on one's gender and other life history features, such as age, relationship status, and whether or not a person has (young and dependent) children. Some preliminary support for that assumption comes from recent work by Neel, Kenrick, White, and Neuberg (2016), who found, for example, that a mate-seeking motivation decreased with age, whereas kin care increased among parents, especially those with younger children. This, too, is likely to have important implications for which behavior generates feelings of subjective well-being across individuals.

Thus, achieving success in the domain that is most salient for a person at a particular phase of life history should generate the greatest feelings of subjective well-being. For example, as in the example of the successful hedge fund investor, well-being for a young adult male might be primarily linked to achieving status and esteem. And at that point in his life, caring for a child might actually serve to decrease feelings of subjective well-being. This is consistent with research by Diener and Fujita (1995), who found that having resources in domains related to one's salient goals (e.g., having social skills for people who want to network, having physical attractiveness for people who want to find mates) is a better predictor of happiness than resources unrelated to one's salient goals. Similarly, people feel better on those days when they make progress toward goals they highly value (Oishi, Diener, Suh, & Lucas, 1999).

Further, we can use typical life history trajectories to make informed guesses about what outcomes might evoke feelings of subjective well-being in people, as a function of their ages and sex (and other life history features). For example, caring for a young child might be especially likely to evoke feelings of subjective well-being for somewhat older people who are in stable romantic relationships, whereas this same behavior might be less likely to evoke feelings of subjective well-being for younger people, or those lacking stable romantic partnerships. Similarly, we noted earlier that there tend to be differential levels of mating versus parental investment in males and females, such that men tend to be generally higher in mate-seeking motivation, women tend to be generally higher in kin care motivation. Successfully pursuing mates might be more likely to evoke feelings of subjective well-being among young men than among young women, and caring for a young child might be more likely to evoke feelings of subjective well-being among older women than among older men.

A recent series of studies provides preliminary support for the predictive value of life history features as determinants of psychological well-being (Krems et al., 2017). We assessed which fundamental motives were most strongly reflected in the behavior that people believed would garner them feelings of subjective well-being (as well as other types of well-being). We also linked such assessments to people's life history features (such as age, sex, and parental status). Participants first read descriptions of several different types of well-being, broadly defined: subjective well-being, eudaimonic well-being (meaning in life), hedonic wellbeing (attaining pleasure and avoiding pain), and self-actualization (realizing fully one's own, unique potential). After reading one of these descriptions, participants were asked what they would be doing if they were achieving each of these types of well-being (for subjective well-being, for example, what would you be doing if you were maximizing the extent to which your life, work, health, and social relationships are desirable, enjoyable, and valuable). Later, they asked to view their answers (e.g., "You said that, if you were achieving subjective well-being at this point in your life, you would be doing..."); people then rated the extent to which each of the fundamental motives (self-protection, disease avoidance, affiliation, status-seeking, mate acquisition, mate retention, and kin care) was reflected in their responses, using a 7-point Likert-scale (1 = not at all, 7 = very much). These same people gave information about their life history features (age, sex, relationship status, presence of children, and children's ages).

Table 1 provides illustrative examples of what people reported they would be doing if they were achieving subjective well-being.

Overall, affiliation was the fundamental motive most strongly reflected in the behavior people

believed would garner them subjective well-being (see Figure 2). By contrast, status-seeking was the motive most strongly reflected for self-actualization. For hedonic well-being, on the other hand, self-protection and mate acquisition were relatively more strongly reflected. For eudaimonic well-being, affiliation and kin care were strongly reflected.

Thus, laypeople view well-being as primarily linked to spending time with friends, and also view the profile of motives associated with subjective wellbeing as somewhat distinct from other types of happiness-linked outcomes (e.g., self-actualization).

Table 1

Samples of Lay Perceptions of Behaviors that Would Achieve Subjective Well-Being

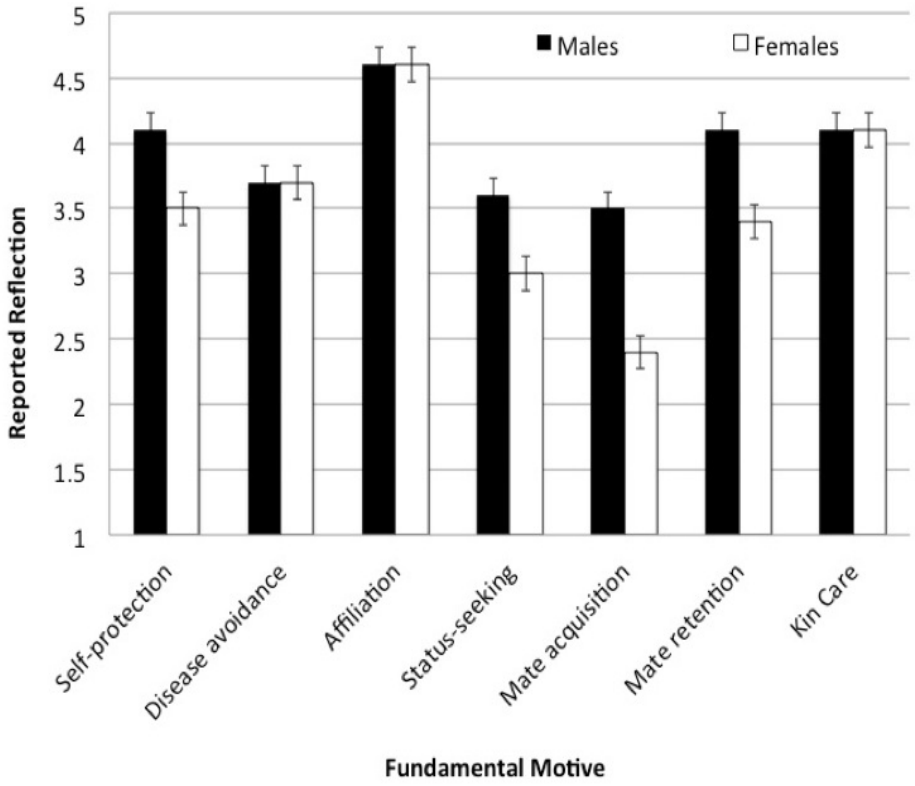
Example	Sex	Age
"Writing, I'd have a book or two published with a few short stories; I'm in shape now but want to be a bit more muscular; I'd be able to go out and socialize more, I love food and craft beer."	Male	28
"Trying my best to have good hearted friends, spending time with close family, working out and dieting, trying to climb the financial, educational, and work related ladders to the top"	Female	25
"Spending more time with my kids"	Female	29
"Rescuing animals while taking care of my family"	Female	43
"Probably sitting in the backyard at a friend's house around a fire"	Male	41
"Out to lunch with close friends."	Female	44
"My life has a whole would include work to keep my brain working, my relationships to keep me grounded and to feel that I am wanted and needed and loved. And try to stay healthy and life a long and happy life."	Male	69
"Meeting new people, finding a job that actually means something, creating something"	Male	56

These findings also supported the prediction that there would be systematic linkages between people's fundamental motives, their life history features (age, sex, relationship status, presence of children), and their expectations of what pursuits would lead to subjective well-being. For example, people's emphasis on affiliation changed across the lifespan; both younger and older people reported that affiliation was linked more to their anticipated subjective well-being than did middle-aged people. This is consistent with what we know about socialization across the lifespan; whereas friends are highly important in youth and young adulthood, romantic partners and one's own children take up more time and energy later on. When children are no longer highly-dependent, however, affiliative relationships again become prioritized (e.g., Neel et al., 2016). Thus, age is one life history feature that affects what motives people believe they are pursuing when they pursue subjective well-being.

Second, men reported that both status-seeking and mate acquisition were more strongly linked to their anticipated subjective well-being than did women. This demonstrates that gender also affects what

motives people believe will maximize subjective well-being, and that these pursuits might truly reflect progress towards those different goals that are adaptive for different people, again as based on their particular combination of life history features (e.g., Kenrick et al., 2010; Krems et al., 2017; Miller, 2000).

Figure 2. The extent to which men and women report each motive as being reflected in their pursuit of subjective well-being. Error bars represent 95% standard errors. Data taken from Krems et al. (2017).



Third, people's relationship status (i.e., whether they were single or partnered) affected the extent to which various fundamental motives were reflected in their anticipated subjective well-being, again in ways consistent with predictions made from an evolutionary life history perspective. For example, single men (but not women) linked seeking status and acquiring mates more strongly to their anticipated subjective well-being than partnered men did, whereas partnered women (but not men) linked mate retention and kin care more strongly to their anticipated subjective well-being than single women did. Fourth, whether or not people had children also affected the extent to which various fundamental motives were reflected in anticipated subjective well-being, again in ways consistent with an evolutionary life history perspective. For example, both fathers and mothers linked kin care more strongly to their anticipated subjective well-being than did men and women without children, respectively.

Taken together, these findings suggest that subjective well-being does not mean the same thing to different people. What is required to achieve well-being varies for individuals in systematical predictable ways. That is, subjective well-being looks somewhat different for people as a function of their ages, sexes, and other life history features. This has implications for how people go about pursuing subjective well-being, as well as for how health professionals and others instruct people to go about achieving this flavor of happiness. Although it may seem obvious that giving a grandfather and a young single woman the same advice about how to achieve subjective well-being is likely to make neither happy, it is worth exploring further how this might be useful for mental health interventions. There may be no one-size-fits-all advice for achieving this outcome. Our framework suggests that some features might help determine what subjective well-being might look like for different folks.

Different outcomes evoke feelings of subjective well-being as a function of ecology and culture. This perspective also leads to the expectation that behaviors evoking subjective well-being might be systematically different in different environments, as a function of the ecological features of those

environments (e.g., resource availability, pathogen prevalence, sex ratio, local levels of violence).

Consider a resource-scarce environment characterized by high levels of violence. In this environment, self-protection is likely to be a chronic priority. Likewise, in an environment characterized by high pathogen loads (e.g., high infectious disease), disease avoidance is likely to be a chronic priority. Self-protection might be more strongly linked to subjective well-being for people living in the violent environment, whereas disease avoidance might be more strongly linked to subjective well-being for people living in the high-pathogen environment. Thus, ecological conditions are likely to drive the functional prioritization of the fundamental motives, meaning that people living in different ecologies might have different conceptualizations of what constitutes their own subjective well-being.

Because these different motives direct attention, perception, cognition, and behavior in specific, potentially functional ways, an ecologically-influenced prioritization of some motives over others could have major implications for predicting what behavior would contribute to feelings of subjective well-being in different environments. This might help explain why, for example, although people living in ecologically-developed and relatively wealthy nations are among the happiest (e.g., Diener, Kahneman, Tov, & Arora, 2010)—likely because their basic needs are met (Tay & Diener, 2011)—there is not a monotonic relationship between income and reported subjective well-being across cultures (e.g., Diener & Oishi, 2000) and why, within countries, rich people are only slightly happier than poor people (Diener, Horwitz, & Emmons, 1985).

Environments characterized by high income inequality are also characterized by higher levels of violence (e.g., Daly, Wilson, & Vasdev, 2001; Krems & Varnum, 2017; Varnum & Grossmann, 2017; see also Helliwell et al.'s *World Happiness Report*, 2016, 2017). Thus, people living in environments with high income inequality might also relatively prioritize self-protection on average. Likewise, some research has also asserted that environments with female-biased sex ratios might have more male-male violence, but that environments with male-biased sex ratios might have more male-female violence (e.g., Krems & Varnum, 2017), implying that men in the male-biased environments and women in the female-biased environments might also relatively prioritize self-protection. An implication of this is that some environments might cause (certain) people to spend their finite time and energy on more "basic" fundamental motives, meaning that these people cannot spend that time and energy on "higher" motives such as seeking status, findings mates, and caring for kin. This is consistent with both Inglehart's (1990) and Maslow's (1943) propositions that individuals only pursue self-fulfillment after they have met their basic material needs.

In environments where meeting these needs requires constant vigilance, then, perhaps self-fulfillment seems like an impossible pursuit. Graham (2017) proposes that income inequality can lead to inequality in people's hopes, dreams, and happiness. In essence, she argues that the experience of daily stresses can inhibit an individual's ability to plan for the future (because he/she must instead be focused on getting by day-to-day). This ecologically-necessitated present-focus prevents people from planning for the future, and, therefore, from pursuing lives filled with pleasure and meaning.

Whereas these and other ecologically-evoked aspects of culture can affect the prioritization of fundamental motives, there are also aspects of transmitted culture that are likely to do the same. That is, the value system of any one culture (e.g., which achievements are prioritized) tells its people what is important (and unimportant); achieving outcomes one's own culture prioritizes might be especially likely to lead to feelings of subjective well-being. Because cultures can differ in what they prioritize, this implies that what gives rise to subjective well-being might also differ across cultures. In more individualistic and capitalistic cultures, for example, people might link subjective well-being more strongly to achieving status, whereas in more collectivistic and equalitarian societies, people might link subjective well-being more strongly to affiliation. This prediction seems consistent with work by Diener and Diener (1995), which showed that self-esteem was more strongly correlated with life satisfaction in individualistic than collectivistic societies. Similarly, in more highly religious nations, higher religiosity was more strongly linked to happiness (Diener, Tay, & Myers, 2011); and in richer countries, which presumably prioritize earning money, those with higher incomes reported more life satisfaction (Tay, Morrison, & Diener, 2014).

Other Evolutionary Approaches to Well-Being

Several other social scientists have made interesting bridges between evolutionary psychology and happiness, well-being, and self-actualization (e.g., Buss, 2000; Diener, Kanazawa, Suh & Oishi, 2015; Grinde, 2002, 2005; Nesse, 2004). These authors have generally shared an assumption that positive affect /feelings of well-being would be expected to occur when an individual is engaging in behaviors or facing situations that would likely have enhanced fitness in the ancestral past. Since some situations pose more threats than opportunities, negative emotions also have a positive side, in motivating avoidance of situations that would have typically lowered fitness in ancestral fitness (e.g. Nesse, 2004). Diener, Oishi,

and Lucas (2015) go a step further, arguing that a chronically mild positive affect state might itself be adaptive, in that people in a good mood are likely to engage in social and exploratory behaviors that increase the odds of enhancing fitness. Several authors have also pointed out that an evolutionary approach leads to a focus on situations as well (certain situations are more likely to pose opportunities, others to pose threats). Buss (2000) points out, for example, that well-being is likely to be associated with being near kinship support groups. Humans evolved in small, kin-based groups of about 50 to 150 individuals (Dunbar, 1993), but live today is massive groups (e.g., the population of New York City is around 8.5 million individuals). Exposure to so many people might not only be daunting, in general, but it might also affect us in unexpected and negative ways; for example, seeing many physically attractive women can lower men's commitments to their existing mateships (Kenrick, Gutierres, & Goldberg, 1989; Kenrick, Neuberg, Zierk, & Krones, 1994), and can also affect women's self-concepts, making them feel less attractive and less happy (Gutierres, Kenrick, & Partch, 1999). Moreover, others have similarly linked living in modern, anonymous cities can increase depression by removing the social supports associated with ancestral living conditions (Nesse & Williams, 1994). The life history approach we have presented here is largely compatible with these other evolutionary approaches, differing mainly in specifying the different ways in which adaptive threats and opportunities would vary systematically with different life history phases.

Some Unanswered Questions

As we noted, there is preliminary support for the heuristic value of thinking about psychological well-being in an evolutionary life history perspective. Nevertheless, most of the research on this topic remains to be done. We present some findings above, for example, that show U.S. adults perceive a primary link between the fundamental motive of affiliation and feelings of subjective well-being, and also that what these adults believe generates feelings of subjective well-being differs in ways, as systematically predicted by their life history features (Krems et al., 2017). It would be interesting to extend this work to compare perceptions of subjective well-being across cultures. For instance, future work may wish to explore how fundamental motives interact with ecological and other cultural predictors of country-level scores on the national index of subjective well-being (Diener, 2000).

Similarly, the empirical work we discussed presented findings on what people thought they would be doing if they were achieving self-actualization, or various other types of well-being (Krems et al., 2017). However, we do not yet know whether there is actually a relationship between anticipated well-being and one's success at satisfying different fundamental motivations. Perhaps achieving status would actually lead to a higher sense of subjective well-being than engaging in affiliative behavior would. Further, perhaps achieving success in parental goals does not actually lead to a sense of eudaimonic well-being. Indeed, there is a controversy about how parenting is linked to happiness, with some authors suggesting that parenting is actually linked to unhappiness while others suggest it is linked to meaning in life (e.g., Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004; Nelson, Kushlev, English, Dunn, & Lyubomirsky, 2012). Perhaps using behavior-sampling methods might be useful for answering these questions.

Another avenue of work suggested by an evolutionary life-history approach would be to explore the extent to which there are in fact multiple, domain-specific subjective well-being*s* linked to different fundamental goals. Above, we suggested not only that different behavior might evoke feelings of subjective well-being for different people (e.g., with some prioritizing mate acquisition and others kin care), but also that a person might have multiple subjective well-beings simultaneously—one for each fundamental motive. Perhaps it is only when the self-protection and disease avoidance subjective well-being meters are at adequate levels can one pursue "higher" motives, for example. Moreover, this notion raises the question of how people might aggregate across domain-specific subjective well-beings when answering typical assessments of their global subjective well-being.

Some existing work might speak to this, suggesting that subjective well-being in some fundamental motive domains might be of especially high importance. For example, whereas Suh, Diener, and Fujita (1996) found that the effects of many major life events (e.g., being fired or promoted) on well-being had waned almost entirely after three months, Winter, Lawton, Casten, & Sando (1999) found that romance-linked life events (i.e., marriage and widowhood) were still effecting subjective well-being six to eight months later. Similarly, other work suggests that, whereas people can rapidly adapt to some seemingly crippling life events rather quickly, other events have potentially longer-lasting effects—and again, these other events were linked to romance (Frederick & Loewenstein, 1999). This convergence might begin to suggest that mating motives are highly important for subjective well-being, or at least that events affecting mating motive-linked outcomes have particularly high and long-lasting impact on subjective well-being. Or those findings may be linked to the age and parental status of the research participants in the different studies.

Beyond replicating and extending work taking an evolutionary approach to understanding subjective well-being, future work may also wish to take advantage of the unique, generative power of this approach to understanding subjective well-being (see, e.g., Buss, 2000; Nesse & Ellsworth, 2009). That is, one of the interesting suggestions of an evolutionary perspective is that negative affect is as adaptive as positive affect; a person's *unhappiness* (or dissatisfaction, etc.) with his station in life can lead him or her to pursue achievements that garner status and esteem, which can facilitate the acquisition of a desirable mate, having children, and so on.

One implication of this perspective is that it might reframe the happiness gap discussed by Graham (2017); she argues that perhaps poor Americans feel less subjective well-being because they are necessarily more concerned with the day-to-day business of survival rather than making meaning, planning for the future, and other activities that might typically lead to feelings of subjective well-being. On an evolutionary view, whereas poor Americans might lack subjective well-being, they are nevertheless engaging in behavior that, for their environment, may be adaptive. People for whom getting by day-to-day might would be expected to have different conceptualizations of what behaviors give rise subjective well-being, as compared to people from more privileged environments. Perhaps feelings of personal safety, for example, generate phenomenologically similar feelings of subjective well-being for poor people as does pursuing what might be considered by some to be "higher" motivations does for wealthier people. Ellis and colleagues (2009) have made similar arguments about the "fast" life history strategies pursued by people from ecologies characterized by harshness and unpredictability. Whereas middle-class people, such as most highly educated researchers, frequently make moral judgments about fast strategists' levels of risk-taking, earlier sexual debuts, and lesser investment across more children, this suite of behavior may be adaptively calibrated to the environment which evokes it. Pathologizing the lack of subjective well-being among the American poor may be akin to moralizing how they (ought to) spend their time.

A second implication of pointing out the possible functionality of unhappiness serves to underscore the fact that the possible upsides of nonclinical levels of dissatisfaction, too, are worthy of study (e.g., Buss, 2000). For example, Buss (2000) cites how the negative emotion of jealousy, whereas it might feel unpleasant, motivates adaptive behavior designed to counter threats to valued mateships (Daly, Wilson, & Weghorst, 1982). Thus, negative feelings can generate functional outcomes. Nesse (2004), too, argues that focus on reliving negative status and achieving positive states has left 'diagonal psychology' ignored; but an evolutionary approach would emphasize the adaptive benefits of negative emotions. Further, just as we argue above that progress toward adaptive goals makes people happy, thwarted progress toward those same goals makes people unhappy. And just as the prioritization of goals is affected by one's life history features (e.g., age, sex, relationship status) and perhaps ecology/culture, what makes people unhappy in functional ways may similarly vary across cultures in important ways. Identifying what behavior makes different people happy—or functionally unhappy—and why, on an ultimate level, is an area ripe for future empirical work. Indeed, what makes someone less happy is not necessarily the same thing that makes that person unhappy; studying unhappiness and dissatisfaction merely as low scores on happiness and satisfaction scales might obscure the distinct, important features of negative affect (especially if such scales have no possible negative scale points for reporting unhappiness but rather start at 0 or 1 to indicate ""no" or "low happiness"). From an evolutionary point of view, just because unhappiness is less pleasant than happiness, this does not make it any less adaptive or any less worthy of study.

Abstract

Decades worth of research on subjective well-being provides evidence for the idea that personality plays a strong role reports of positive affect, negative affect, and life satisfaction. Specifically, this research shows that subjective well-being, like personality traits themselves, is moderately stable over time and moderately heritable. In addition, some of the strongest correlates of well-being reports are personality traits like extraversion and neuroticism. In this chapter, I review evidence for the importance of personality in explaining subjective well-being, focusing both on the strengths and limitations of existing research and complexities in the interpretation of the empirical evidence that does exist. Ultimately, research on personality and well-being can be seen as a model for how research on other predictors of subjective well-being can proceed.

Keywords: Personality, Subjective Well-Being, Stability

Subjective well-being (SWB) reflects a person's overall evaluation of the quality of his or her life as a whole. Presumably, when constructing life satisfaction judgments, people consider the various events and circumstances in their lives (e.g., their income, their social relationships, their health, and the various positive and negative life events that have occurred), weight these circumstances by importance, and then aggregate to derive an overall evaluation. If this intuitive model of how SWB judgments are made is correct, then one might expect the objective circumstances in one's life to be the primary determinant of his or her SWB. Furthermore, people's behaviors are often guided by their beliefs about what external circumstances will make them happy (Gilbert, 2006). Thus, psychologists and lay people alike often express surprise about the relatively weak associations between specific external life circumstances and well-being judgments (e.g., Gilovich & Eibach, 2001; Kahneman, 1999; Schwarz & Strack, 1999).

In contrast to the relatively small associations with life circumstances, decades of research show that the strongest and most consistent predictors of SWB are typically the stable individual differences that personality psychologists study (Diener, Suh, Lucas, & Smith, 1999; Lucas & Diener, 2015; Steel, Schmidt, & Shultz, 2008). For instance, although research typically shows correlations around .20 between SWB and intuitively appealing predictors like income (R. T. Howell & Howell, 2008; Lucas & Dyrenforth, 2006; Lucas & Schimmack, 2009), correlations with personality traits like extraversion and neuroticism are often around .40 or .50 (Lucas & Fujita, 2000; Steel et al., 2008).

Indeed, the strong evidence for the stability and heritability of SWB, along with the relatively strong associations between scores on SWB measures and various personality traits, have led some to suggest that well-being judgments themselves are trait-like and may even be impervious to lasting effects of changing external circumstances (Brickman & Campbell, 1971; Headey & Wearing, 1991; Lykken & Tellegen, 1996). Clearly, if SWB were so strongly determined by personality that external circumstances simply do not matter, then this would have serious implications for research on SWB. Specifically, it would suggest that the search for external predictors of the construct would ultimately be fruitless. Perhaps more importantly, it would suggest that striving for improved well-being may be impossible, as personality processes would inevitably return people to their genetically determined set points. In this chapter, I review the evidence for the role that personality processes play in SWB, focusing on what we know about the links between personality and well-being and what this means for our understanding of the role of external circumstances for SWB.

Evidence for the Importance of Personality

Before addressing the role that personality plays in SWB judgments, it is important to define the construct itself. As noted above, I start with the idea that SWB reflects a person's overall evaluation of the quality of life as a whole (see Diener, Lucas, Schimmack, & Helliwell, 2009, for a more detailed discussion). Researchers who study SWB acknowledge that such evaluations can be assessed in a variety of ways. For instance, Diener (1984) noted that there are least two ways to evaluate SWB. First, one can simply ask respondents to think about the features of their lives and to provide an overall rating of their satisfaction with these conditions. Measures of life satisfaction or domain satisfaction assess this more

cognitive approach to the evaluation of well-being. Alternatively, if one's life is going well, it is reasonable to assume that that person would experience frequent positive emotions and infrequent negative emotions; and thus, it is possible to use respondents' typical levels of affective experience as an indicator of how well their lives are going (see Busseri & Sadava, 2011; Schimmack, 2008, for a discussion of these multi-component models of SWB).

It is also important to note that even for the same component of SWB, there are multiple ways to obtain an assessment of the underlying construct. For instance, Kahneman and Riis (2005) noted that if we want to assess the typical level of positive affect that a person experiences, researchers could either ask respondents to reflect on their lives and report their typical experiences or they could assess these momentary experiences using more intensive procedures such as ecological momentary assessment (Stone, Shiffman, & DeVries, 1999) or the day reconstruction method (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004). The various components of SWB and even the various measures of the same component can show differential associations with predictors and outcomes, and thus, it is important to consider when and why these various measures behave the same or differently. Thus, when possible, I will discuss how personality differentially relates to different measures.

As reviewed elsewhere (Lucas & Diener, 2008, 2015), there are at least three main lines of evidence that suggest that personality matters for SWB. First, SWB measures, like personality traits themselves, are stable over time. Specifically, people exhibit *rank-order stability*, where those who are relatively happy at one moment tend to be happier than average when assessed at a later time. Second, SWB is moderately heritable, which suggests that something inside the person plays a role in the well-being that people report. And finally (and most directly), SWB measures tend to be moderately strongly correlated with scores on personality traits. Below I review some of the primary findings for each line of evidence.

The Stability of SWB

The importance of research on the stability of SWB is nicely summarized in a quote from an early article by Costa, McCrae, and Zonderman (1987). They noted that the evidence for high levels of stability that they found in their study "[points] out the need for caution in interpreting well-being scores as indices of the quality of life, because well-being is strongly influenced by enduring characteristics of the individual" (p. 299). In other words, if we assume that the circumstances of one's life change over time, then evidence for strong stability means that these changing circumstances have little effect on SWB, and that something internal to the person must be the primary determinant of individual differences in this construct.

The article by Costa et al. (1987) is useful in highlighting some of the issues involved when considering research on the stability of SWB. First, this early study, which used high quality data to examine the test-retest stability of SWB, clearly shows that responses to SWB measures are stable over a reasonably long period time. Specifically, in this 10-year longitudinal study, which included a nationally representative sample of the United States with thousands of participants, the stabilities of positive and negative affect were .44 and .43, respectively. As Costa et al. (1987) emphasized, these relatively high stability coefficients contrast with the relatively weak correlations with demographic factors like income or age. Furthermore, they showed that the correlations are equally strong for those who went through major life transitions like a change in employment or marital status and those who did not. Thus it appears to provide strong evidence that SWB judgments are impressively stable over time.

Although the early study by Costa et al. (1987) provides important evidence for the long-term stability of SWB, there are a number of limitations that would need to be addressed by subsequent research. First, the study used a simple two-wave design that results in just a single stability coefficient. This single stability coefficient is difficult to interpret (Fraley & Roberts, 2005; Kenny & Zautra, 1995, 2001): Would stability coefficients decrease with longer intervals, or do they remain impressively strong even over many decades? Multi-wave studies can be used to assess the pattern of stability coefficients across varying intervals, which provides clearer answers to the questions about the role of stable internal factors in determining SWB.

Second, the study relies solely on global, self-report measures of SWB, and specifically on self-report measures of the affective components of SWB. This limitation leaves open a number of questions: How stable are other components, such as life satisfaction; how stable are non-self-report measures of SWB; how much of the stability is due to the shared method variance that results from the reliance on a single method or to stability in method factors such as response styles?

Finally, although Costa et al. acknowledge that stability in SWB could either be due to the influence of personality or to the fact that important life circumstances tend to be stable over time, their methods for dealing with this ambiguity (which focused on assessing stability separately among people who experienced a major life event versus those who did not) were quite limited. Thus, the question of whether

SWB can change after the experience of life events is mainly left unanswered by studies like this. Over the subsequent decades, answers to these questions became much more clear.

More recent attempts to investigate the stability of well-being measures have led to clearer conclusions about the degree of stability that exists. Specifically, more recent studies have used long-running panel studies or meta-analytic summaries from studies that vary in interval length to derive more precise estimates of how stability coefficients change with increasingly long intervals and across different types of measures (see Sheldon & Lucas, 2014, for an overview of issues related to the stability of SWB). To clarify why these multi-wave studies are necessary, it is useful to discuss the conceptual underpinnings of one model for analyzing multi-wave data, the Stable Trait-Autoregressive Trait-State (STARTS) model (Kenny & Zautra, 1995, 2001).

The idea behind the STARTS model is that at any given occasion, there are three types of influences that could affect responses to a measure. First, there are perfectly stable influences, those that impact responses in the same way no matter the occasion. These can be considered *stable trait* influences. Second, there are completely unstable influences that affect responses at one wave, but are completely independent from responses at any other wave. These can be considered *state* influences.[1] Finally, it is possible to identify the influence of characteristics that change systematically over time in an autoregressive manner. For instance, factors whose influence wanes with increasing time will lead to stronger correlations over shorter intervals, and weaker correlations over longer intervals. These influences are reflected in an *autoregressive trait* component.

Kenny and Zautra (1995) noted that each component implies a different pattern of stability coefficients over time (also see Fraley & Roberts, 2005). For example, if responses to life satisfaction were due entirely to the effects of unstable state influences, then responses should be completely uncorrelated over time. In contrast, if life satisfaction judgments were due entirely to the influence of stable-trait factors, then stability coefficients would equal one, no matter the interval that was chosen. Finally, if life satisfaction ratings were due entirely to autoregressive factors, then stability coefficients should decline as the length of the interval increased. Specifically, these coefficients should show an exponential decline. For example, if the one-year stability was .75, then the two-year stability would be 0.56 (i.e.,) and the three-year stability would be 0.42 (i.e.,).

Of course, if all three sources of variance contribute to a person's score on a well-being measure, then the pattern of correlations will not fall into one of these three ideal patterns. However, structural equation modeling techniques can be used to decompose the pattern of correlations and to estimate the amount of variance accounted for by the three sources. For instance, if a measure of SWB was influenced equally by transient state influences, autoregressive trait influences, and stable trait influences, then the correlation between two waves that were very close in time would be .66 (reflecting the fact that one-third of the variance was completely transient), the correlation between two waves that were very distant would be .33 (reflecting the constant effect of the perfectly stable trait), and the correlation between waves of increasing intervals would decline in a regular fashion (due to the impact of the slowly changing autoregressive trait; the precise rate of decline would then depend on the wave-to-wave stability of this autoregressive component).

Lucas and Donnellan (2007) and Lucas and Donnellan (2012) used these techniques with data from four different long-running panel studies, including the German SocioEconomic Panel Study, the British Household Panel Study, and the Household Income and Labour Dynamics in Australia study. Results showed that approximately one-third of the variance was pure state variance (including measurement error), one-quarter to one-third of the variance was purely stable trait variance, and approximately one-third of the variance was moderately stable autoregressive variance. This leads to the expectation that year-to-year stability will be about .60, stability coefficients will initially decline with increasing length of interval (e.g., over interval lengths from 2 to 10 years), but that stabilities will eventually asymptote at around .25 to .30, where they will remain even as interval lengths continue to increase. This pattern of results supports the idea that there is a core, trait-like aspect to SWB judgments, but that this component accounts for only a modest percentage of the variability in SWB judgments.

Complex analyses like this help address the ambiguities of early, two-wave longitudinal studies like the one by Costa et al. (1987) described above because they can provide information about the causes of the stability that is observed. For instance, the results from Lucas and Donnellan (2012) suggest that the one-year stability will be considerably higher than the 20-year stability because the former is a result of both the influence of a stable trait and slowly changing factors that lead to high stability over shorter intervals. However, this slowly changing factors could be due to changes in personality or to external factors. Further increases in complexity of design can help clarify these additional issues. For instance, Schimmack and Lucas (2010) expanded the use of latent state-trait models to incorporate information from

couples who were followed over time. This allowed them to examine how two members of a couple change in similar or different ways over time. If, after accounting for initial similarity, two members of a couple change in similar ways, then it suggests that shared environmental experiences are driving this change. In addition, the models they used allowed them to test how much of the variance can ultimately be explained by these external influences (though see the paper itself for some caveats about the strength of conclusions that can be drawn). Their results suggested that sizable component of the variance in life satisfaction judgments is due to the accumulating effects of external circumstances. This design is important because it can help clarify the relative importance of person factors and situational factors even without direct measures of either.

Although the studies reviewed used above rely on very large, long-running panel studies that include nationally representative samples, it is also possible to use alternative methods for assessing stability of SWB measures. Anusic and Schimmack (2016) meta-analytically combined results from many different studies that reported stability estimates across varying intervals to isolate stable and changing components from SWB measures. Importantly, they were able to expand their analyses beyond life satisfaction to focus on both cognitive and affective components of SWB. Their meta-analytic results showed results that were quite similar to those from the panel studies, with reliabilities ranging from .58 for affect to .67 for life satisfaction. Furthermore, they found that approximately half of the reliable variance was due to stable factors and half due to changing factors. Results were somewhat similar for affect and life satisfaction, though the contribution of the stable component was slightly lower for affect than satisfaction. Importantly, Anusic and Schimmack were also able to compare the results for SWB measures to those from personality traits, and they found that the stable component accounted for a much larger percentage of variance in personality traits than for SWB measures (also see Fujita & Diener, 2005). For instance, the stable component accounted for about 40-50% of the variance in well-being measures, compared to about 80% of the personality measures. Thus, by decomposing stability coefficients in this way, it is possible to provide a very nuanced understanding of the stability of well-being measures; and these analyses strongly suggest that SWB measures are quite different from personality traits in terms of the levels of stability they exhibit.

The results reported above relied primarily on global assessments of well-being to derive estimates of stability. As noted previously, however, there are different ways to assess the various components of well-being, including the use of more *experiential* measures that track SWB over time. Because of the increased burden on respondents, experiential measures have been used much less frequently in large-scale studies that track representative samples over long periods of time, and thus, there is not as much information available about the long-term stability of such measures. One might expect stability to be weaker, as these experiential measures track immediate reactions to ongoing experiences, typically over at most a few days.

Recently, some studies have begun to test the stability experiential measures, including some large-scale panel studies. This provides important initial information about the longer-term stability of such measures. For instance, Baird, Le, and Lucas (2006) examined the six-month test-retest reliability of multiple measures of SWB, including life satisfaction and both global and experience-sampling-based measures of positive and negative affect. They found quite high stability (*r*s around .75) for all the measures they assessed. However, this study focused entirely on student samples. Krueger and Schkade (2008) examined the two-month test-retest stability of a day-reconstruction-based measure and found a correlation of .64, which was comparable to that for a life satisfaction measure assessed twice over the same period of time.

More recently, Hudson, Lucas, and Donnellan (2016) used day-reconstruction-method data from the German Socio-Economic Panel study over a three-year period. Even though the day reconstruction method used in this study sampled just a single day at each wave, one-year latent stability coefficients ranged from .30 for negative affect to .47 for positive affect; and two-year stabilities were approximately the same size. These stabilities were lower than the stability of a single-item life satisfaction measures, which ranged from .50 to .59 in this sample (because just a single-item was used, these could not be adjusted for measurement error; thus comparisons between the measures must take this difference into account). Together with the results from Anusic and Schimmack (2016), this suggests that both experiential and global measures of affect exhibit moderate stability over time, and that this stability tends to be somewhat weaker than that for global life satisfaction measures.

The results reviewed above suggest that there is some degree of stability in SWB measures, regardless of which component is assessed and which type of measure is used. At the same time, long-term studies and meta-analytic evidence suggests that stabilities decline with increasing intervals, eventually leveling out to asymptote at long-term stability coefficients around .25 to .30, or .40 to .50 after correcting for measurement error. Together, this suggests that some truly stable personality factors contribute to well-being judgments, but that real change, including change that could potentially be linked to external circumstances, does occur. However, an important piece of evidence in early arguments for the role of

personality as a determinant of SWB was the fact that well-being scores remained stable in spite of changing life circumstances (Brickman & Campbell, 1971; Costa et al., 1987). Thus, to fully address questions about the relative role of personality and external circumstances, it is necessary to review studies that explicitly focus on change that occurs following the experience of changing life circumstances.

Early evidence was interpreted as support for the idea that life circumstances simply do not matter. Most famously, Brickman, Coates, and Janoff-Bulman (1978) examined the SWB of a small group of patients with spinal cord injuries, a group of matched controls, and a group of lottery winners. Although the authors' conclusion was simply that scores of the patients with spinal cord injuries were not as low as one might expect (rather than that there were no differences at all), this study has had a strong impact on perceptions of people's ability to adapt. As Lucas (2007b) noted, the differences between groups was, in fact, quite large, and the extent of adaptation that occurred has been overstated. More recent studies that rely on large samples of participants with similar spinal cord injuries consistently show that the differences between these participants and those without such injuries are medium to large in size.

Simple cross-sectional studies like this are difficult to interpret. Better evidence for the impact of changes in life circumstances comes from studies that follow individuals before and after such changes occur. Of course, such studies are hard to conduct, as it is difficult to predict when rare events like the onset of a disability will occur. However, researchers have again relied on large-scale panel studies that follow large samples of participants for many years to examine these questions. With large enough samples and a long enough period of time, some small percentage of participants will experience an event. As long as SWB has been tracked throughout the study, pre-event levels can be estimated and compared to post-event levels to examine the effects of the changing circumstances.

Many studies have now been conducted that use this approach (see Lucas, 2007a, for a review). These studies show that changing life circumstances can have lasting effects on SWB, but the extent to which lasting changes occur depend on the specific event in question. For example, Lucas, Clark, Georgellis, and Diener (2003) found evidence that people quickly adapt to marriage (though see Anusic, Yap, & Lucas, 2014a, 2014b for complications regarding the interpretation of these effects), but that widows seem to be affected by the loss of their spouse for much longer. Similarly, Lucas, Clark, Georgellis, and Diener (2004) found evidence that life satisfaction permanently changes after a bout of unemployment, and Lucas (2007b) found evidence for large and permanent effects of the onset of disability on life satisfaction, especially for more severe conditions. Taken together, this evidence from longitudinal studies provides relatively clear support for the idea that life circumstances do matter for SWB and that personality is not the sole determinant of long-term individual differences (see Luhmann, Hofmann, Eid, & Lucas, 2012, for a meta-analytic review).

In summary, there is now considerable empirical evidence about the stability of subjective well-being measures over time. These studies reveal that in the short term, all components and measures of well-being are reasonably stable. As the test-retest interval increases, stability declines. Eventually, however, stability coefficients asymptote, and it appears that approximately one-third to one-half of the reliable variance (or one-quarter to one-third of the total variance) in these measures is truly stable trait variance that does not change even over very long periods of time. There is some indication that stability is slightly higher for life satisfaction than affect, but this may be due to differences in the measures (Anusic & Schimmack, 2016). Most studies that examine stability rely on self-report measures, which means that stability estimates may be inflated by stability in method factors such as response styles; thus future research should take a multimethod approach. Finally, studies that directly assess whether subjective well-being changes following major changes in life circumstances shows that such changes can and do occur, even though some amount of adaptation happens. Again, however, these studies of life events typically focus on life satisfaction as an outcome, and there are fewer studies looking at the effects of life events on experienced affect.

The Heritability of SWB

The research reviewed above focused on the stability of SWB over time. One reason that this research has been used to support the idea that personality matters is that personality itself is thought to be stable, which leads to the idea that evidence for stability in SWB is evidence that personality matters. Of course, it is possible that situations and life circumstances are also quite stable over time, which would provide an alternative explanation for any stability in SWB that is observed. In addition, research that directly assesses the impact of stable situations on SWB is limited in its ability to clarify these issues because it is difficult to consider and assess all aspects of the situation and environment that may matter. Thus, researchers have turned to other designs to help clarify whether stability in well-being that is examined is truly due to the influence of internal factors versus stability in external, environmental features. One powerful set of techniques for answering these questions comes from behavioral genetic studies (also see Røysamb, this volume).

Although behavioral genetic studies represent a broad set of research designs, here I focus on evidence from the most common of these: the twin study and its variants (see Røysamb, Nes, & Vitterso, 2014, for a detailed review of these issues as they apply to research on SWB). Twin research takes advantage of the fact that identical twins have identical DNA, whereas fraternal twins share on average 50% of their genes. Thus, it is possible to estimate the influence of genes on SWB (or other observable characteristics) by comparing the similarity of identical twins to the similarity of fraternal twins. A simple estimate of heritability can be derived multiplying the difference between the identical twin correlation and the fraternal twin correlation by two.

Some of the earliest studies that examined the associations among twins found heritabilities close to .50 (Tellegen et al., 1988). However, the specific measures that were included were actually measures of stable personality traits, even though the traits that were examined had an affective focus. Since these initial studies were conducted, many additional studies have been reported, and these studies also find moderate heritabilities, even for traditional measures of subjective well-being such as the Satisfaction With Life Scale (Diener, Emmons, Larsen, & Griffin, 1985) or single-item measures of life satisfaction. For instance, Stubbe, Posthuma, Boomsma, and De Geus (2005) examined the broad heritability of life satisfaction in a sample of over 5,000 participants from the Netherlands Twin Registry, and they found a heritability estimate of .38. Bartels and Boomsma (2009) found heritabilities between .40 and .50 for different measures related to SWB, including a measure of life satisfaction. Indeed, enough studies have been conducted that Bartels (2015) was able to conduct a meta-analysis of heritability estimates for well-being measures, resulting in an average effect of .38 for general well-being and .32 for life satisfaction measures.

Studies focused on the heritability of SWB can be controversial because there is a tendency to interpret these studies as providing direct evidence about the extent to which SWB can change. Specifically, it is sometimes assumed that if something is highly heritable, then that means that change is not possible, or even that early interventions are doomed to failure. This mistaken assumption can even occasionally be reinforced by behavioral genetic researchers, such as when Lykken and Tellegen (1996) suggested that "It may be that trying to be happier is as futile as trying to be taller and therefore is counterproductive" based on their analysis of a longitudinal twin study. As Røysamb et al. (2014) point out, there are no clear and direct implications for the potential for change from heritability estimates on their own. Heritability estimates reflect a sample-based estimate of the variance that can be accounted for by genes, and this estimate can vary across populations. They note that in modern industrialized nations, the heritability of height is above 80%; but in the past, it presumably was much lower. This is because the environmental factors that may have caused appreciable variation in height in the past are now much more consistent, at least among individuals living in industrial nations. As a particularly salient example of this, Cheung et al. (2017) showed that overall levels of life satisfaction have declined by more than two standard deviations in Syria as the nation has descended into civil war; the severe environmental conditions clearly impacted global well-being despite the influence of any personality characteristics. These results show that caution is needed when drawing conclusions about the implications of high heritabilities for SWB. Røysamb et al. walk through a number of important caveats about the interpretation of heritability studies of SWB.

Ultimately, behavioral genetic studies of SWB are useful because they begin to constrain the possible explanations for individual differences in SWB that are observed. If meta-analytic estimates suggest that approximately one-third of the variance in life satisfaction is heritable (Bartels, 2015), then it will be necessary to develop theories that incorporate mechanisms that can account for such effects. The consistent result emerging from decades of behavioral genetic studies with many thousands of twins is that SWB is moderately heritable, suggesting that some inborn features of people's personality have an influence on the stable levels of SWB that they experience. It is up to future investigations to clarify exactly how these processes work and how these inborn tendencies are translated into the individual differences in well-being that we observe.

Associations with Personality Traits

The most direct evidence for the importance of personality in SWB comes from studies that examine the association between specific personality factors and SWB. A quick review of the research that has been conducted on SWB shows that there is considerable empirical evidence for this idea. Even in one of the earliest reviews on the topic, Wilson (1967) stated that the happy person is best described as a "young, healthy, well-educated, well-paid, extroverted, optimistic, worry-free, religious, married person with high self-esteem, job morale, modest aspirations, of either sex and of a wide range of intelligence" (p 294). Although this description emphasizes what is known about demographic predictors of SWB, it is clear that personality factors like extraversion, optimism, high self-esteem, and even constructs related to goals and aspirations play a role. Since the time of Wilson's review, these early impressions have been confirmed with increasingly sophisticated research designs.

In one of the earliest systematic investigations of the links between personality and subjective well-being, Costa and McCrae (1980) specifically tested whether two personality traits---extraversion and neuroticism---were uniquely linked to specific SWB variables. Costa and McCrae argued that extraversion was associated with positive affect, neuroticism was related to negative affect, and together these dimensions formed the affective core of the broader SWB construct. Interestingly, the associations between personality traits and the affective dimensions were not especially strong, generally falling in the range of .20 to .30. However, this early study provided a precedent for later work on the topic. Subsequent studies focused on the structure of affect and the personality underpinnings of these dimensions often linked the independent traits of extraversion and neuroticism to separable positive and negative affect dimensions (e.g., Tellegen, 1985).

Perhaps because of the "disappointing" associations between SWB and objective life circumstances, along with the consistently larger correlations between SWB and personality traits; research on personality predictors of SWB flourished in the 1980s and 1990s (Diener & Lucas, 1999; Diener et al., 1999). Researchers examined the association of hundreds of trait/well-being combinations. For instance, DeNeve and Cooper (1998) conducted a meta-analysis of associations between various SWB components and 137 different personality traits. The traits that were most strongly associated with well-being were: "repressive-defensiveness, trust, emotional stability, locus of control-chance, desire for control, hardiness, positive affectivity, private collective self-esteem, and tension" (p. 197). DeNeve and Cooper also noted that well-being components of satisfaction, happiness, and positive affect were predicted equally well from personality traits, but that the association with negative affect tended to be weaker. Importantly, the overall estimates that they arrived at were relatively small, typically below .20.

The meta-analysis by DeNeve and Cooper (1998) illustrates a number of issues that must be taken into account when evaluating the associations between personality traits and SWB variables. First, the fact that they were able to include 137 different traits in their meta-analysis makes the entire endeavor somewhat overwhelming. Although 137 different measures can be identified, do these measures truly reflect 137 different constructs that need to be considered, each on its own? One goal of personality research over the past decades has been to reduce the number of constructs that are examined so that more parsimonious models can be developed (John, Naumann, & Soto, 2008). Indeed, of the traits that exhibited the strongest correlations in DeNeve and Cooper's meta-analysis, many are not widely studied.

Perhaps even more problematic is that by necessity, meta-analyses often aggregate across scales that have the same or similar names, but that reflect somewhat divergent content. For instance, Lucas and Fujita (2000) suggested that by aggregating across very different types of measures of extraversion, DeNeve and Cooper (1998) underestimated one association that, theoretically, should be quite strong: that between extraversion and the specific component of positive affect. Lucas and Fujita conducted a more targeted meta-analysis, which found much stronger associations between extraversion and positive affect, with an average correlation of .37. Furthermore, their analyses showed that the size of this correlation varied depending on which measures of extraversion and positive affect were used, supporting the idea that more targeted analyses provide important information about the nature of this effect.

In a related, but much larger investigation, Steel et al. (2008) updated the meta-analysis of DeNeve and Cooper (1998), focusing only on established measures of the Big Five personality traits and their associations with well-being components. Like Lucas and Fujita (2000), Steel et al. found much larger associations when these established measures were used. Importantly, their study showed that traits beyond extraversion and neuroticism showed substantial associations with SWB. For instance, although in their analyses extraversion showed an average correlation of .44 with positive affect and neuroticism showed an average correlation of .54 with negative affect, even the traits of agreeableness and conscientiousness showed moderate correlations with some well-being components (with correlations in the range of .20 or .30). This meta-analysis confirmed that extraversion and neuroticism are especially important for SWB; but it also showed that additional traits may play a role and should not be ignored when considering the impact of personality on well-being.

Given these results, it is reasonable to ask what we should do about the rest of the 137 variables that DeNeve and Cooper (1998) examined. For instance, Wilson (1967) highlighted traits such as optimism and self-esteem as being particularly important for SWB, a finding that has been confirmed in subsequent systematic research (e.g., Lucas, Diener, & Suh, 1996). Furthermore, these traits have a long history of being studied independently from the Big Five (even if they are clearly related), and there are strong theoretical reasons to expect them to be linked with well-being, perhaps even having an effect beyond traits like extraversion and neuroticism. One recommendation for researchers interested in traits other than those in the Big Five is to (a) consider prior evidence like that included in DeNeve and Cooper's meta-analysis, (b) think carefully about the psychological mechanism that would link the trait to SWB, (c) include measures of extraversion and neuroticism in studies that examine the associations between the narrower

trait and the well-being outcomes to ensure that there is incremental validity.[2] As the DeNeve and Cooper meta-analysis makes clear, there is a danger that personality researchers will continually be "reinventing the wheel" as they study related traits with different names as predictors of well-being outcomes. This is particularly important given that many "positive" characteristics tend to go together, just as many "negative" characteristics tend to correlate. Thus, it will be important to focus on personality-SWB relations that provide unique information about the role that personality plays in SWB.

The idea that good things tend to go together raises one additional issue that must be addressed when interpreting correlations between measures of personality traits and measures of SWB. That is, as typically assessed, these two types of measures share method variance, which may inflate correlations substantially. Remember, a critical part of the argument for the importance of personality traits as predictors of SWB is that the correlations between personality and well-being variables tend to exceed correlations between objective factors and SWB. However, if the former are inflated by shared method variance, then this comparison may not be fair.

For example, Lucas and Fujita (2000), in their meta-analysis, separately examined correlations between extraversion and positive affect that used the same method of assessment for both variables and those that used different methods of assessment. Not surprisingly, the correlation was significantly larger when the same method was used (r = .37) than when different methods were used (r = .25). Indeed, the correlation when different methods were used was only slightly larger than the correlation between SWB and income (Lucas & Schimmack, 2009), a correlation that has often been dismissed as being very small (Myers, 2000). Lucas and Fujita's meta-analysis confirmed that the association is not due *solely* to shared method variance, but it does highlight the role that shared method variance plays. Few systematic investigations of the role that shared method variance plays in other personality-SWB associations have been conducted, but it is highly likely that the effect is similar in these different domains. Thus, we encourage researchers to consider using alternative methods of assessment when examining the links between personality and well-being to separate the substantive associations from those due to shared method variance.

A final issue regarding the associations between personality traits and SWB concerns the extent to which specific personality traits (or even specific facets of personality traits; Sun, Kaufman, & Smillie, 2017) exhibit differential associations with different components and measures of SWB. The meta-analysis by Steel et al. (2008) showed that indeed, extraversion correlated most strongly with positive affect (compared to other components of SWB) and neuroticism correlated most strongly with negative affect. These results are consistent with the idea first raised by Costa and McCrae (1980) that extraversion and neuroticism affect global well-being through their unique associations with positive and negative affect, respectively. In support of this idea Schimmack, Oishi, Furr, and Funder (2004) showed that the facets of extraversion and neuroticism that were most closely linked to positive and negative affect accounted for most of the association between these traits and life satisfaction. This also suggests that future work examining the associations between traits beyond extraversion and neuroticism and well-being related outcomes such as life satisfaction can focus specifically on mechanisms that link these constructs independently from extraversion and neuroticism.

Some research has also begun to investigate the links between personality and alternative measures of well-being variables. For instance, Lucas and Fujita (2000) showed that self-reports of extraversion predicted more experiential measures of well-being, such as daily reports of positive affect, somewhat less strongly than they predict global measures of well-being (r = .28 versus r = .39). Similarly, Lucas, Le, and Dyrenforth (2008) found larger correlations with extraversion for global reports of positive affect (r = .53) than for aggregated daily or experience-sampling-based reports (rs = .39 and .31, respectively). More recently, Anusic et al. (2017) compared self and informant reports of personality to global and experiential (day reconstruction method) measures of subjective well-being. Across two student samples, global measures of affect were at least as strongly, if not more strongly correlated with both self and informant-rated personality than the day-reconstruction-based measures. This result was replicated in a community sample by Hudson et al. (2016). These results indicate that experiential measures based on experience sampling or the day reconstruction method tend to correlate somewhat less strongly with personality measures than do traditional measures of affect.

Overall, this review confirms the importance of personality traits as correlates of various components of SWB, while also pointing to some substantial caveats. First, meta-analytic summaries show that personality traits do show some of the strongest associations with SWB, with the associations between extraversion and positive affect and between neuroticism and negative affect being particularly strong. A close look at the literature, however, suggests that these associations are inflated somewhat by shared method variance, meaning that the associations between personality and well-being outcomes are not as

much larger than correlations between SWB and external circumstances as it might first appear. The meta-analytic evidence is rich enough to show that the associations themselves do not result entirely from method variance, but future research should take concerns about method variance more seriously when examining these effects. The research also shows that correlations do vary across different components and measures of well-being, with somewhat weaker associations for experiential measures like the day reconstruction method or experience sampling method, as compared to global reports of affect. Future research can help clarify whether these discrepancies are due to differences in the underlying processes or to psychometric differences across measures.

Why Does Personality Matter?

The literature reviewed above provide clear evidence that the stable individual differences that personality psychologists typically study are related to the SWB that people report. SWB scores are somewhat stable over time, even in the face of changing life circumstances; this stability appears to be due, at least in part, to in born genetic factors; and there are robust and moderately strong associations between specific personality traits and SWB measures. Thus, an important question concerns the mechanisms that may underlie these associations. Once the empirical links are established, research can proceed to explain why these effects exist.

In terms of general mechanisms, may different approaches have been considered. For instance, one class of mechanisms suggest that the behaviors that result from stable individual differences in personality traits can directly or indirectly lead to well-being related outcomes. Decades of research has now shown that personality can predict consequential outcomes, often with effect sizes that are larger than other widely studied predictors such as intelligence or socioeconomic status (Ozer & Benet-Martinez, 2006; B. Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). It is possible that the associations between personality and well-being-related outcomes flow through the different behaviors that individuals with different personalities exhibit or different environments that they choose.

Alternatively, a different class of explanations focuses on the way that people perceive the world around them. The fact that different people respond differently to the same external circumstances suggest that there may be fundamental differences in outlook and perception that contribute to individual differences in well-being. For example, early work by Rusting (1998) focused on basic cognitive processes that may differ across individuals and that could promote greater or lesser well-being. Some people may attend more to positive things in their environment, whereas other people's attention may be naturally drawn to threats in the environment. Some people may find it easier to remember positive life events, whereas for others, negative experiences may more easily come to mind. Even the interpretation of the same event may differ across individuals; Diener, Lucas, Oishi, and Suh (2002) suggested that there are stable individual differences in whether people use information about who is better or worse than they are when evaluating their standing on a domain. These fundamental, low-level processes could add up to stable individual differences in the well-being that people experience and report (see Robinson & Compton, 2008, for a review).

Currently, there is no single, comprehensive model that clarifies how either a specific personality trait or a set of individual differences affect SWB outcomes. However, there are good examples of what such a theory would look like. Therefore, in the next section, I focus on one example where considerable theoretical and empirical work has been done to investigate a specific personality/SWB association: The link between extraversion and positive affect.

An Example: Extraversion and Positive Affect

As noted above, even in the earliest reviews, the importance of extraversion for SWB was emphasized (e.g., Wilson, 1967). Costa and McCrae (1980) suggested that extraversion directly influenced one of two major affective dimensions (positive affect), and these affective dimensions formed the core individual differences underlying reports of SWB. Later factor analytic work confirmed and clarified the links between extraversion and an activated form of positive affect (Depue & Collins, 1999; Lucas, Diener, Grob, Suh, & Shao, 2000; Tellegen, 1985; Watson & Clark, 1997).

Attempts to clarify the mechanisms underlying these effects have proceeded in a number of different directions. For instance, McCrae and Costa (1991) posited two broad classes of explanations that could be considered: an *instrumental* explanation, which focuses on well-being as an indirect outcome of the behaviors that extraverts tend to do; and a *temperament* model, which focuses on the direct links between underlying physiological systems and the affective experiences that people have.

In regard to the former class of explanations, many researchers have looked closely at what extraverts do differently than introverts that might explain why they are happier. For instance, Diener, Larsen, and Emmons (1984), Emmons, Diener, and Larsen (1986), and Pavot, Diener, and Fujita (1990) used daily

diary and experience sampling studies to assess whether extraverts participated in social activity more than introverts or enjoyed that experience more, as a way of explaining extraverts' greater positive affect. Later, a number of researchers followed up on this work with larger samples and more sophisticated sampling designs (Lucas et al., 2008; Oerlemans & Bakker, 2014; Srivastava, Angelo, & Vallereux, 2008). These studies consistently showed that extraverts do participate in greater amounts of social activity and that social activity is associated with higher levels of positive affect, but that these differential experiences cannot fully account for extraverts' greater positive affect. A related line of research focuses on experimental evidence linking extraverted behaviors with experiences of positive affect. Specifically, Fleeson and his colleagues have shown that asking people to act in an extraverted manner increases levels of experienced positive affect (Fleeson, Malanos, & Achille, 2002).

Other researchers have more directly examined the temperament-based explanations. Many of these investigations are at least loosely based on a model of personality developed by Gray (Gray, 1970, 1991; Gray & McNaughton, 2000), in which different physiological systems regulate responses to rewarding or punishing stimuli in the environment. For instance, one possible mechanism underlying extraversion is an underlying sensitivity to reward, such that extraverts have stronger responsiveness to reward, which could manifest in the form of increased wanting for potential rewards or increase liking of achieved rewards (see Smillie, 2013, for a recent review). Some have posited that the precise system that underlies these effects relates to individual differences in dopamine function (Depue & Collins, 1999), though evidence for specific hypotheses related to this possibility is mixed (Wacker & Smillie, 2015).

A variety of specific research questions follow from the idea that extraverts may be more sensitive to rewards than introverts and that this difference is responsible for their greater happiness. For instance, early studies suggested that extraverts, when exposed to positive emotional stimuli (e.g., a positive mood induction procedure in the lab), would respond more positively than introverts (Larsen & Ketelaar, 1991). However, this initial effect frequently failed to emerge in laboratory studies (Lucas & Baird, 2004), and more naturalistic studies rarely found support for the idea that extraverts respond more positively to positive experiences or events (Anusic et al., 2014a; Lucas et al., 2008; Yap, Anusic, & Lucas, 2012). More recently, however, Smillie and colleagues found support for a possible resolution to the contradictory evidence, showing that extraverts appear to respond more strongly to *appetitive* stimuli, rather than simply *pleasant* stimuli. This distinction fits with the underlying reward sensitivity and may explain inconsistencies in past research.

Together, the studies from this large literature provide ample avenues for future research on the association between extraversion and positive affect. To be sure, existing studies do not yet provide a complete answer about why these constructs are related. However, the various approaches that have focused on behaviors, cognitive factors, emotional reactions, etc., provide a clear model for how research on personality and well-being variables can proceed. These studies posit various mechanisms by which one can get from relatively basic, low-level mechanisms that can be tested in the lab or in more naturalistic studies. It is likely that research on extraversion and positive affect will provide useful information not just for understanding this pair of constructs, but for researchers who are beginning to think about mechanisms that may link other trait/well-being associations.

Summary

Research on the links between personality and SWB is important partly because the strong associations have been so surprising to lay people and scientists alike, partly because of the amount and breadth of evidence that has accumulated for the robustness of these effects across different constructs and methods of assessment, and partly because of the rich theories that have emerged to explain the correlational findings that alerted early well-being researchers to the stable individual differences in well-being that exist. Incredible progress has been made on all of these questions, so much so that perhaps more than any area in psychology, researchers are able not only to specify that some degree of stability or heritability exists, or that some personality traits predict well-being variables, but also to make relatively precise point predictions about the size of these effects. Thus, research on personality and well-being can serve as a model for how research on the factors underlying well-being can proceed.

That being said, there is still considerable work to be done. This area of research, like many areas within SWB more broadly, suffers from an over-reliance on self-report methods. This makes comparisons between various predictors of SWB somewhat difficult to make, as personality predictors often share method variance. Future work that relies on multiple methods of assessment, both of the personality predictors and the well-being outcomes, will help further clarify these associations. And, as with most areas of well-being research, greater emphasis on the processes that underlie these associations will advance not only theories of SWB, but basic theories of personality themselves.

Footnotes

[1]It is also important to note here that random measurement counts as a *state-like* influence that leads to instability from one occasion to the next.

[2]It is also important to use techniques for testing incremental validity that provide a conservative test of the importance of the new construct; see Westfall and Yarkoni (2016) for a discussion.

Abstract

One way to pursue happiness is to improve the objective levels of external outcomes such as wealth; that is an economic approach. Another way to pursue happiness is to improve the arrangement of and choices among external outcomes without substantively altering their objective levels; that is a *hedonomic* approach. This chapter reviews research adopting the latter approach. Specifically, we present a list of subtle yet significant determinants of happiness from four aspects: (1) pattern of consumption, (2) procedure of consumption, (3) (mis)match between the choice phase and the consumption phase, and (4) type of consumption. Although far from comprehensive, these factors offer implications for "choice architects" – government, companies, and individual consumers – on improving happiness.

Keywords: hedonomics, happiness architecture, judgement and decision making, consumption

It is almost truism to say that happiness is the ultimate pursuit – or, at least, one of the ultimate pursuits - of life. Hence, "formulas" for improving happiness have always been of interest not only to academics (Diener & Seligman, 2004; Gilbert, 2006; Huppert, Baylis, & Keverne, 2005; Seligman, 2002; Seligman & Csikszentmihalyi, 2000), but also to policy makers and individuals. Intuitively, happiness is correlated with wealth - people in affluent countries are happier than those in poor countries, and people with higher annual income are happier than those with lower annual income, presumably because wealthier individuals have access to more and better material goods (e.g., more and tastier food, larger and better houses, appliances and technologies that liberate them from labor). Indeed, research generally finds a reliable positive link between wealth and happiness (Diener & Oishi, 2000; Lucas & Schimmack, 2009). Yet, the impact of wealth on happiness has its boundaries – their relationship follows a concave curve, such that an increase in wealth will cease to increase experienced happiness in daily life once wealth reaches a certain point (Diener & Biswas-Diener, 2002; Kahneman & Deaton, 2010).

Then, are there non-economic approaches to increase daily affective well-being, in particular in affluent societies where people already possess and consume a large quantity of external resources? In this chapter, we review research on hedonomics (Hsee, Hastie, & Chen, 2008), which studies how to increase happiness by improving the arrangement of and choices among external outcomes without substantively increasing the objective levels of the external resources. Hedonomics involve many factors. In this chapter, we focus on four examples: (1) the pattern of consumption, (2) the procedure of consumption, (3) the (mis)match between the choice phase and the consumption phase, and (4) the type of consumption. We also explain the corresponding psychological underpinnings. These factors seem subtle, but can produce significant impacts on happiness.

We should note that "happiness" has different meanings, and that in this chapter we focus on only one type of happiness—valenced (positive or negative) hedonic experiences with external stimuli. We do not study specific emotions such as anger and excitement; nor do we study overall life satisfaction or meaning in life.

Pattern of Consumption

A fixed amount of consumption resources can be divided into several chunks and consumed sequentially on separate occasions. The characteristics of these chunks, including the number of chunks, the size of each chunk in the sequence, and the changes in the sizes of chunks, can influence happiness.

Segregation of Gains: Segregating a Fixed Amount of Consumption Resources into Several Small Chunks Can Lead to Greater Happiness

Prospect Theory's value function (Kahneman & Tversky, 1979) posits that subjective utility derived from gains follows a concave curve, with diminishing marginal utility. Therefore, for a large quantity of consumption resources, dividing them into a few chunks and treating them as distinct consumption units can take advantage of the steep gain of happiness from "zero consumption" to "some consumption" (i.e., the region close to the reference point) and increase happiness. Indeed, segregating

gains is one of the four hedonic editing rules Thaler (1985) formally proposed. It suggests that, for example, a person who plans to eat in a fancy restaurant and get a relaxing massage should arrange these two activities on separate days rather than on the same day, in order to derive greater overall happiness from these two activities. Similarly, a person who receives a notification that a new season of her favorite sitcom is available on Netflix should spread her viewing experience over two weeks, rather than binge-watching all the episodes in two days, in order to maximize the overall pleasure obtained from watching the entire season.

Note that usually segregation inevitably means introducing non-consumption periods into the consumption sequence and lengthening the overall consumption duration. This way, people have more time to recover from satiation or hedonic adaption (see " Adding Delays" and " Adding Interruptions and Slowing Down" in this chapter for more information), in addition to taking advantage of the high marginal utility of a small portion of consumption resources. Then, will the segregation principle be effective above and beyond the satiation account, when the total length of consumption is held constant? Redden (2007) offers supporting evidence by merely having participants mentally segregate their consumption (i.e., a manipulation of perceived segregation). In one study, participants ate several jelly beans of different flavors. They either sorted these jelly beans into one broad category (i.e., jelly beans) and treated their eating experience as one unit, or sorted the same amount of jelly beans into several specific categories (e.g., orange jelly beans, banana jelly beans) and treated their experience as a combination of several distinct units. Redden (2007) found that participants reported greater happiness over the course of eating jelly beans in the latter condition, when their eating experience was only mentally segregated and the total duration of consumption is fixed.

Improving Sequence: Arranging Chunks of Consumption Resources of Different Sizes in an Ascending Order Can Lead to Greater Happiness

Without doubt, people desire a happy ending, but do they prefer a happy ending at the cost of inferior experiences early in the sequence? Loewenstein and Prelec (1993) find that, holding the objective amount or value of consumption resources constant, people prefer a course during which the quality of experience gets better and better, compared with when the quality of experience remains the same or when the quality of experience gets worse and worse. In one study, when scheduling a dinner at a fancy French restaurant and a dinner at a local Greek restaurant, people preferred the "Greek first French second" sequence over the "French first Greek second" sequence. In a similar vein, Prelec and Loewenstein (1998) show that people preferred the decoupling of payment and consumption, willing to incur losses (e.g., payment) before gains (e.g., consumption experience). Outside the lab, panel data on British employees' wage change and well-being also provides support to this principle (Clark, 1999) - employees who experienced a positive wage change were happier and more satisfied with their job, regardless of the absolute amount of salary. To illustrate in a stylized way, the annual income stream "$50k, $60k and $70k" generated greater overall happiness than the stream "$60k, $60k, and $60k" or the stream "$70k, $60k, and $50k."

Noticeably, this preference runs against the economically rational solution based on calculating the present value of a flow of future values via discounting. Specifically, because both future gains and future losses "deflate" in value when evaluated at the present, expediting future gains (to increase their present utility) and postponing future losses (to decrease their present disutility) can maximize the present value of the consumption flow. Nevertheless, this economically optimal arrangement is sub-optimal for happiness.

Accelerated Increase (Velocity of Positive Change): Arranging Chunks of Consumption Resources of Different Sizes in an Acceleratedly Increasing Pattern Can Lead to Greater Happiness

Not only are people sensitive to the change of the sizes of the consumption chunks, as reviewed in "Improving Sequence," but also they are sensitive to the velocity of the change (Hsee & Abelson, 1991). Specifically, a sequence of consumption resources that increase in quantity or value faster and faster will generate greater happiness than does a sequence of consumption resources that increase in quantity or value at a constant rate (Hsee, Salovey, & Abelson, 1994). For example, a video game player will be happier and more motivated to continue to play the game if the score on the game increases in an accelerating pattern (e.g., 10, 20, 40, 80, 160, 320,….) than if it increases in a uniform pattern (e.g., 100, 200, 300, 400, …), and this is true even if the score does not correspond to any external rewards and is spurious (Shen & Hsee, 2017).

Procedure of Consumption

The same amount of consumption resources can be consumed in different ways. The characteristics of the procedure – delays, interruptions, speed, and curiosity towards the experience – influence overall happiness.

Adding Delays: Delaying Consumption Can Increase Overall Happiness

Obviously people get pleasure from their moment-to-moment experiences with the consumption stimuli, but can they get pleasure outside the consumption phase? Research shows that, by imagining positive experiences prior to the occurrence, people can get anticipated utility or savoring value (Kahneman, 1999) too. It follows that delaying consumption can generate additional "free" happiness. Indeed, in one study, participants either waited 30 minutes before eating two chocolate candies or ate them immediately, and those who waited reported greater overall enjoyment of the chocolate candies (Nowlis, Mandel, & McCabe, 2004). Therefore this principle suggests that, for example, families should book vacations in advance and online shoppers should not select expedited shipping (especially when it costs extra) to get higher overall enjoyment.

Despite evidence that an externally imposed delay can produce a hedonic boost, do people choose to delay consumption? It is possible that, because waiting requires self-control and people tend to act on impulsive desires immediately (Frederick, Loewenstein, & O'Donoghue, 2002; Mischel, Shoda, & Rodriguez, 1989), people may not opt for it when given the choice. However a few studies documented that, at least in some contexts, people can choose optimally. For example, Loewenstein (1987) finds that, when people can choose to get a kiss from their favorite movie star or enjoy a fancy dinner either immediately or later, they preferred the latter. Similarly, Lovallo and Kahneman (2000) show that gamblers were more inclined to delay learning about their outcome when the potential reward was larger, in order to derive greater savoring value from imagining winning the reward.

However, the delaying principle should be applied with caution because it runs against a few other accounts. First, the waiting period is usually unpleasant, which may result in anxiety and stress (Houston, Bettencourt, & Wenger, 1998; Osuna, 1985). Second, the negative experience during waiting is likely to be transferred to the target consumption, and hence reduce overall satisfaction (e.g., Dellaert & Kahn, 1999). Third, from an economic perspective, waiting decreases the present value of the consumption experience. Fourth, because imagined experience sometimes can substitute for real experience (Morewedge, Huh, & Vosgerau, 2010), the anticipation period may lead to adaptation and thus decrease pleasure from the actual consumption.

Adding Interruptions and Slowing Down: Adding Interruptions to a Flow of Consumption and Slowing Down Consumption Can Increase Overall Happiness

Whereas the previous section ("Adding Delays") deals with the procedure of consuming a single unit, this section is about improving overall happiness in consuming a single stimulus repeatedly (e.g., listening to one's favorite song 10 times) or a series of similar stimuli (e.g., watching 10 episodes of a TV show), during which people generally experience hedonic adaption, get satiated, and enjoy the stimuli less and less (Frederick & Loewenstein, 1999; Kahneman & Snell, 1992). In these situations, adding interruptions (i.e., introducing "breaks" into the course of consumption) can boost happiness because it gives people time to naturally recover from satiation. Indeed, Nelson and Meyvis (2008) find that adding a short break to when participants were receiving a massage or listening to a pleasant song elevated their overall enjoyment of the period as compared with no interruption. Moreover, adding interruptions can help even when the interruption itself is somewhat negative. For example, Nelson, Meyvis, and Galak (2009) show that TV commercials (i.e., not-so-pleasant distractors) can help "reset" people's feeling toward the TV program, restore the intensity of the positive experience, and increase overall enjoyment. However, people usually do not foresee the benefit of adding interruptions, and do not choose to break up positive experiences (Nelson & Meyvis, 2008; Nelson, Meyvis, & Galak, 2009).

Relatedly, these findings also suggest that people will benefit from consuming more slowly when repeatedly experiencing similar stimuli, since a slower pace means more and longer inter-consumption intervals. Indeed, Galak, Kruger, and Loewenstein (2012) provide empirical support for this proposition. In one study, they had participants eat six Hershey's Kisses while watching a 20-min video. In the forced slow rate condition, participants were instructed to eat each of the chocolates when prompted by the computer, and received the prompt every 200 seconds. In the self-paced condition, participants were instructed to eat at a rate that they thought could maximize their overall enjoyment of the Hershey's Kisses. All of the participants then ate the chocolates and rated their enjoyment of each piece when they finished that piece. At the end of the study, they also rated their overall happiness retrospectively. Results show that, first, participants in the self-paced condition ate faster than those in the forced slow rate condition. Second, more importantly, participants' enjoyment of each chocolate declined much faster and their enjoyment of the entire eating experience was lower in the self-paced condition than in the forced slow rate condition. These results confirm the hedonic benefit of slowing down, and also suggest that people do not seem to anticipate how fast they may get satiated from repeated consumption, and as a result consume too rapidly when they have control over the consumption pace.

Inducing Curiosity: Adding a Curiosity-Induction Period Before Consumption Can Increase Overall Happiness

Curiosity is conceptualized by Loewenstein (1994) as the desire to "close an information gap," and is a form of "cognitively induced deprivation." Just like deprivations of sleep, sex and food that lead people to seek restoration, the deprivation of one's cognitive state can also result in a natural resolution, meaning that the desire to resolve curiosity can be a goal in and of itself, beyond getting practical benefits such as information (Litman, 2005) and entertainment (e.g., gossip; McNamara, 2011). For example, in one study (Hsee & Ruan, 2016), participants saw 10 pens and learned that 5 of them were prank electric-shock pens that would deliver a painful (yet harmless) shock and that 5 of them were regular pens. In one condition the prank electric-shock pens were labeled so no curiosity was evoked, whereas in the other condition the prank electric-shock pens were unknown so curiosity was induced. Participants then, purportedly, entered into a waiting period for another study during which they could click these pens if they would like to. Hsee and Ruan (2016) find that participants clicked more of the pens (and as a result received more unpleasant electric-shocks) in the latter condition. They coined this effect - that curiosity leads people to opt for expectedly negative outcome - the Pandora Effect, which provides evidence that people can get positive hedonic value through curiosity resolution.

It follows that adding a curiosity-induction stage prior to the target consumption period which resolves the curiosity can increase overall happiness. Ruan, Hsee, and Lu (in press) provide empirical support for this possibility. In the study, participants learned that they would read a biography of Einstein. Prior to the reading period, those in the curiosity-inducing condition read 10 questions about the life of Einstein and were prompted to think about the answers, whereas those in the control condition viewed 10 pictures of Einstein and were not prompted to think about anything related to the biography. Participants then rated their experiences in the prior-to-reading period, read the biography, and rated their experience in the reading period too. Ruan, Hsee, and Lu (in press) find that participants were happier in the curiosity-inducing condition than those in the control condition during the entire experiment (i.e., the prior-to-reading phase and the reading phase together), and that the greater overall happiness in the curiosity-inducing condition was mainly driven by happiness in the reading period. In other words, while participants obtained greater satisfaction when reading the biography of Einstein after thinking about questions about Einstein (than not), thinking about those questions per se did not decrease their happiness in the first stage. Importantly, people do not seem to be aware of the hedonic benefit of inducing curiosity and do not choose optimally. For example, in another condition, when given a choice between viewing questions about Einstein or pictures of Einstein before they read the biography, participants did not prefer the curiosity-induction method.

(Mis)Match Between the Choice Phase and the Consumption Phase

Because people possess malleable (i.e., context-dependent and time-dependent) preferences, if the circumstance under which people choose a consumption option mismatches with the circumstance under which they consume the option, they may choose sub-optimally. Therefore, matching the choice phase with the consumption phase, in terms of people's visceral state (hot or cold), evaluation mode (joint or separate), timing of choice (simultaneous or sequential), and focus (wide or narrow), can improve happiness.

Hot Versus Cold Visceral States: People's Visceral States in the Choice Phase and the Consumption Phase May Differ; Matching the Visceral State in the Choice Phase with That in the Consumption Phase Can Improve Happiness During Consumption

Loewenstein (1996) made the distinction between two visceral states - a "cold" state when people are rested, satiated, sexually unaroused, or intellectually satisfied, and a "hot" state when people are tired, hungry, sexually aroused, or intellectually curious. Individuals in one state usually cannot accurately anticipate or predict their preferences and experiences in the opposite state, experiencing an empathy gap. For example, a person who just had dinner will have difficulty simulating how hungry she would feel the next morning.

People's visceral states change over time. Therefore, when choosing for future consumption too early in advance, people may experience a mismatch in visceral states between the choice phase and the consumption phase. Yet, people tend to project their current state to estimate their future state, exhibiting the projection bias (Loewenstein, O'Donoghue, & Rabin, 2003; see also Loewenstein, 1996; Van Boven, Dunning, & Loewenstein, 2000; Van Boven & Loewenstein, 2003), and choose accordingly and sub-optimally. For example, a grocery shopper who just had dinner may not buy enough for her upcoming breakfast, impairing her satisfaction during breakfast, whereas a grocery shopper who just finished work at 5pm, feeling hungry and thirsty, may add an unplanned dessert item (e.g., a big box of ice cream) to her

shopping cart, only to find herself too full to eat anything after dinner (Nisbett & Kanouse, 1969; Gilbert, Gill, & Wilson, 2002; Read & Van Leeuwen, 1998). Similarly, right after visiting an art museum, one may be particularly curious (i.e., intellectually aroused) about the stories behind the artwork and purchase related books or DVDs. However, later she may find the books and DVDs gathering dust on her bookshelves, as her curiosity about the artwork fades. To optimize choice and increase consumption happiness, one should engage in more deliberative projection of his or her future states, or reduce the temporal interval between the choice phase and consumption phase.

Joint Versus Separate Evaluation Modes: People Are Usually in a Joint Evaluation Mode in the Choice Phase but in a Separate Evaluation Mode in the Consumption Phase; Matching the Evaluation Mode in the Choice Phase with That in the Consumption Phase Can Improve Happiness During Consumption

All decisions and judgments are made in the joint evaluation mode (JE), or the single evaluation mode (SE), or some combination of the two (Hsee, 1996). In the joint evaluation mode, two or more options are juxtaposed together and evaluated comparatively; in the single evaluation mode, each option is presented in isolation and evaluated in an absolute sense, without comparison to alternatives. These two modes can systematically shift people's attention to different attributes of the options and further influence their evaluations. Specifically, when attributes differ in terms of "evaluability" – that is, the extent to which people can evaluate the value of the attribute when it is presented alone, easy-to-evaluate attributes receive more attention and more decision weight in the single evaluation mode, and difficult-to-evaluate attributes receive more attention and more decision weight in the joint evaluation mode (Hsee, 1996; Hsee, Loewenstein, Blount, & Bazerman, 1999; Hsee & Zhang, 2004). Take 4K TVs, the size of the screens is more difficult to evaluate (since they are all very big) than the aesthetic design. Thus when evaluating different 4K TV models one by one (in the single evaluation mode), people will give more weight to aesthetic design than size, whereas when evaluating these models together (in the joint evaluation mode), people will give more weight to the size dimension, suggesting the possibility of a preference reversal. (Note that the evaluability of an attribute differs across individuals. In general, expertise or familiarity with the attribute will improve its evaluability. For example, although the size of a 4K TV might be a difficult-to-evaluate attribute for most consumers, it might be an easy-to-evaluate attribute for Best Buy personnel.)

Importantly, people often make choices in the joint evaluation mode, comparing different options, yet they often consume in the single evaluation mode, experiencing one option only. Because people value difficult-to-evaluate attributes more in the joint evaluation mode and easy-to-evaluate attributes more in the separate evaluation mode, they may make suboptimal choice for consumption. For example, one may spend a large sum of money to obtain the bigger 4K TV, only to find that day-to-day she does not enjoy looking at the TV in the living room. To alleviate the impact of such a mismatch, one should try to adopt the single evaluation mode in the choice phase, evaluating options one by one and forming holistic impressions of each of them.

Simultaneous Choices Versus Sequential Consumption: While People Usually Consume Options Sequentially, They May Choose the Options Simultaneously; Minimizing This Mismatch Can Improve Happiness During Consumption

Another mismatch between the choice phase and the consumption phase is that while consumption usually happens sequentially, choices may be made simultaneously (i.e., choosing for multiple future consumption episodes). A huge body of literature shows that people are subject to the "diversification bias" that they over-diversify their consumption portfolio when making combined choices for multiple future consumption occasions (Read, Antonides, van den Ouden & Trienekens, 2001; Read & Loewenstein, 1995). For instance, in one study (Simonson, 1990), participants chose three yogurts to eat on three consecutive days in the upcoming week, either in advance (simultaneous choice), or right before each consumption (sequential choice). Those in the simultaneous choice condition incorporated more variety of flavors, including flavors they did not like that much, than those in the sequential choice condition. However, when it came to the consumption period, those in the simultaneous choice condition found themselves having to consume some less-preferred flavors and felt less happy than those in the sequential choice condition who stuck more to their favorite flavor.

This effect is accounted for mainly by three psychological mechanisms (Read & Loewenstein, 1995; Simonson, 1990). The first one is related to the perception of future time – people subjectively contract the interval between future consumption occasions, and thus overestimate satiation. Second, people possess the heuristic that a choice portfolio should incorporate variety and simultaneous choice facilitates the construction of a choice portfolio. Third, because people are uncertain about their future preferences, selecting more variety is a safer choice.

To alleviate the impact of this mismatch, one may deliberately reduce variety when making

simultaneous choices, applying a choose-my-favorite rule, or make choices in a sequential manner. Note that the impact of this mismatch can be mitigated if in the consumption stage, the interval between consumption episodes is short, to the extent that the perceived interval and objective interval match.

Narrow Versus Wide Focus: People Tend to Fix Their Attention to the Focal Event in the Choice Phase but Even Out Their Attention to Both the Focal Event and Contextual Events in the Consumption Phase; Minimizing This Mismatch Can Improve Happiness During Consumption

When predicting future experiences, people tend to narrowly focus on the target stimuli and ignore the impact of contextual factors, such as ambient environment, mood fluctuations, and other life events. Consequently, this focalism bias leads people to overestimate both the intensity and the duration of the focal stimuli's impact (i.e., the impact bias; Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000; Wilson & Gilbert, 2003). For example, college football fans thought the victory of their favorite team would make them happier and feel happy for a longer time than it actually did.

In the context of making choices for future consumption, the mismatch of attention span between the choice phase and the consumption phase may lead people to overvalue the focal option in the choice phase, resulting in regret and dissatisfaction in the consumption phase. For example, when a new iPhone comes out, one may be drawn to the new or better features it offers (e.g., a faster chip, a more sensitive 3D touch system, a brighter and more clear screen with retina display), overestimate its hedonic impact in one's daily life, and willingly pay a high price to purchase the new iPhone. However, once she owns the new iPhone, the phone will gradually lose its attentional prominence, because it will become one of many things – such as mundane activities (e.g., laundry), work duties, and environmental factors (e.g., good or bad weather) – that influence her overall happiness. As a result, this consumer may feel unsatisfied and regret the purchase. To alleviate the impact of this mismatch, one may deliberatively widen the span of focus in the choice phase, for instance, by actively considering other factors that may contribute to his/her future happiness, in order to make a more accurate estimation of the hedonic impact of the target option.

Type of Consumption

Different types of consumption produce different intensity and durability of happiness. Compared with material consumption and consumption that satisfies one's learned preference (i.e., preferences that are formed recently), experiential consumption and consumption that satisfies one's inherent preference (i.e., preferences that are formed early in evolution), respectively, generate greater happiness and longer-lasting happiness.

Experiential Versus Material Consumption: Experiential Consumption Generates Greater and More Durable Happiness Than Material Consumption of Equivalent Monetary Value

In their seminal research, Van Boven and Gilovich (2003) defined material consumption as "spending money with the primary intention of acquiring a material possession – a tangible object that you obtain and keep in your possession" and experiential consumption as "spending money with the primary intention of acquiring a life experience – an event or series of events that you personally encounter or live through." Research generally finds that compared with material consumption, experiential consumption generates more intensive happiness and more durable happiness. For example, in terms of the intensity of happiness, in one study (Van Boven & Gilovich, 2003), participants recalled either a most recent material purchase or experiential purchase of similar price, and rated the enjoyment that purchase brought to them. Results show that experiential purchases generated greater enjoyment than material purchases. In terms of the durability of happiness, in one study (Nicolao, Irwin, & Goodman, 2009), participants made a purchase either from a set of experiential options (e.g., watching videos, listening to songs, playing video games) or from a set of material options (e.g., a ruler, a keychain, a picture frame) that were all priced the same in the lab. Researchers tracked participants' happiness with their purchases for an extended period of time and found that their happiness declined more slowly in the experience purchase condition than in the material purchase condition, suggesting that happiness engendered by experiential purchase is more resistant to hedonic adaptation.

The different hedonic impacts of experiential and material consumption have three major psychological underpinnings. First, experiential consumption is more important to one's identity than material consumption; specifically, it constitutes a larger proportion of one's identity, and is also more central to one's identity. After all, "we are what we do, not what we have." Carter and Gilovich (2012) offered a straightforward test of this notion by asking participants to first list five most significant experiential purchases and five most significant material purchases they had made in their lives, and then write a summary of their "life story" in which they could incorporate their significant purchases. Results show that participants weaved their experiential purchases into the life story more often than their material purchases, suggesting that experiential consumption contributes more to one's identity. Besides, when

asked to draw a large circle to represent the self and a few small circles to represent their material and experiential consumptions, participants draw the circles that represent experiential consumption, rather than material consumption, closer to the circle that represents the self, suggesting that people view their experiential consumption as more central to their personal identity. Second, people are less likely to engage in potentially invidious alternative-wise comparison and social comparison after making experiential than material purchases (Carter & Gilovich, 2010; Howell & Hill, 2009). This is because (a) experiences are more inherently evaluable which makes comparison unnecessary (Carter & Gilovich, 2010) and (b) experiences have a lot more variation among experiencers than material possessions have among owners which makes comparisons difficult (Van Boven, 2005). The third reason experiential consumption is more satisfying than material consumption lies in its greater value in enhancing social relationships. Specifically, experiential consumptions are more often shared with others than enjoyed alone (Caprariello & Reis, 2013), making it inherently more social. Besides, experiential consumptions are better conversation topics and people like a conversation partner that talks about experiences more (Van Boven, Campbell, & Gilovich, 2010).

Inherent Versus Learned Preferences: Consumption That Satisfies Inherent Preference (i.e., preferences that are formed early in evolution) Produces Longer-Lasting Happiness than Consumption That Satisfies Learned Preferences (i.e., preferences acquired more recently)

Preferences can be categorized by the timing of its formation in human evolution — a million years ago, a millennium ago, or a year ago (Tu & Hsee, 2016). Preferences that formed earlier in evolution are inherent. Examples include our preference for a warm ambient temperature (e.g., 70 °F) over a cold ambient temperature (e.g., 40 °F), for high calorie food (e.g., French fries) over low calorie food (e.g., kale salad), for a good night's sleep over sleep deprivation, and for being socially accepted over being socially excluded. These preferences are related to our basic biological and psychological needs, are hard-wired, and persist regardless of time and contexts. Preferences that formed later in evolution are learned. Examples include our preference for genuine diamonds over synthetic diamonds, for a $3000 Gucci bag over a $300 Coach bag, for French wine over Californian wine, and for Crocs' hole-filled shoes over normal looking shoes. These preferences are malleable and vary with time and contexts. Whether a preference is an inherent preference (IP) or a learned preference (LP) falls on a continuum, but for ease of exposition, we treat it as categorical here.

Based on this distinction, Tu and Hsee (2016) proposed that happiness derived from IP attributes needs no social comparisons and is absolute, whereas happiness derived from LP attributes requires social comparison and is relative. Therefore, an improvement on an IP attribute will always increase happiness, whereas an improvement on an LP attribute does not necessarily increase happiness. A field study that compares happiness derived from ambient temperature in winter (a representative IP attribute) and happiness derived from the value of jewelry one owns (a representative LP attribute) within and across 31 major cities in China lent support to this proposition (Hsee, Yang, Li, & Shen, 2009). Specifically, researchers interviewed residents in these cities via phone and collected their answers to four questions: (1) their present room temperature, (2) how happy they are with their present room temperature, (3) the value of their jewelry, and (4) how happy they are with their jewelry. Because social comparison is more likely to happen among people within the same city than between different cities, the researchers compared the impacts of temperature value and jewelry value on happiness both within cities and across cities. Results show that, for room temperature, within each city people with higher room temperature were happier (within-city effect), and between cities people with higher room temperature were also happier (between-cities effect) (see Figure 1). However, for jewelry value, there was only a within-city effect (see Figure 2). These results suggest that happiness derived from room temperature, an inherent-preference attribute, increases as the value of this attribute increases; whereas happiness derived from jewelry value, a learned-preference attribute, only increases when the value of this attribute is higher relative to the values other people have.

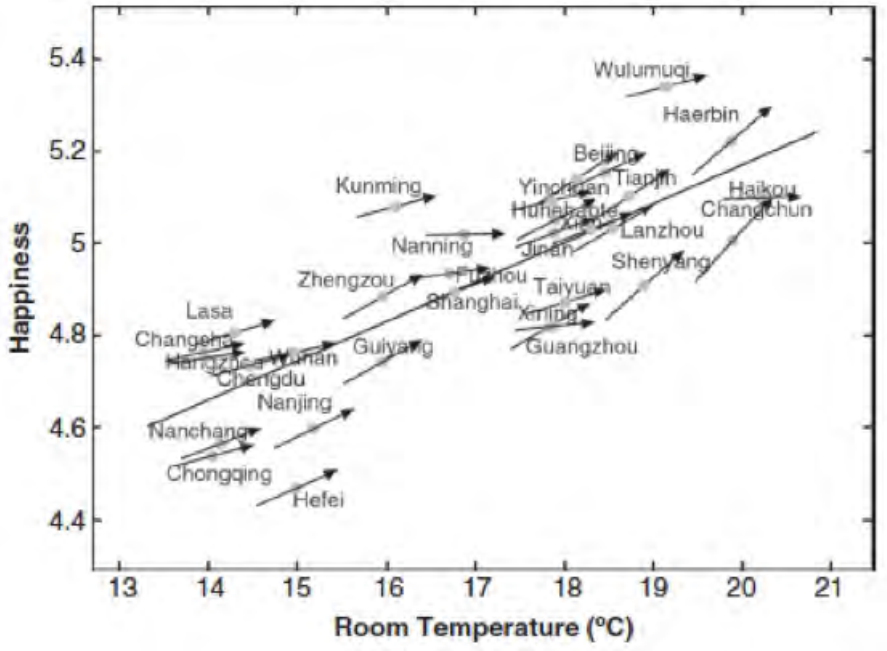

Figure 1. The impact of room temperature on happiness within cities and across cities. The slope of each small line indicates the effect of temperature within a particular city, and the slope of the long (trend) line indicates the effect of temperature across all the cities. As the graph shows, temperature has a positive effect within most cities (within-city effects), and also a positive effect across cities (between-city effect).

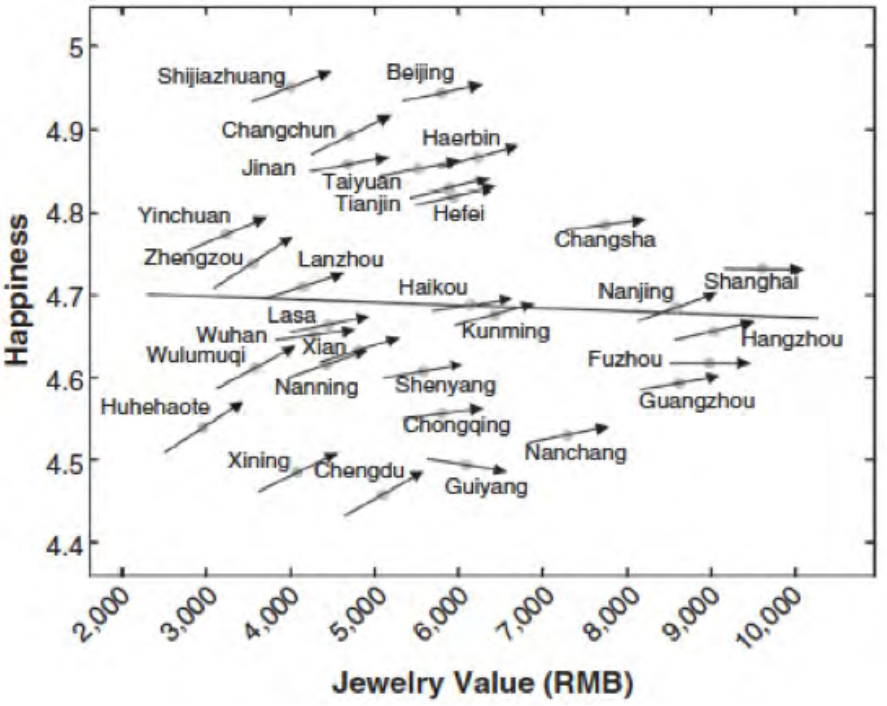

Figure 2. The impact of jewelry value on happiness within cities and across cities. The slope of each small line indicates the effect of jewelry value within a particular city, and the slope of the long (trend) line indicates the effect of jewelry value across all the cities. As the graph shows, jewelry value has a positive effect within most cities (within-city effects), but does not have a positive effect across cities (between-city effect).

The second proposition based on this distinction is that the durability of happiness derived from IP

and LP will differ. Because inherent preferences have a stable and hard-wired internal reference scale, an improvement on an IP attribute will likely to be permanent and long-lasting. On the contrary, because learned preferences do not have a stable reference scale and rely on external reference points (e.g., other people's status, one's past status), an improvement on an LP attribute will likely disappear once the external reference points lose salience in one's mind or change. For instance, while the increase in wellbeing when a person gets social acceptance will endure regardless of whether other people get socially accepted, the increase in wellbeing via getting a luxury bag will fade when other people catch up or when one forgets the experience of not owning one in the past.

Two empirical studies by us (Tu, Hsee, & Li, 2017) lend support to this hypothesis. In both studies, participants first learned the definitions and examples of IP and LP and then passed a comprehension test before answering further questions. (While IP and LP fall on a continuum, we created comprehension questions in relatively obvious contexts. For example, we asked participants to indicate whether "the preference for a warm ambient temperature to a cold ambient temperature in winter" or "the preference for earning $100,000 a year to earning $80,000 a year" is more inherent. The former is the correct answer. We find that the correction rates are generally high, suggesting that people can intuit and identify the distinction between IP and LP. This approach is similar to what was used in studying material and experiential consumption (Van Boven & Gilovich, 2003)). In one study, we asked participants to think about a purchase made with the intention of satisfying an inherent or learned preference. We specified the time frame ("more than two years ago"), the cost ("between $50-$500"), and the durability of the purchase ("something you still have and are still using"). Participants recalled such a purchase, described the type of preference they tried to satisfy, and then rated their immediate happiness and current happiness due to the purchase. We find that, although happiness derived from both types of purchases decreased over time, the decline is greater for the LP-oriented purchase than the IP-oriented purchase. In another study, we replicated this effect in the context of life events, and controlled for immediate happiness. Specifically, we asked participants to recall two improvements in their life within the past 5 years, one satisfying an inherent preference and the other a learned preference. We specified that these two improvements must have had similar immediate impacts on their happiness. Participants described two such improvements and rated whether the improvements had a long-lasting effect on happiness. Supporting our prediction, participants rated improvements that satisfied an inherent preference as having a longer-lasting effect on happiness than those that satisfied a learned preference.

Together, we aim to make two related contributions in conducting this program of research (Hsee et al., 2009; Tu & Hsee, 2016; Tu, Hsee, & Li, 2017). First, we draw a distinction between inherent preferences and learned preferences, a distinction that has potentially profound implications for both theory building and policymaking. Second, we provide empirical evidence suggesting that improvements related to inherent preferences produce more sustainable gains in happiness than do improvements related to learned preferences. This insight is important, in light of the fact that most improvements that have been made over the years are only about learned preferences and not about inherent preferences.

Conclusion

In this chapter, we review research on hedonomics. We present a representative, but not comprehensive, list of determinants of happiness, mainly drawing upon research on judgment and decision making. These factors are subtle but can significantly influence happiness. More importantly, they offer implications for "choice architects" – government, companies, and individual consumers– to design better consumption pattern and procedure, to offer proper timing of choice and consumption, to produce and stimulate the right type of consumption experiences, and ultimately, to improve daily happiness without significantly increasing the possession or consumption of external materials.

Abstract

Research into the genetic and environmental origins of human wellbeing has made tremendous progress over the last two decades. Genetic effects on subjective wellbeing (SWB) are well established, and meta-analyses reveal average heritabilities in the 32-41% range. Behavior genetic studies also provide strong evidence for the causal role of environmental factors in SWB. In this chapter we review exciting developments within the intersecting fields of wellbeing and genetically informative research. We start by elaborating on the concept of heritability and the basics of twin studies. The beauty of the twin study lies in the potential to examine causal factors, without observing them, by the logic of a research design. Next, we review findings of genetic and environmental influences on SWB, and the role of such influences in the multivariate associations between different types of wellbeing, between wellbeing and ill-being, and between personality and wellbeing. We also outline recent developments within molecular genetics, and strategies to identify specific genes. A separate section addresses the issue of gene-environment interplay, and we discuss concepts such as vantage sensitivity and differential susceptibility. Throughout the chapter, we will seek to elaborate on what is known – and what is yet to be known.

Keywords: Genetic, Twin, Molecular genetics, Heritability, Wellbeing

To what extent, and in what ways, is wellbeing influenced by genes? What is the role and interplay of genetic and environmental factors in wellbeing and illbeing? Is the genetic effect on wellbeing due to personality-related genes? Which specific genes influence wellbeing? These are among the questions that researchers have addressed in recent years – and for which we do have some answers and are searching for more.

Recent meta-analyses have documented that the weighted average heritability of subjective wellbeing (SWB) is in the range of 32-41% (Bartels, 2015; Nes & Røysamb, 2015; Vukasovic, Bratko, & Butkovic, 2012). Heritability is, however, not a fixed statistic. There is considerable heterogeneity across population groups, measures and methods (Nes & Røysamb, 2015). There is also evidence of substantial heritability for personality traits, and the genetics of wellbeing appear to be partly about personality genes (Keyes, Kendler, Myers, & Martin, 2015; Weiss, Bates, & Luciano, 2008). Similarly, the genes that influence wellbeing appear to be partly the same as those protecting against depression (Haworth, Carter, Eley, & Plomin, 2017; Kendler, Myers, Maes, & Keyes, 2011; Nes, Czajkowski, Røysamb, Reichborn-Kjennerud, & Tambs, 2008; Nes et al., 2013).

Behavior genetic studies reporting heritability estimates also provide strong evidence for the substantial environmental effects involved. Causality of specific variables (e.g., life events) is generally hard to prove in correlational studies, but genetically informative studies reporting a heritability of 40% imply that 60% of the variance in wellbeing is caused by environmental factors, and random measurement error. Despite considerable progress in estimating genetic influences on wellbeing, several pieces of knowledge are still missing. Whereas behavior genetic studies, using twin, family and adoption designs, have been able to estimate total genetic effects (heritability), molecular genetic studies have so far had limited success in identifying the specific genetic variants involved (Okbay & al., 2016; Weiss et al., 2016). However, with collaborative efforts, extensive sample sizes and new technology for analyzing DNA, the field of molecular genetics is moving ahead at high speed.

In this chapter we aim to review some of the exciting recent findings on the role of genetic and environmental factors in wellbeing. We start by clarifying the concept of *heritability*, and move on to outline the logic involved in estimating heritabilities from twin and adoption studies. Next, we review findings pertaining to the role of genes and environment in wellbeing, and in the associations between wellbeing, illbeing and personality traits. Are the observed relationships between such phenotypes due to shared genes, shared environments or both? Next, we outline recent findings and prospects from molecular studies, and finally we address various types of interplay between genes and environment.

Heritability - What it is (Not) About.

What is the heritability of the number of fingers of human hands? Most of us have two hands and ten

fingers, and we know that these features are genetic in origin. Without genes coding for hands and fingers in the developing fetus, we would not have any. Yet, the heritability of the number of fingers on human hands is probably quite low. How can that be? To understand the scientific concept of heritability (h^2) we need a simple formula:

$$Heritability = h^2 = \frac{V_g}{V_g + V_e} = \frac{V_g}{V_{tot}}$$

where V_g equals genetic variance, V_e is the environmental variance and V_{tot} represents the total variance (sum of all genetic and environmental effects). Thus, heritability is the proportion of the total variance that is due to genetic variance.

Now, returning to the number of fingers, in general there is not much variance in this figure. If everybody have ten fingers the variance is zero and it would not be meaningful to estimate the heritability (also, mathematically, division by zero is undefined). However, some people do not have ten fingers. This is usually due to accidents, which mostly are environmental in origin. The genetic variance in number of fingers is minimal. With the exception of rare mutations that generate other numbers of fingers, varying finger-numbers are due to environmental factors. Thus, the larger part of the total variance is environmental, rather than genetic, in origin – and therefore the heritability is low. This also implies that if the environmental variance for any trait is reduced in a population (e.g., less social inequalities or less accidents), the heritability increases, and with rising environmental variance (e.g., by introduction of an intervention), heritability will be reduced.

As heritability is about variance we need to keep in mind that it is a population statistic. It is not meaningful to translate a heritability estimate directly into an estimate of the genetic contribution to a single person's traits – regardless of whether the traits are wellbeing, personality, body height or number of fingers. For example, human body height has a heritability around 80% (Bergin et al., 2012; Silventoinen, Kaprio, Lahelma, & Koskenvuo, 2000; Yang et al., 2010). However, that does not mean that a person with height 170 cm has received 136 cm (170x80%) from her genes and 34 cm (170x20%) from the environment. Correspondingly, if the heritability of wellbeing is about 40% it does not mean that 40% of your wellbeing is genetic and 60% is environmental. In each one of us, the genetic and environmental factors have operated together in creating a unique blend that cannot be partitioned into percentages of effects.

In this sense, heritability is an estimate of explained variance in the same way that we can estimate the variance of wellbeing accounted for by personality traits or life events. When we obtain explained variance (R^2) in a multiple regression analysis, this parallels the estimate of heritability – the variance accounted for by genetic factors. It does not make sense to say that a certain life event explains for example 30% of a single individual's wellbeing. The same holds for genetic factors.

How then, may we envision the genetic effects on individuals without partitioning a person into genetic and environmental effects? One useful thought experiment includes imagining a person with 99 other identical twins, that is, in total 100 genetically identical persons. All differences between these 100 people would necessarily be due to environmental differences, and this group of people would have a certain mean, variance and total range of scores. Thus, the hypothetical wellbeing range among the 100 clones would represent the potential wellbeing range for each individual. In this sense, we all have a genetically based wellbeing set-point (in the sense of the average of our own clones), and a range to operate within (the range of our clones). Although this perspective involves a genetically based set-point, note that most of the 100 people will not be at this exact point: roughly half will be above and half below. This example may function as a basis for thinking about a person's wellbeing range as rather wide, with potential for both upward and downward movements. However, without the 99 other clones available, we cannot know whether a particular person is actually below or above her own genetic midpoint.

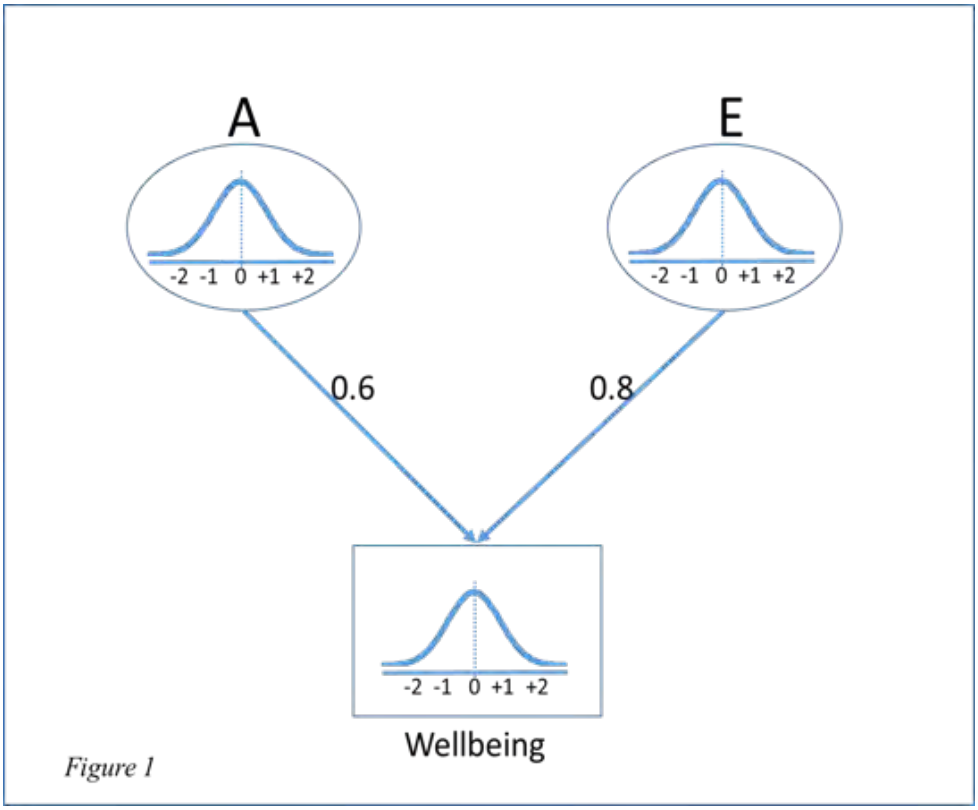

Figure 1

Figure 1 illustrates the effect of genetic and environmental factors on wellbeing. The latent factors (ovals) represent additive genetic effects (A) and environmental effects (E), and the observed (rectangular) variable represents wellbeing. In this illustration, all three variables are standardized (with *mean*=0 and *sd*=1). The effect of the genetic factor is set to 0.60, implying a heritability of 36% (0.6x0.6=.36), and the effect of the environmental factor is set to 0.80. Thus, in this scenario a person's wellbeing is given by the formula:

Wellbeing=0.60xA+0.80xE

A certain person X with a genetic disposition to happiness of -0.5 (i.e., 0.5 *sd* below the mean on the latent genetic variable A) but a favorable environment of +0.5 would end up with a wellbeing score of +.10 (i.e., 0.6x-0.5 + 0.8x0.5), whereas a person Y with a happy disposition of +1.0 but a total negative environmental load of -1.0 would have a wellbeing score of -0.20 (0.6x1.0 + 0.8x-1.0). Now, this illustration represents a basic model as it only includes an additive genetic and a non-shared environmental variable, and have disregarded potential correlations and interactions between them. We will return to the notions of gene-environment interplay later.

How to Estimate Heritability

The elegance of twin studies lies in their potential to estimate genetic and environmental effects by the logic of a design, without necessarily measuring any specific genes or given environments (Plomin, DeFries, Knopik, & Neiderhiser, 2013; Røysamb & Tambs, 2016). In the classic twin design we collect data from *monozygotic* (MZ) and *dizygotic* (DZ) twins, and the observed similarity within pairs among MZ versus DZ twins represent a core element of information. MZ twins share 100% of their genes, whereas DZ twins share on average 50% of segregating genes, and we use this knowledge to test hypotheses about the influence of four major types of factors: *Additive genetic factors* (A) are correlated at unity among MZ twins and at 0.5 in DZ twin pairs. *Non-additive genetic influences* (D) also correlate 1.0 in MZ twins, and 0.25 (or below) in DZ twins. The non-additive effects include *dominance* (hence D), interaction at a certain locus whereby one allele (genetic variant) is dominant, and *epistasis*, which involves interaction between alleles at different chromosomal loci. Shared or *common environmental factors* (C) are per definition shared by the twins in a pair, for both MZ and DZ twins, and correlate at unity. C effects are often, but not necessarily, expected to reside within the family. Note that C factors reflect environmental influences leading to similarity among twins. A certain parenting style or event in a family may or may not represent a C factor, depending on whether the effect on the twins is the same or different. Finally, *non-shared*

environmental influences (E) include all factors that contribute to twin differences (including random error), and are therefore uncorrelated between twins in a pair (Plomin et al., 2013).

Broad-sense heritability (H^2) includes both additive (A) and non-additive (D) genetic effects, whereas narrow-sense heritability (h^2) includes additive effects only. A crude estimate of the heritability (disregarding D-effects for now) can be calculated based on the difference in observed twin-cotwin correlations across zyosity groups:

$$h^2 = 2(r_{MZ} - r_{DZ})$$

Thus, the heritability equals two times the difference between the MZ and DZ correlations. Correspondingly, the shared environmental variance (C) is given by the formula

$$c^2 = 2r_{DZ} - r_{MZ},$$

and non-shared environmental variance (E) is resolved by

$$e^2 = 1 - r_{MZ}.$$

These formulas can give important information about the magnitude of various effects, but more sophisticated methods are used to test specific models and obtain measures of uncertainty.

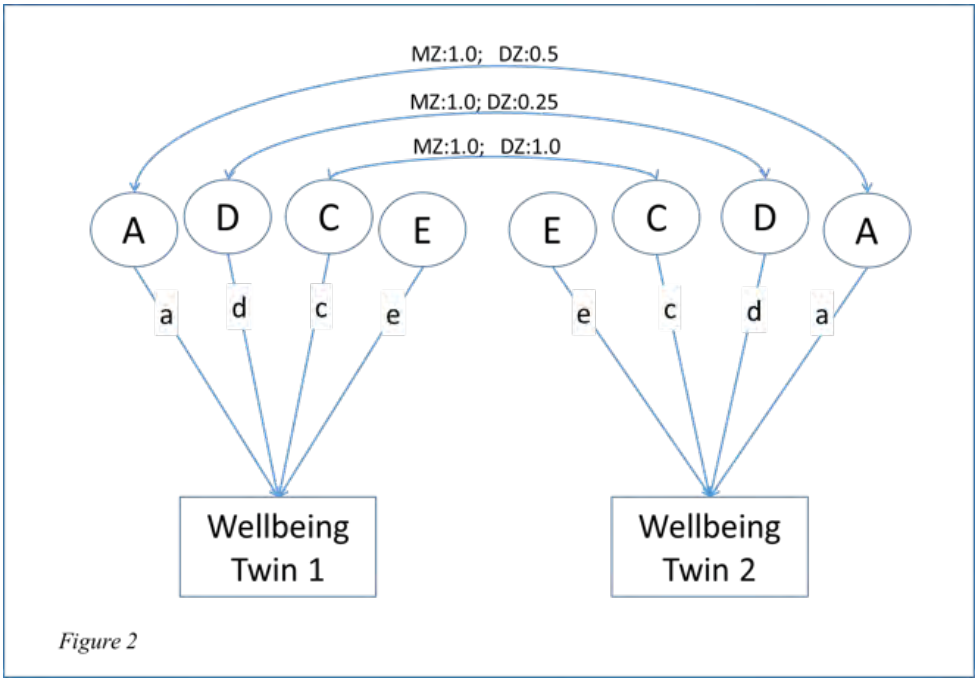

Figure 2

Figure 2 illustrates a basic biometric model with the four latent factors, A, D, C and E, and one observed wellbeing variable. Correlations between latent factors are shown for MZ and DZ twins. This is a univariate twin model, in the sense that only one observed variable is analyzed, but measured in two twins. The model can be tested as a structural equation model (SEM) in software such as Mplus, Mx or OpenMx (Boker et al., 2011; Muthen & Muthen, 2017; Neale, 1996). The twin-cotwin correlations for the latent factors, as shown in the figure, are fixed at the depicted values, for example in a two-group model with MZ and DZ twins, and the paths *a, d, c* and *e* are estimated. Typically, nested submodels (e.g., an AE model) are compared to full models (e.g., ACE) and the presence of the various latent factors is determined by the fit and the comparison of the different models. Note that the full ADCE model is underidentified in the classic twin design, which includes only MZ and DZ twins reared together. Therefore, the full model is typically an ACE, or ADE, model – depending on the structure of correlations.

The basic univariate model may be extended along several lines. First, sex-differences may be examined by testing for *quantitative* (different magnitude of effects for women and men) or *qualitative* (partly different genes operating for women and men) effects (Neale, Røysamb, & Jacobson, 2006; Røysamb, Harris, Magnus, Vitterso, & Tambs, 2002). Testing of quantitative sex-differences can be performed in samples including only same-sex twins, whereas qualitative differences require opposite-sex DZ twins as well. Second, the univariate model may be extended into different multivariate models,

including two or more phenotypes. The multivariate models comprise several subtypes, such as independent factor models, common factor models, phenotypic causality models, and Cholesky models (Neale et al., 2006; Røysamb & Tambs, 2016), which partly differ in their underlying assumptions. However, all may be informative regarding the shared and unique contributions of genes and environmental factors to a set of variables. For example, we know that wellbeing (e.g., life satisfaction) and illbeing (e.g., depression, anxiety) are negatively correlated in the population (Haworth et al., 2017; Nes et al., 2008; Nes et al., 2013). Twin studies may help resolve the question about whether this association is due to shared genetic factors or shared environmental factors (more about this below).

Genetically informative designs comprise twin (including MZ and DZ twins), family (including relatives of varying genetic relatedness, and step-relatives) and adoption (with or without twins involved) studies. The classic twin study represents the core logic and is the most widely used design. It has been criticized for limitations in distinguishing genetic and common environmental effects that contribute to similarity between twins, but a number of findings have been replicated in for example adoption studies, thus lending support to the general twin study findings (Plomin et al., 2013).

A recent meta-analysis of heritability estimates in *Nature Genetics* (Polderman et al., 2015) covered more than 2700 twin studies based on altogether 14,558,903 twin pairs, published during the last fifty years. The study included more than 17,000 phenotypes or traits and reported almost all of these to be heritable. Although genetic effects vary across traits, substantial heritabilities have been reported for phenotypes such as height and weight, metabolic functions, blood pressure, longevity, educational attainment, personality traits, drug use, mental disorders and wellbeing (Boomsma, Busjahn, & Peltonen, 2002; Plomin et al., 2013; Plomin, DeFries, Knopik, & Neiderhiser, 2016; Polderman et al., 2015). Thus, wellbeing is a human condition that falls into a widely-observed pattern of both substantial genetic and environmental origins.

Heritability Findings – What Do We Know?

A fair number of studies have reported on the genetic and environmental influences on SWB. The heritability estimates commonly range between 25 and 50% across the different studies (Bartels & Boomsma, 2009; Eid, Riemann, Angleitner, & Borkenau, 2003; Nes, Czajkowski, & Tambs, 2010; Nes, Røysamb, Tambs, Harris, & Reichborn-Kjennerud, 2006; Røysamb et al., 2002; Røysamb, Tambs, Reichborn-Kjennerud, Neale, & Harris, 2003; Schnittker, 2008; Stubbe, Posthuma, Boomsma, & De Geus, 2005; Tellegen et al., 1988). The remaining variation tends to be accounted for by *nonshared*, rather than shared environmental influences. Table 1 gives a selection of estimates of genetic and environmental influences on SWB and closely related phenotypes.

Three *meta-analyses* have reported weighted average heritability estimates for wellbeing. First, Vukasovic et al. (2012) examined nine independent studies and reported an average heritability of 39%. Second, Bartels (2015) analyzed ten independent samples including a total of 55,974 individuals and obtained a general heritability estimate of 36% for SWB. She also constrained a set of analyses to life satisfaction, obtaining an estimate of 32%. Finally, Nes and Røysamb (2015) included 13 unique studies from seven countries, and used structural equation modelling to estimate average heritability. The best fitting model yielded a heritability of 40% in the total sample, and 41% in a more restricted sample (e.g., excluding outliers). These three meta-analyses varied in the inclusion criteria used, the studies included, and the statistical approaches adopted. Yet, they converge on finding average heritabilities in the range of 32 to 41%.

Notably, Nes and Røysamb (2015) also examined the variability of heritability estimates across studies, and found a significant and substantial deviation from homogeneity. Heritabilities varied beyond the level expected by random fluctuations, with roughly 70% of the variability due to true heterogeneity. Thus, the study confirmed the theoretical notion that heritability is not a fixed statistic, but can vary across populations and groups, and will depend on the range of environmental factors involved and the measures studied. This finding also accords with several studies reporting evidence of heritability-environment interaction (Johnson & Krueger, 2006; Nes, Røysamb, Harris, Czajkowski, & Tambs, 2010; van der Aa, Boomsma, Rebollo-Mesa, Hudziak, & Bartels, 2010).

Some of the biometric studies have shown the heritability of SWB to primarily reflect additive genetic effects (Nes et al., 2006; Røysamb et al., 2003; Schnittker, 2008). Other studies have indicated mainly non-additive genetic effects (Lykken & Tellegen, 1996; Stubbe et al., 2005). Perhaps the largest biometric study of SWB to date, combining data from 6,600 twins and 54,450 nuclear family members, reported both additive and non-additive genetic influences. Broad-sense heritabilities were estimated to be 36 and 33 percent for males and females, respectively (Nes, Czajkowski, et al., 2010). This large-scale study also suggested additional effects such as assortative mating and a shared twin environment, the latter accounting for 8% of the total environmental variation.

Table 1.

Selected key twin studies of genetic and environmental influences on subjective wellbeing

First author	Year	Phenotype	Measure	N	Age	h^2	c^2	e^2

BMSLSS=Brief Multidimensional Student Life Satisfaction Scale; SWLS=Satisfaction With Life Scale; SHS=Subjective Happiness Scale; MPQWB=Multidimensional Personality Questionnaire Well-being scale;

PA=Positive Affect; WB=Wellbeing; SWB=Subjective wellbeing; LS=Life satisfaction; h^2=heritability; c^2=common/shared environment (C); e^2=non-shared environment (E).

(Bartels & Boomsma, 2009; Caprara et al., 2009; De Neve, Christakis, Fowler, & Frey, 2012; Franz et al., 2012; Haworth et al., 2017; Keyes, Myers, & Kendler, 2010; Nes et al., 2008; Røysamb et al., 2003; Schnittker, 2008; Stubbe et al., 2005; Tellegen et al., 1988; Weiss et al., 2008)

The collective findings thus indicate that SWB is moderately heritable with differences in the magnitude of the heritability estimates likely to be related to the specific constructs explored, the psychometric qualities and the given research design, including the number and type of respondents (i.e., relative classes) – and the environmental context.

As noted above, the non-genetic influences on SWB primarily reflect *non-shared* environmental effects, and when not accounted for; measurement error (Bartels & Boomsma, 2009; Nes et al., 2006; Røysamb et al., 2003). *Shared* environmental influences appear to be minor, or entirely negligible. Thus, family resemblance for SWB appear to be mainly due to shared genes, and not to shared environments. It is important to note, however, that family factors might still impact on SWB. Rather than undermining the importance of family features, the biometric findings imply that environmental influences do not generally operate in a family-by-family fashion (e.g., parenting styles or socioeconomic conditions do not have general effects), but rather on an individual-by-individual basis (i.e., affect the different siblings in a family differently). Importantly, negligible influences from shared environments may primarily indicate that shared environmental influences are very small and smaller than the non-additive genetic effects.

How do the findings of heritability fit with findings of substantial *national differences* in wellbeing (Diener, Helliwell, & Kahneman, 2010; Helliwell, Layard, & Sachs, 2017; Morrison, Tay, & Diener, 2011; Oishi & Schimmack, 2010; Tay & Diener, 2011)? It should be noted that heritability is a statistic referring to a variance component within a certain population, and as such has no say on differences across

populations. It seems reasonable to assume that national differences in wellbeing are mainly environmental in origin (e.g., economy, governance, health care, education, culture, peace and safety). Thus, when including the cross-national differences in the equation, the total environmental variance will increase, and the 'global heritability' of wellbeing should consequently be reduced. Today there is also limited knowledge about systematic interaction effects between cultural and societal factors on the one hand and genetic factors on the other. Future studies should aim to disentangle how genetic expression is moderated by environmental factors also at the national and cultural level.

Multivariate Findings: Shared and Unique Factors

The same set of genes and environmental factors may underpin several correlated characteristics simultaneously. In fact, most genes involved in complex traits (e.g., SWB) tend to have pleiotropic effects - affecting a number of different characteristics, for example due to coding for "endophenotypic" neurobiological mechanisms (e.g., neurotransmitter systems) involved in different characteristics. Multivariate biometric designs permit us to decompose the correlation between variables (e.g., SWB and extraversion) into genetic and environmental sources. They also allow us to quantify the extent to which the genetic and environmental variation is specific to one characteristic only (e.g., SWB), and the extent to which it is shared by other characteristics (e.g., extraversion, depression). Such commonality or specificity is reflected in the genetic (r_g) and environmental (r_e) correlations between the given characteristics. The r_g and r_e may differ substantially from the genetic and environmental contributions to the covariance. For example, the genetic influence on two given traits may be minor (i.e., low genetic covariance). Yet, the genetic correlation could be very strong, indicating that the same genetic sources affect both traits (although weakly).

Partly overlapping genetic factors have been indicated for different wellbeing indicators. For example, by means of an extended twin-sibling design, Bartels and Boomsma (2009) reported correlations between four common SWB indicators (quality of life in general, quality of life at present, life satisfaction, subjective happiness) to largely reflect shared genes (i.e., the same genetic core). Partly overlapping sets of genes have also been reported for emotional, social, and psychological wellbeing (Keyes et al., 2010), and for self-esteem, SWB, and optimism (Caprara et al., 2009). In the latter study, the genetic correlations (r_g) were estimated to range from 0.80 (self-esteem and SWB) to 0.87 (SWB and optimism). The environmental influences were considerably more distinct, with environmental correlations (r_e) ranging from 0.18 to 0.32.

What about the association between SWB and *psychopathology*? Can SWB inform us about vulnerability to mental illness? The correlations between SWB and mental illness tend to be moderate and inverse, typically around -0.50 (Franz et al., 2012; Kendler, Myers, Maes, et al., 2011; Nes et al., 2008; Nes et al., 2013; Okbay et al., 2016). Moreover, a meta-analysis reported an average heritability of depression of 37% (Sullivan, Neale, & Kendler, 2000), thus paralleling that found for SWB. However, similar magnitudes of heritability for different characteristics do not per se inform us about the degree of shared genetic factors.

Biometric studies have indicated a partly different genetic and environmental etiology for positive and negative affect (Baker, Cesa, Gatz, & Mellins, 1992) as well as for optimism and pessimism (Plomin et al., 1992). A few studies have examined the genetic and environmental sources underpinning the negative associations between mental health problems and SWB and closely related constructs. Most of these studies are based on adult samples with mental health problems such as internalizing problems or disorders (i.e., anxiety and depression). For example, Vinberg, Bech, Kyvik, and Kessing (2007) investigated quality of life in first-degree relatives of patients with affective disorder, finding quality of life to be impaired in twins with an affected co-twin. Nes and colleagues examined the etiology underpinning the covariance between SWB (i.e., life satisfaction) and self-reported symptoms of anxiety and depression (Nes et al., 2008), and later on the association between dispositional SWB and life time major depression (Nes et al., 2013). In addition, Kendler, Myers, Maes, et al. (2011) examined the generality and specificity of etiological influences on the association between internalizing psychopathology (MDD, generalized anxiety disorder, panic attacks) and mental well-being (MWB), comprising emotional, psychological, and social well-being. All of these studies show a moderate inverse correlation between SWB and internalizing mental health problems, a substantial but far from complete overlap in genetic factors, and modest commonality of environmental influences (Kendler, Myers, Maes, et al., 2011; Nes et al., 2008). Thus, the genes that contribute to wellbeing are only partly the same as those protecting against depression. However, environmental influences with a long-term impact on vulnerability to internalizing problems seem to influence SWB to a greater extent than environmental influences with mainly transient effects (Kendler, Myers, Maes, et al., 2011).

Although most studies to date are based on adults, a recent study of 4,700 pairs of 16-year-old twins reported similar findings (Haworth et al., 2017). This recent study has also indicated different patterns of overlap for life satisfaction and subjective happiness. More specifically, the phenotypic correlations between the constructs were highly similar. Yet, the authors observed stronger genetic links between life satisfaction and depression, than between subjective happiness and depression. About 45% of the genetic influences on life satisfaction and 70% of the genetic influences on subjective happiness were independent of the genetic factors underpinning internalizing symptoms. In line with previous studies, non-shared environmental influences were also in this study largely specific to each particular trait. Thus, certain environmental factors influence illbeing, whereas another, mostly independent set of environmental factors contributes to (low) wellbeing. The multidimensional nature of the etiological influences on wellbeing, and the overlap with mental health problems, has also been reported in a smaller study based on 613 pairs of middle-aged male twins (Franz et al., 2012).

Overall, the biometric studies thus indicate that SWB do not merely constitute the "other end" of a genetic liability to internalizing problems such as anxiety and depression. Some genetic factors for SWB convey protection against internalizing psychopathology, but high levels of SWB also reflect independent genetic sources associated with healthy, or salubrious psychological functioning. This specificity in etiological influences on SWB and internalizing problems suggests that different interventions might be needed for healing problems and promoting wellbeing, and that interventions may need to target partly different biological pathways.

The etiology underpinning associations between SWB and other mental health problems, is scarcely studied. Nevertheless, one study investigated common risk factors for (low) mental wellbeing and *externalizing* psychopathology (EP), the latter measured as a history of alcohol-related problems and smoking behavior last year (Kendler, Myers, & Keyes, 2011). The two latent constructs (i.e., EP and mental wellbeing) were modestly correlated (r = -0.28) in this study. The genetic and environmental risk factors for EP were negatively associated with wellbeing, and accounted for 7% and 21% of its genetic and environmental influences, respectively. Of note, when adding recent (last year) internalizing psychopathology (IP) to the model (i.e., controlling for genetic risk factors common to IP and EP), the genetic factors related only to EP (5% of the total genetic variation) were associated with higher wellbeing, while the unique environmental risk factors for EP were related to lower wellbeing. One tentative explanation of the positive genetic association between the unique EP factor and wellbeing could involve an underlying genetic disposition to for example extraversion that might contribute to both characteristics. Further, the authors suggested that shared genetic risk factors to EP and IP reflect genetic risk for EP associated with the negative consequences of substance use commonly decreasing wellbeing – such as anxiety and depression. The corresponding environmental influences were suggested to reflect psychosocial adversities that contribute to drug use and misuse, and in turn compromise wellbeing.

Personality and Wellbeing

What is the relationship between personality traits and wellbeing? To what extent do people's *extraversion* and *neuroticism* influence their happiness and life satisfaction? And what is the role of genetic and environmental factors in these associations?

Personality psychology focuses on a number of different tendencies and traits. Within the trait perspective, the five factor model (FFM) of personality has obtained a dominant role. The *Big Five* factors comprise five broad personality traits, including neuroticism, extraversion, openness to experience, agreeableness and conscientiousness. A number of studies have examined relations between these personality traits and wellbeing, and already in 1998, a meta-analysis concluded that in particular neuroticism is a strong (negative) predictor of life satisfaction and happiness (DeNeve & Cooper, 1998). In addition, extraversion and partly conscientiousness show substantial relations to wellbeing whereas the findings involving agreeableness, and in particular openness, are mixed and mainly indicate weak or negligible associations (DeNeve & Cooper, 1998; Lucas & Diener, 2008; Vitterso, 2001).

The importance of personality for wellbeing contrasts findings of the limited effect of demographic and background variables. In general, age and sex differences in wellbeing are usually minor or totally absent, and variables such as educational level, income or geographical location appear to explain considerably less variance in wellbeing than personality traits do (Diener, Suh, Lucas, & Smith, 1999; Lucas & Diener, 2009). Also, whereas the impact of negative and positive life events (e.g., divorce, accidents, winning a lottery) are mostly short-lasting, the associations between personality and wellbeing tend to be enduring.

Personality traits are influenced by genetic factors, and studies have shown substantial heritabilities (Boomsma et al., 2002; Jang, Livesley, & Vernon, 1996; Vassend, Røysamb, Nielsen, & Czajkowski, 2017). Given the genetic influence on both personality traits and wellbeing, and the phenotypic

associations between them, it seems pertinent to address the question of what role genes and environment play in generating relations between the two sets of characteristics. Is the heritability of wellbeing due to personality related genetic factors? Are there unique genetic influences on wellbeing, independent of personality? Are there environmental factors that influence both personality traits and wellbeing?

A few recent studies have addressed these questions. Weiss et al. (2008) found that both genetic and environmental factors contributed to the relations between wellbeing and three of the Big Five traits, namely neuroticism, extraversion and conscientiousness. However, the authors found no unique genetic effects on wellbeing. That is, the entire heritability of wellbeing was accounted for by genetic factors in personality. Correspondingly, Hahn, Johnson, and Spinath (2013) reported shared genetic factors for personality and wellbeing. Associations were found for extraversion and neuroticism, but not conscientiousness, and the personality-related genetic factors explained the entire heritability of wellbeing. Finally, Keyes, Kendler, Myers, and Martin (2015) studied a global latent factor of flourishing, finding substantial genetic overlap with personality. However, contrasting the two previous studies, the authors also found a unique genetic influence on wellbeing, unrelated to personality traits.

Some studies have also moved beyond the general level of the five broad factors and examined associations between *personality facets* and wellbeing. For example, given that extraversion is related to wellbeing, researchers have investigated which particular facets (e.g., warmth, sociability, novelty seeking, assertiveness, positive emotions), are the most important drivers of this association. One study found the facet of positive emotions in extraversion, and the facet of depression in neuroticism to be consistent predictors of life satisfaction (Schimmack, Oishi, Furr, & Funder, 2004). More recently, Quevedo and Abella (2011) reported depression, but not positive emotions, to be important, and also found a unique association for the facet of achievement striving in conscientiousness. Next, Albuquerque, de Lima, Matos, and Figueiredo (2012) replicated the finding of depression and positive emotions as central, but also found an effect from the facet of vulnerability in neuroticism.

Whereas these studies examined associations between personality facets and wellbeing at the phenotypic level, ongoing efforts try to disentangle the role of genes and environment in the facet-wellbeing relations. A recent study identified four facets that were particularly important for wellbeing, namely anxiety and depression in neuroticism and positive emotions and activity in extraversion (Røysamb, Nes, Czajkovski, & Vassend, 2017; Røysamb, Nes, & Vassend, 2014). These four facets accounted for the larger part of the genetic variance in life satisfaction, but there was also a unique genetic factor in wellbeing. Environmental factors also contributed to the associations between personality facets and wellbeing, and were the major source of unique variance in wellbeing.

The studies on personality facets and wellbeing are somewhat divergent on which specific factors that contribute uniquely to wellbeing, and this divergence is probably partly due to different measures being used, different levels of facets, and different populations being sampled. Still, the studies seem to replicate and converge on pointing to the depression facet of neuroticism and positive emotions in extraversion as important. It is noteworthy that out of 30 facets in the NEO-PI model, these two *basic emotional tendencies* seem more important for wellbeing than facets such as sociability (gregariousness), competence, warmth, excitement seeking, self-discipline and trust.

Stability and Change

Our levels of wellbeing fluctuate, but tend to be relatively stable over time, with substantial variance shared with personality traits. The stable variance in wellbeing typically amounts to approximately 50% of the total variation, and the heritability of this stable component is usually high – in the 70% to 90% range (Lykken & Tellegen, 1996; McGue, Bacon, & Lykken, 1993; Nes et al., 2013; Nes et al., 2006). As such, the heritability of stable, or dispositional wellbeing resembles that of strongly heritable characteristics like human body height (Silventoinen et al., 2003) and adult intelligence (Haworth et al., 2009). Biometric studies have also shown the genetic influences on wellbeing to be fairly stable, reporting cross-time correlations between the genetic factors (r_g) in the 0.8 to 0.9 range. By contrast, corresponding correlations for environmental factors (r_e) are reported in the 0.2 to 0.3 range (Nes et al., 2006; Paunio et al., 2009).

How do findings of (genetic) stability fit with evidence of changeability? National comparison studies have indicated quite substantial population changes over time (Diener, Tay, & Oishi, 2013; Helliwell et al., 2017; Veenhoven, 2009). Wellbeing levels also change in response to formative events (Dyrdal, Røysamb, Nes, & Vitterso, 2011; Luhmann, Hofmann, Eid, & Lucas, 2012; Nes et al., 2014), psychotherapy and interventions (Bolier et al., 2013; Lyubomirsky & Layous, 2013; Seligman, Steen, Park, & Peterson, 2005). Longitudinal twin studies show that environmental factors account for the major share of change variance, in the 80-90% range (McGue et al., 1993; Nes et al., 2006). Interestingly, as the remainging change is due to genetic factors, these findings suggest that partly different genes affect

wellbeing at different ages and life stages.

Interventions have proved effective despite substantial heritability and stability. A recent twin study by Haworth et al. (2016) showed significant improvements in wellbeing along with reductions in internalizing problems over a 10-week intervention involving kindness and gratitude tasks. The authors reported increased wellbeing despite high heritability (48%) and the same genetic influences were operating throughout the intervention. The overall magnitude of environmental influences also remained stable, but new non-shared environmental influences emerged over time in response to the intervention. In summary, wellbeing is both heritable and changeable (Røysamb, Nes, & Vitterso, 2014), and whereas genetics play a major role in the stability of wellbeing, environmental factors play an equally important role in generating change.

Molecular Genetic Findings

Development and refinement of molecular genetics in the 1990s led many to assume that specific genes with causal effect on happiness, health and illness would be easily identified. These expectations have not been met, perhaps primarily due to such traits being *multi-factorial* and *polygenetic* (i.e., many genes with differing effects are involved in genetic variation) with risk and protective factors acting in a complex, probabilistic fashion. Additionally, complex characteristics like wellbeing are likely to be *pleiotropic* (i.e., the genes are involved in multiple functions such as biochemical processes throughout the brain). Due to very modest effects, genetic heterogeneity, and intricate patterns of interplay with environmental influences - as well as psychometric challenges; the relationship between the genotype (i.e., genetic constitution) and the phenotype (i.e. observed characteristic) is far from understood. Nevertheless, molecular genetics have made immense progress over the past few years, and wellbeing is now clearly placed on the molecular genetic research agenda and examined by means of a number of different strategies and techniques.

Molecular genetics examine the structure and function of specific genes, aiming to trace the causal pathways from the DNA to a given phenotype (e.g., SWB) using a multitude of research strategies. Traditionally, molecular genetics employed linkage analyses and candidate gene association studies, and SWB has been studied using these methods. For example, by means of a linkage design, Bartels et al. (2010) reported a signal at the end of the long arm of chromosome 19 and a second suggestive linkage peak at the short arm of chromosome 1 for SWB measured with the Subjective Happiness Scale. However, the sample was fairly small and the linkage peaks were not clearly significant.

Several candidate gene studies have focused on the *5-HTTLPR* (associated with decreased availability of the serotonin transporter protein) and suggested a link between the neurobehavioral effects of the *5-HTTLPR* and enhanced sensitivity to motivationally relevant stimuli. Recent reports also suggest that the short *5-HTTLPR* variant is likely to confer heightened sensitivity to both negative and positive stimuli (Beevers et al., 2011; Belsky et al., 2015; Belsky & Pluess, 2009b; Fox, Zougkou, Ridgewell, & Garner, 2011). The "short" variant might therefore constitute a plasticity factor rather than a risk factor, coding for a general sensitivity to the environment.

Genome-wide association studies (GWAS) constitute a widely-used approach. GWAS are not hypothesis driven and commonly sequence all or most of the genome, usually focusing on correlations between particular traits (e.g., SWB) and common gene variations (i.e., *polymorphis*ms), or structural variations in the DNA such as *copy number variations* (CNVs). GWAS usually test for a million genetic markers and permit scanning the whole genetic sequence with simplicity and low cost, and may thus include a large number of participants. In a recent GWAS of SWB (n = 298,420), depressive symptoms (n = 161,460), and neuroticism (n = 170,911), Okbay et al. (2016) identified three variants associated with SWB, two associated with depressive symptoms, and 11 associated with neuroticism. These findings support the view that GWAS may successfully identify genetic associations with large sample sizes. However, mixing of different measures make the discovered associations somewhat difficult to interpret. The heritabilities estimated in this study were based on specific genetic variants, or *single-nucleotide polymorphisms* (SNPs) - and were also quite low (0.04 for SWB, 0.05 for depressive symptoms, and 0.09 for neuroticism). Overall, the effect sizes reported in this GWA study imply that to account for even a moderate share of the heritability estimated in twin studies, hundreds - or perhaps more likely thousands of genetic variants will be required.

High genetic correlations (r_g > .75) between SWB, positive affect, neuroticism, and depressive symptoms suggest a common, or partially shared etiology. By means of a multivariate genome-wide meta-analysis (n= 958,149) of these four traits - collectively referred to as "the well-being spectrum", the authors reported 63 significant independent signals, of which 29 were not previously identified (Baselmans et al., 2017).

Genetic influences for SWB have also been examined using Genome-wide Complex Trait Analysis (GCTA), which allows for estimation of the variance accounted for by all the common SNPs on the genome. Using this method, Rietveld et al. (2013) reported that up to 18% of the variance in SWB can be explained by cumulative additive effects of genetic polymorphisms that are frequent in the population. Other contemporary methods include the use of polygenic scores, resembling a sum or factor-score for multiple genetic loci and their associated weights. Polygenic scores may allow us to test genetic overlap between different dimensions of wellbeing, to detect and control for genetic confounding in the outcomes, and to explore gene-environment interaction (Plomin, 2013; Weiss et al., 2016).

Yet another molecular genetic strategy using RNA transcripts as outcomes (i.e., "expression profiling", "transcriptome profiling") has been used to examine SWB. Genes which are transcribed from genomic DNA (i.e., transcriptome) constitute an important determinant of cellular function. Using such procedures, Fredrickson et al. (2013) have reported divergent transcriptional response to adversity (CTRA; pro-inflammatory, anitviral and antibody-related genes) for hedonic and eudaimonic wellbeing despite the two constructs being highly correlated, suggesting that the two types of wellbeing engage distinct gene regulatory programs despite similar effects on overall wellbeing. These findings have been subject to heated debate however (Brown, MacDonald, Samanta, Friedman, & Coyne, 2014), but have been partly replicated (Fredrickson et al., 2015).

In summary, different genetically informative designs have provided somewhat divergent estimates of the genetic influence on wellbeing. First, twin studies (and adoption/family studies) typically yield heritability estimates in the 25-50% range. Second, genome-wide complex trait analysis, examining genome similarities in unrelated individuals, report heritabilities based on common polymorphisms up to 18% (Rietveld et al., 2013). Third, genome wide association studies, so far have only identified specific genetic variants that explain 4% of the variance in wellbeing (Okbay et al., 2016). The apparent discrepancy between quantitative genetic studies and molecular genetic studies is often referred to as *missing heritability* (Manolio et al., 2009; Plomin, 2013; Yang, Zeng, Goddard, Wray, & Visscher, 2017). Why do molecular genetic studies not find the same heritabilities as twin studies? Notably, only quantitative genetic studies (twin/adoption/family studies) are able to capture the entire genetic effects, including rare genetic variants, epistasis and dominance effects – and there is a general consensus that the estimates from such studies are mostly valid (Manolio et al., 2009; Polderman et al., 2015; Visscher, Yang, & Goddard, 2010). Possible explanations for the lower estimates found in molecular genetic studies include the limited ability to examine non-additive effects, rare mutations, epigenetics, and a high number of tiny effects. Note that the genome wide significance level is typically set at $p<0.00000005$, instead of the ordinary p-levels of 0.05, 0.01 and 0.001. This is due to the excessive multiple testing involved, and implies that huge sample sizes, in the range of hundreds of thousands of participants, are required to identify small effects (Manolio et al., 2009; Okbay et al., 2016). Note also that missing heritability has a certain parallel in 'missing environment'. Although we know from twin studies that environmental factors in total account for roughly 60% of the variance in wellbeing, and numerous studies have identified correlates of wellbeing, we have limited evidence about which specific factors that are truly causally related to wellbeing and thereby add up to this percentage.

The recent interest in the molecular genetic underpinnings of wellbeing testifies to the importance of these fields. However, there are still few published studies, most findings have not, yet, been replicated, and the scientific understanding of the molecular genetic mechanisms in SWB is rather limited, thus awaiting new discoveries. Based on the combined findings from molecular and quantitative genetics it seems fair to conclude that the total genetic effect on wellbeing is substantial. Yet there is no major happiness gene that explains most of the heritability, but rather a high number of genetic variants, each with very tiny effects, which appear to operate and interact in complex ways.

A Structural Model of Wellbeing and Illbeing

As outlined above there are substantial negative correlations between wellbeing and illbeing, and genetic factors contribute to these associations (Franz et al., 2012; Nes et al., 2008). Yet, wellbeing and illbeing are not necessarily polar opposites and a nuanced picture of relationships is emerging. Illbeing comprises various conditions such as depression, anxiety, drug abuse, eating disorders and psychoses – and the relations to wellbeing vary across disorders (Keyes, 2007; Nes et al., 2008; Ryff et al., 2006; Røysamb et al., 2011).

Moreover, as the general field of wellbeing research has moved forward, a number of concepts and terms have been launched. In addition to examining SWB, researchers have proposed terms such as psychological wellbeing (Ryff, 1989; Ryff & Singer, 1996), mental wellbeing (Keyes et al., 2010), social wellbeing (Keyes, 1998; Shapiro & Keyes, 2008), and a general distinction between hedonic and eudaimonic wellbeing (Disabato, Goodman, Kashdan, Short, & Jarden, 2016; Goodman, Disabato,

Kashdan, & Barry, 2017; Ryan & Deci, 2001; Waterman, 2008). Here, we mainly refer the interested reader to the relevant literature for these different concepts and types of wellbeing. Yet we see it fitting to integrate some of the current knowledge into a general structural model, in order to illustrate some of the mechanisms of environmental and genetic factors.

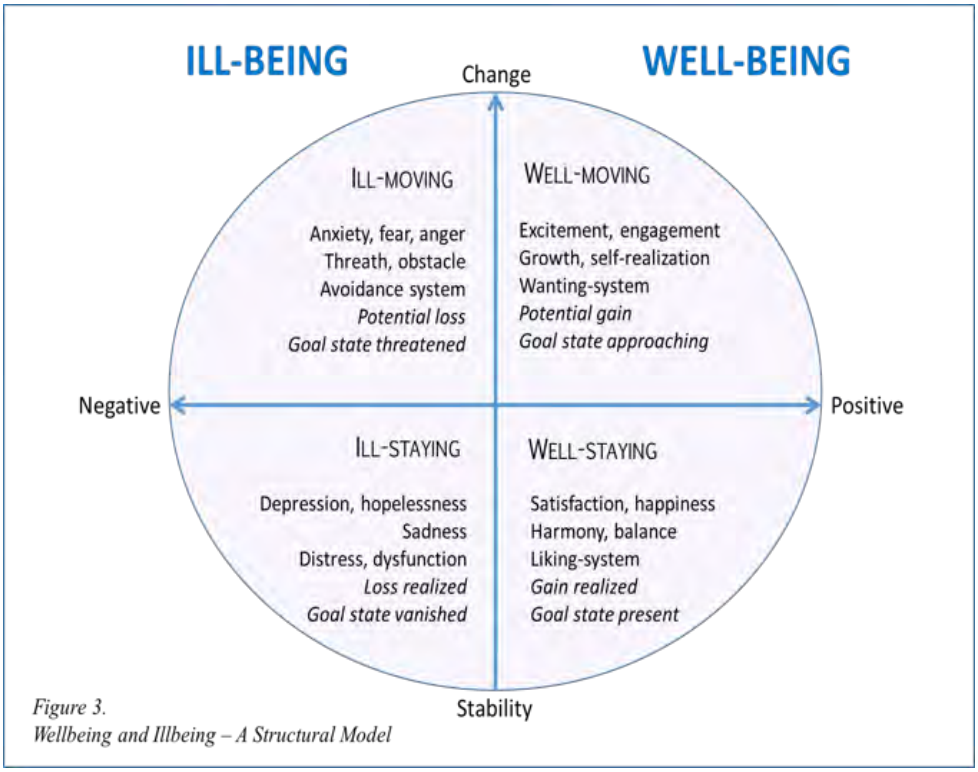

Figure 3.
Wellbeing and Illbeing – A Structural Model

Figure 3 shows a *structural model of wellbeing and illbeing* , also termed the Well/Ill-Staying/Moving (WISM) model (Røysamb & Nes, 2016). This model is partly based on the circumplex model of affect (Posner, Russell, & Peterson, 2005; Russell, 1980) and recent findings of relationships between mental disorders and different types of wellbeing (Kendler, Myers, & Keyes, 2011; Nes et al., 2013; Ryff et al., 2006).

The model involves two basic dimensions: One *positive-negative* dimension and one of *stability-change*. Environments can be (or perceived to be) positive or negative to us, and may represent continuity and stability, or development and change – with all shades of grey in between. Central to the model is the notion that humans have various ideals, needs or *goal states* (Emmons & Diener, 1986; Lyubomirsky, Sheldon, & Schkade, 2005; Oishi & Diener, 2001; Ryan, Huta, & Deci, 2008). We may experience the presence of an obtained goal state (e.g., a university grade, a good relationship, or a home), in which we are satisfied, happy and in harmony. This condition is termed *well-staying*. Sometimes we are not yet in this state, but nevertheless moving towards it (e.g., climbing a mountain, applying for a job, dating a wonderful person); we are in a process involving excitement, growth and fulfilling of potentials – thus we are *well-moving*. In other situations we realize there are threats to our goal states (e.g., a potentially failed exam, a dream-date meets someone else, or serious illness emerges); we experience fear, anxiety or anger, and are basically *ill-moving*. Note that both well-moving and ill-moving are partly future-oriented. Finally, when a goal state is lost or has vanished (e.g., failed exam, lost job, relationship break-up), we might experience sadness, depression and hopelessness – a situation of *ill-staying*.

In this model, wellbeing comprises both well-staying and well-moving. Illbeing correspondingly involves ill-staying and ill-moving. As we face life's challenges and opportunities, we perceive and respond to environmental factors (e.g., events, people, circumstances) that are seen as good or bad, and as involving continuation of the current situation, or change. We all have a repertoire of evolutionary based tendencies (e.g., fear, sadness, joy) with which we respond (Belsky & Pluess, 2009a; Hill & Buss, 2008; Izard, 2009). However, there are also individual differences in the threshold for activation and in the strength of response, and these differences seem to be partly genetic. Thus, finding a heritability of 40% for SWB tells us about the genetic contribution to individual differences in seeking, creating and responding to environmentally based life challenges and opportunities. As life happens, and is constructed, mastered and

celebrated, we all move around in this space of illbeing and wellbeing with the help of our genetic make-up. A *good life* may involve movement mainly between the well-staying and well-moving areas. However, some inevitable trips to the illbeing side might result in important turning-points, contrasts and sources of meaning, and thereby a potential return into the wellbeing sphere.

Gene-Environment Interplay

It is increasingly acknowledged that genetic and environmental factors are neither independent nor static. Rather, the genetic and environmental factors transact and interplay throughout development. Several types of gene-environment interplay are likely to be important for wellbeing. *Heritability-environment interaction* constitutes one type of such interplay and refers to environmental moderation of genetic effects. This type of interaction has been indicated in several biometric studies of SWB. The heritability of SWB has for example been shown to vary across gender (Nes, Czajkowski, et al., 2010; Røysamb et al., 2002), socio-economy (Johnson & Krueger, 2006), marital status (Nes, Røysamb, et al., 2010), and parental divorce (van der Aa et al., 2010). In one study, the genetic and environmental contributions to SWB were indicated to vary across marital status in both men and women, with lower heritability observed among the married (Nes, Røysamb, et al., 2010). Marriage or marital-like relationships are thus associated with greater impact of environmental influences on SWB.

Another type of interplay is *gene-environment interaction* (GxE), which refers to interaction between specific DNA variants and specific measured environments. A number of GxE studies and meta-analyses (Karg, Burmeister, Shedden, & Sen, 2011; Kim-Cohen et al., 2006; Risch et al., 2009) have found that individuals often differ quite markedly in how they respond to their environment depending on whether they carry specific genes. Most such studies have investigated associations between specific polymorphisms (e.g., *5-HTTLPR*) and vulnerability to *negative* health outcomes (e.g., depression, conduct disorder) given *negative* life circumstances (e.g., abuse, maltreatment) (Caspi et al., 2003; Moffitt, Caspi, & Rutter, 2006). Recently more salubrious phenotypes have also been explored. The concept of *vantage* sensitivity (Pluess & Belsky, 2011) indicate that some people for genetic reasons may benefit more than others from positive life experiences. The related construct of *differential susceptibility* (Belsky, 1997; Belsky & Pluess, 2009a) refers to some individuals being disproportionally susceptible to both negative *and* positive environmental influences – thus they are particularly malleable or plastic. So, differential susceptibility pertains to situations in which given factors - like specific genetic polymorphisms, may increase risk of adversity (e.g., depression, anxiety) given a harsh environment, but may contribute to particular benefits (e.g., optimism, wellbeing, self-esteem) given a positive and supportive environment.

The concept of *gene-environment match-making* (Røysamb, Nes, & Vitterso, 2014) builds on gene-environment interplay and suggests a pathway to increased wellbeing through pursuing and creation of environmental conditions that allow for flourishing of genetic potentials. People have various (genetically influenced) potentials, and these may be nourished and allowed to develop when matched with an appropriate environment. For example, a person with a genetic talent for creativity or musicality would benefit from creating and seeking environments that are conducive to these potentials. Such match-making occurs naturally, for example when we choose to go into sports or academia or get new friends. However, acknowledging the phenomenon also provides a basis for developing interventions and exercises that build on the importance of such match-making. The notion of gene-environment match-making is a new concept, awaiting further exploration. But it corresponds to the well-established *diathesis-stress* model of mental disorders (Belsky & Pluess, 2009a; Monroe & Simons, 1991), which postulates that disorders occur as a result of a genetically influenced vulnerability in combination with stressful life events. The diathesis-stress model can be seen as focusing on gene-environment *mismatch*, and as such the match-making perspective represents an antidote to this model.

Gene-environment interplay will commonly be concealed in the standard variance components (i.e., A, C, E). The same goes for another common type of gene environment interplay, namely *gene-environment correlation* (rGE), known as *social selection* in the developmental sciences and *reverse causation* or *confounding* in epidemiology and refers to the fact that genetic factors tend to imply exposure to a non-random selection of environments (i.e., the nature of nurture). rGE is usually classified as *passive, active*, and *evocative* (Scarr & Weinberg, 1983). Individuals tend to inherit their parents' genes and environment and these are likely to reinforce each other (passive rGE): children of happy and optimistic parents inherit "positivity" genes *and* experience positive and supportive parenting (i.e., double advantage). Individuals also actively select and shape their environments (active rGE), and in turn, these environments reliably respond to their behavior (evocative rGE), amplifying or strengthening genetic traits and dispositions. Happy, sociable, and optimistic children actively seek situations matching their partly genetic positivity disposition (active rGE) - and tend to evoke more positive and supportive responses in others (evocative rGE). Such active and evocative rGE will be incorporated in the heritability estimate. That is, the effect is genetic in origin but the mechanism in play can be environmental. Consequently,

heritability reflects more than direct genetic effects.

Most biometric studies on wellbeing have not examined such niche building and co-responsive processes explicitly (Johnson & Krueger, 2006; Krueger & Johnson, 2008). However, Krueger and colleagues have shown that youths with high levels of positive emotionality tend to elicit positive regard in their parents (Krueger, South, Johnson, & Iacono, 2008). Additionally, Kandler, Bleidorn, Riemann, Angleitner, and Spinath (2012) have reported genetic factors to mediate associations between personality traits (i.e., Extraversion and Openness) and controllable positive life events - and shown that genetic factors play a major role in continuity and repetition of controllable positive events. The nature of nurture, and the nurture of nature suggest fascinating ways in which genes and environments interact and correlate, and we are only beginning to understand the processes involved.

Conclusion

Subjective wellbeing is influenced by genetic factors. There is solid evidence of substantial heritability for different wellbeing components. Correspondingly, there is evidence for equally strong, or stronger, causal effects of environmental factors. Nevertheless, despite these replicated findings (Bartels, 2015; Nes & Røysamb, 2015), heritability is not a fixed statistic. Rather, as a representation of explained variance, heritability is found to vary significantly across studies – probably due to differing constructs and measures, differing demographics, and differing environmental and cultural conditions.

Genetic factors seem to play an important role for associations between different aspects of wellbeing, including life satisfaction and positive affect, as well as eudaimonic components. Likewise, associations between wellbeing, illbeing and personality are also substantially influenced by genetic factors. The genes that protect against depression are partly overlapping with those that contribute to wellbeing.

Despite exciting progress in studies of genetic and environmental effects on wellbeing, this is also a field where new questions arise continuously. Future research is needed to identify specific genes, and specific environments, involved in components of wellbeing and illbeing – and in their associations. We need a more profound understanding of the mechanisms at play and the way the underlying factors interact. As such, the intersection of genetics and wellbeing promises to be a tremendously exciting research area in the years to come.

Abstract

Abundant evidence highlights the important role of personality traits, age, and social relationships in the experience of subjective well-being. Experiential factors influence well-being, and evidence shows that specific forms of training, such as physical exercise and mindfulness meditation, can produce strong and enduring beneficial effects on well-being. These factors also shape the structure and function of our brains throughout the lifespan, with fascinating implications for our well-being. However, understanding how well-being is created (and changed) by our brains has only recently become the focus of neuroscientific investigations. In this chapter, we review recent neuroscientific evidence revealing how the neurocircuitries underlying personality traits (i.e., optimism, negative bias, self-esteem, extraversion, and neuroticism), successful emotional aging, and social relationships (i.e., love and loneliness) contribute to well-being, and how these circuits and systems are altered in chronic stress, anxiety, and depression. Identifying the neural correlates of well-being can illuminate the processes that cause higher levels of well-being, which, in turn, can inform promising training interventions that can induce neuroplastic changes and help people live happier, healthier, and more successful lives.

Keywords: Affective biases, Neuroplasticity, Prefrontal cortex, Amygdala, Orbitofrontal cortex, Ventral striatum.

The study of well-being has deep philosophical roots dating back to Aristotle, who proposed that well-being has at least two components: hedonia and eudaimonia (Aristotle, 2009; Seligman, Steen, Park, & Peterson, 2005). The term "hedonic" originates in the ancient Greek word "Hedone", which means pleasure. Hedonic well-being is exemplified in Ed Diener's concept of subjective well-being, which encompasses a combination of positive affect and life satisfaction. Thus, hedonic well-being highlights positive affect as a defining feature of well-being. Eudaimonic well-being emphasizes aspects of a life experienced as meaningful (with purpose, growth, etc.), and may or may not be accompanied by positive affect. Studying the neural substrates of eudaimonic well-being is more challenging, as it is harder to define life meaning and to link it to specific brain regions or networks. Therefore, in this chapter we will focus mostly on the hedonic component of well-being.

Subjective well-being is influenced by a combination of individual characteristics, such as genetics, personality traits (Lucas & Diener, 2008), and age (Carstensen et al., 2011), by psychosocial factors, such as having a reasonable income (Diener & Oishi, 2000; Luhmann, Schimmack, & Eid, 2011), being married (Diener, Gohm, Suh, & Oishi, 2000), or having meaningful social relationships (Cacioppo & Patrick, 2008), as well as by lifestyle-related factors, such as exercise (Hassmén, Koivula, & Uutela, 2000) and engagement in mindfulness meditation (Carmody & Baer, 2008). Although a large amount of evidence accumulated during the last decade has advanced our understanding of the roles of these factors in the experience of subjective well-being, a number of essential issues remain unclear. Among these, a key issue refers to the brain mechanisms supporting well-being, which could help clarify *why some people experience greater well-being than others*, *what might go wrong in affective disturbances, and how different types of interventions can enhance brain function and well-being*. Recent brain imaging advances enabling the investigation of the neural correlates of positive emotions and overall well-being have provided essential contributions to answering these fundamental questions.

The goal of this chapter is to review recent neuroscientific evidence revealing how the different brain regions and systems contribute to well-being, how these are different in affective disturbances, and how this knowledge about the brain can inform interventions aimed at helping people lead happier, healthier, and more successful lives. We start with a general overview of the brain and how it works, while also introducing some of the main brain regions typically involved in general emotion processing and in positive emotions associated with well-being (pleasure, reward). Then, we examine how the structure and function of these regions is different in people experiencing low levels of well-being, such as in stress and affective disorders (anxiety and depression). Next, we review evidence pointing to links between various brain regions and factors that contribute to well-being, including individual differences (i.e., personality- and age-related) and psychosocial factors (i.e., social connectedness). Finally, we conclude with evidence highlighting changes in the brain resulting from interventions focused on increasing well-being.

Neural Correlates of Well-Being

Brief Introduction to How the Brain Works

All of our mental life—our thoughts, emotions, memories, and decisions—is brought about by the physical substance of the brain. To understand how the brain enables well-being, it is necessary to first understand the basics of its organization (or structure), function, and modes of communication. All brain activity depends on the workings of neurons—cells that carry information from one place to another through a combination of electrical and chemical signals. Information is transferred between neurons at synapses, and is typically mediated by chemical signaling molecules, called neurotransmitters. The most relevant neurotransmitters that facilitate the enjoyment of a wide range of experiences and the desire to engage in these experiences are dopamine and opioids (the endogenous brain variety of opiates) (Kringelbach & Berridge, 2010). The outer layer of the brain forms the cerebral cortex, which is responsible for many of the attributes that we consider inherently human, like language, reasoning, and imagination. The cerebral cortex is divided into four lobes. The frontal lobe, the front section of the brain, is involved in the planning, guidance, and evaluation of behavior. The parietal lobe, located in the middle section of the brain, is involved in integrating information from multiple sensory modalities within the body, and information from memory. The temporal lobe, located in the bottom section of the brain, is associated with auditory processing, memory, visual item recognition, and emotion. Finally, the occipital lobe, located at the back of the brain, is mainly involved in processing visual information. Below the cortex, in the center of the brain, are the subcortical structures, which contain many of the core areas involved in emotion and reward processing, and contributing to the experience of well-being. An abundance of neuroscientific evidence indicates that the subjective experience of happiness, pleasure, rewards, and general well-being depends on shared or overlapping networks of interacting subcortical and cortical regions. These networks involved in processing emotions and rewards include subcortical structures such as the amygdala, ventral tegmental area, nucleus accumbens, and ventral pallidum, and portions of the prefrontal cortex regions, including the medial prefrontal cortex, orbitofrontal cortex, anterior cingulate cortex, and insula.

Neural Correlates of Emotion

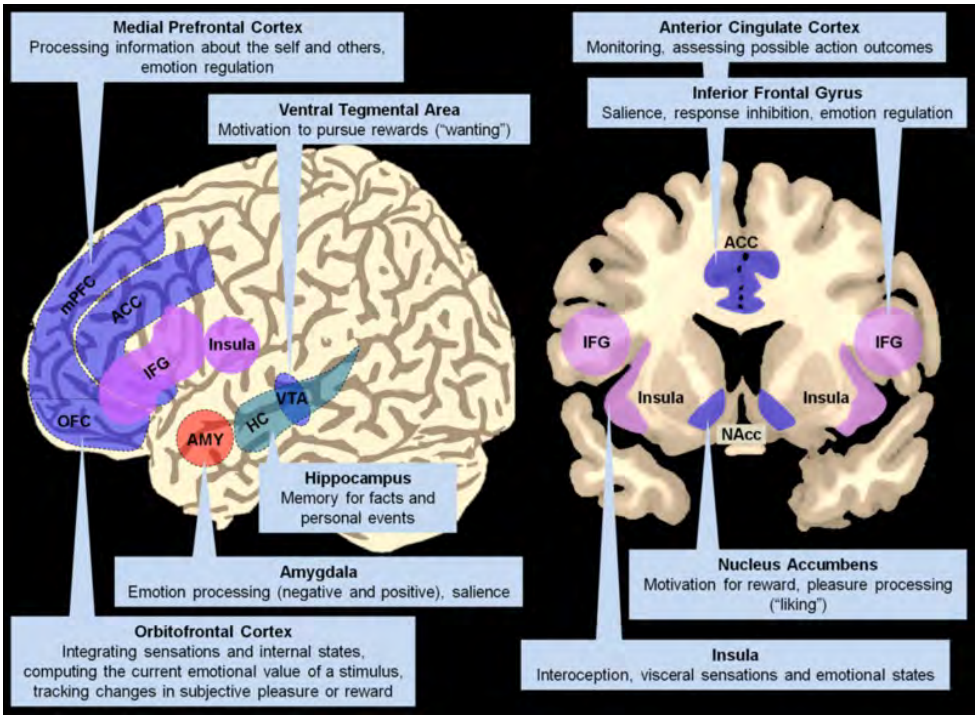
Emotion processing has been associated with a wide range of interacting brain regions (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). In this review we focus on regions that have been typically associated with well-being. A region that plays a critical role in the detection of emotional information and in learning the emotional significance of the information is the *amygdala (AMY)*, a small, almond shaped subcortical region located deep in the brain, in the temporal lobe. Traditionally, the AMY was linked exclusively to processing negative emotions, such as fear and anger. However, current views also highlight the AMY's role in processing positive emotions, and more generally in detecting salient stimuli (Adolphs, 2008, 2009; Dolcos, Iordan, & Dolcos, 2011; Whalen, 2007). Positive experiences increase the release of dopamine, the most important neurotransmitter for the experience of reward or pleasure, which makes the AMY react stronger to positive events and experiences, and send signals to the nearby hippocampus (HC) to remember such experiences.

The main cortical areas involved in emotion processing are located in the frontal lobe, which consists of a number of regions. The most relevant for well-being are the prefrontal cortex regions (especially its medial and orbital parts), the inferior frontal cortex, and the anterior cingulate cortex. The *prefrontal cortex (PFC)*, which comprises the anterior regions of the frontal lobe, takes part in the more complex aspects of planning, organizing, and executing behavior. The *medial PFC (mPFC)* plays important roles in processing information about the self and others, emotion regulation, and emotional decision making. The *orbitofrontal cortex (OFC)*, the most ventral part of the PFC, is especially involved in the experience of pleasure, happiness, and well-being. Located just above the orbits, this region receives input from the external senses (vision, hearing, touch, smell, and taste), as well as input related to the internal states of the body (via the insula, described below). By comparing the properties of an external stimulus (e.g., sweet, friendly) with the body's current internal state, the OFC (especially its mid-anterior part) computes the current emotional value of a stimulus at a particular moment, and tracks changes in the subjective pleasure or reward. The *inferior frontal cortex (IFC)*[1] is involved in a diverse range of processes, such as basic processing of emotional and salient information, response inhibition, and emotion regulation. Another frontal lobe structure, the *anterior cingulate cortex (ACC)* is connected to many brain areas, including the PFC and AMY, which allows this region to have an important integrative role in emotion, self-monitoring, and reward anticipation. The ACC is involved in assessing the value of responses; that is, whether an action is likely to elicit a reward or punishment, which is different from the role of the OFC, which computes whether a stimulus is currently rewarding or punishing. Overall, there is also evidence that the left PFC plays a more specialized role in positive affect and approach-driven

behaviors, whereas the right hemisphere is involved in negative affect and withdrawal/avoidance-driven behaviors, but this evidence is not discussed in details here (Davidson, 2004; Eddington, Dolcos, Cabeza, & Strauman, 2007; Eddington et al., 2009; Herrington et al., 2010).

Another brain region involved in emotion processing is the *insula*, which is an area of cortex tucked between the frontal and temporal lobes. Commonly known for its role in disgust, the insula actually has a wider role in emotional processing, being involved in monitoring the internal states of a body. The more complex whole-body sensations associated with emotional states, like feelings of happiness, sadness, or elation, are processed in the anterior insula, whereas basic visceral sensations like pain, temperature, or fatigue are processed in the posterior insula. Figure 1 highlights these brain regions and their main roles.

Figure 1. Neural circuitry of well-being emphasized in the present review. The areas circumscribed by dotted lines shown in the left panel illustrate brain regions located deep inside the brain. Note that the highlighted regions are meant to give a general idea of the locations in the brain, whereas delineations used for analysis might target specifically gray or white matter and use nomenclature specific to one or the other.



Neural Correlates of Reward

Neuroscientific evidence has shown that positive experiences engage a set of reward brain centers, which paint a "hedonic gloss" on some of our experiences. Before talking about these reward centers, we need to define the concept of reward. Reward consists of three components (Berridge & Kringelbach, 2015). The first component is the one most associated with reward, which is the actual pleasure or *liking*. The second component is the motivation for reward, or *wanting*. The third component is *learning* about future rewards based on past experiences. "Liking" is the core process of hedonic pleasure, whereas "wanting" refers to the motivation to obtain the reward, or the incentive salience. "Liking" is a present-moment, interoceptive feeling of well-being, whereas "wanting" is a future expectation of well-being. In addition to these psychological dissociations, "liking" and "wanting" can be also dissociated at the neuroanatomical and neurochemical levels. "Wanting" is generated by more widely distributed subcortical brain circuits, especially by the mesolimbic dopamine system, which connects the dopamine-rich ventral tegmental area to the nucleus accumbens (see Figure 1). The *ventral tegmental area* contains many neurons that produce dopamine. The *nucleus accumbens* (NAcc), a subcortical structure located deep inside the brain, contains many dopamine receptors. Dopamine released from the mesolimbic system into the NAcc regulates the incentive salience of the stimuli. In addition to dopamine, other neurotransmitters, including opioids (natural brain neurochemicals similar to opiate drugs), also contribute to the incentive salience or "wanting" (reviewed in Berridge, 2009). "Liking" is generated by more restricted brain regions than "wanting", and is also more restricted neurochemically. "Liking" is enhanced by opioid stimulation in

opioid hotspots such as the NAcc and the ventral pallidum. Although dopamine was considered by many as playing a role in sensory pleasure, recent evidence suggests that dopamine is only involved in "wanting" something, but not necessarily in "liking" it (Berridge & Kringelbach, 2015). Therefore, "liking" and "wanting" are different aspect of pleasure, and they involve different neurotransmitters. Opioids are the ones causing people to enjoy the experience, and dopamine keeps them coming back for more. While the "liking" component of reward is relatively understudied, the "wanting" part is very well studied, especially in the form of addiction.

In summary, no single brain area is responsible for the experience of emotion, pleasure, and reward. Rather, a number of brain regions interact to produce the different types of emotional experiences that accompany well-being.

When Things Go Wrong: Stress, Anxiety, and Depression

As described above, the experience of positive emotions, pleasure, and well-being is supported by the normal functioning of a number of brain regions and their interconnections[2]. Disturbances in the structure and function of these regions can reduce the ability to experience positive emotions and pleasure, which is commonly seen in chronic stress, anxiety, and depression.

Stress and the Brain

Everyone experiences stress in their life—from minor stressors such as a traffic jam or financial difficulties to major stressors such as divorce or the loss of a loved one. Stressors can cause a wide range of emotional responses, from mild alertness, to a sense of being overwhelmed and literally feeling stressed out. However, not all stress is bad. Acute or moderate stress (eustress), or what we commonly refer to as basic fight-or-flight response, not only helps people get out of danger in unexpected emergency situations, but can also have beneficial effects on people's health, strengthening the immune and cardiovascular systems. However, chronic stress, that is stress extending over longer periods of time, with no end in sight, can have deleterious effects on brain structure and function, and on people's health and well-being, leading to increased incidence of disease, such as generalized anxiety disorder, major depressive disorder, and post-traumatic stress disorder (PTSD) (Dohrenwend & Dohrenwend, 1974; Kendler, Gardner, & Prescott, 1999; Monat, Lazarus, & Reevy, 2007). Before describing the effects of stress on the brain, we need to understand how stress works.

Exposure to stressors activates the body's stress response (the fight-or-flight response), which involves the production of hormones and neurochemicals in the brain. Two key hormones are cortisol, which helps activate our brain and senses to increase alertness to better deal with emergency situations, and adrenaline, which gets the body immediately activated and aroused for action. Cortisol hard-wires the pathways between the AMY, which is important for emotions and for learning about aversive stimuli, and the adjacently located HC, which is critical for episodic memories. The hippocampal cells have the largest number of cortisol receptors in the brain, making the HC highly receptive to any change in cortisol levels. Short exposure to cortisol improves hippocampal activity and memory, but prolonged exposure to high levels of cortisol damages hippocampal cells. Patients with conditions associated with long-term stress exposure, such as depression and PTSD, have significantly shrunken HC (Arnone, McIntosh, Ebmeier, Munafo, & Anderson, 2012; Bonne et al., 2008; Koolschijn, van Haren, Lensvelt-Mulders, Hulshoff Pol, & Kahn, 2009; McEwen, Nasca, & Gray, 2016), suggesting that long-term cortisol exposure has destroyed their hippocampal cells. They also show changes in the size and connectivity of the AMY (Hamilton, Siemer, & Gotlib, 2008; McEwen et al., 2016; Morey et al., 2012). Increased stress in patients with these conditions puts the AMY into overdrive, and the increased AMY activity is accompanied by reduced activity in the PFC (Bremner, 2006).

Anxiety, Depression, and the Brain

Anxiety and depression are associated with symptoms of reduced well-being, such as negative affective biases (Cisler, Bacon, & Williams, 2009; Eysenck, Derakshan, Santos, & Calvo, 2007; Gotlib, Krasnoperova, Yue, & Joormann, 2004), and enhanced encoding of negative stimuli (Hamilton & Gotlib, 2008; Russo et al., 2006). In addition, structural and functional neuroimaging evidence indicates that brain regions implicated in emotion and reward processing are altered in anxiety and depression. For example, individuals with anxiety and depression tend to show decreased volume in frontal lobe regions such as the OFC and ACC (Arnone et al., 2012; Koolschijn et al., 2009; Shang et al., 2014; Talati, Pantazatos, Schneier, Weissman, & Hirsch, 2013), as well as in medial temporal regions such as the HC and AMY (Alemany et al., 2013; Arnone et al., 2012; Fisler et al., 2013; Hayano et al., 2009; Irle et al., 2010; Koolschijn et al., 2009; Meng et al., 2013), suggesting that these conditions are linked to structural changes in key regions engaged during processing and integration of emotional and motivational signals.

Furthermore, anxiety and depression have been linked to reduced integrity of the structural

connections between these brain regions, including between the frontal lobe and the AMY (Cullen et al., 2010; de Kwaasteniet et al., 2013; Kim & Whalen, 2009; Zhang et al., 2012), supporting the idea that the structure within and between key brain regions involved in emotion and reward processing are altered in anxiety and depression. Moreover, anxiety and depression are associated with aberrant brain activity, including communication between brain regions when the brain is "at rest" (i.e., resting state functional connectivity). For instance, anxiety is characterized by reduced resting state connectivity between PFC and the AMY (Hahn et al., 2011; Kim et al., 2011), and depression by increased resting state connectivity within a network of brain regions implicated in autobiographical memory, and decreased connectivity within a network implicated in cognitive control, relative to healthy individuals (Rayner, Jackson, & Wilson, 2016). These findings suggest that maladaptive cross-talk between brain regions occurs in anxiety and depression even when not engaged in a particular task. During tasks, individuals with anxiety or depression tend to show enhanced response in AMY to negative stimuli compared to control groups (Etkin & Wager, 2007; Groenewold, Opmeer, de Jonge, Aleman, & Costafreda, 2013), consistent with the idea that anxiety and depression influence the mechanisms subserving emotion processing.

Together, these findings identify brain mechanisms underlying chronic stress and reduced mental health, which are key factors in understanding the neuroscience of well-being, and highlight potential targets for preventive and therapeutic interventions aimed at decreasing susceptibility and increasing resilience against affective conditions to support improved well-being.

Factors Influencing Well-Being:
The Role of Individual Differences and Social Relationships

Important insight into understanding well-being has been offered by research clarifying the neural substrates of individual differences that play a role in promoting enhanced well-being and protecting against symptoms of reduced well-being. Among these, the most studied are individual differences in personality and age, which are discussed here. The role of social relationships is also discussed, with a focus on *love* and *loneliness*.

Personality, the Brain, and Well-Being

Personality influences many aspects of our lives, including our emotions, thoughts, and ultimately our well-being. Although a breadth of personality characteristics can be considered in the context of well-being, the present discussion focuses on several key factors that emerge from the literature, including *optimism, negative bias, self-esteem, and Big 5 traits.*

Optimism, a deep-rooted mindset defined as the dispositional tendency for people to hold generalized favorable expectancies about their future (Carver, Scheier, & Segerstrom, 2010), has been shown to be associated with coping behavior (Nes & Segerstrom, 2006), to be beneficial in times of adversity (Carver et al., 2010), and to promote psychological well-being (Andersson, 1996; Carver et al., 2010). Optimism is not just feeling good or thinking positively—it also helps us stay engaged in important tasks with important rewards (Scheier & Carver, 1985). Optimism leads to increased well-being because by expecting to do well, people will increase their engagement and persistence, being therefore more likely to achieve their goals.

Emerging evidence shows that optimism is associated with the structure and function of the brain. Structurally, trait optimism has been associated with greater volume in reward-related (Grabenhorst & Rolls, 2011; Kringelbach & Berridge, 2009; Phelps, Lempert, & Sokol-Hessner, 2014) and approach-oriented (Eddington et al., 2007) processing regions, such as the OFC (Dolcos, Hu, Iordan, Moore, & Dolcos, 2016). Moreover, optimism has been shown to mediate the relation between the OFC and symptoms of reduced well-being, thus demonstrating that increased volume in this brain region can play a protective role against anxiety through increased optimism (Dolcos et al., 2016). In addition to the OFC, trait optimism has also been associated with a region of the ACC (rostral anterior cingulate cortex, rACC) when imagining future positive events vs. future negative events (Sharot, Riccardi, Raio, & Phelps, 2007). This region, known to be involved in self-reflection (Moran, Macrae, Heatherton, Wyland, & Kelley, 2006; Paulus & Frank, 2003) and assessing the salience of emotional and motivational information (Bush, Luu, & Posner, 2000), has also shown increased functional connectivity with the AMY when imagining future positive events compared to imagining negative events (Sharot et al., 2007).

Research examining the brain chemistry associated with optimism (Fox, 2013) posits that the optimistic mindset is rooted in the "sunny brain", the pleasure center of the brain, whereas the pessimistic mindset is rooted in the "rainy brain". The sunny brain consists of neurons in a core reward region, the NAcc, that forms links with neurons in particular areas of the PFC, and seems to be left lateralized (Davidson & Irwin, 1999). Converging evidence from healthy and clinical studies support these lateralization findings, suggesting that the two hemispheres are differentially engaged in these fundamental

approaches to life (reviewed in Hecht, 2013).

Overall, the reviewed evidence highlights the role of the OFC, rACC, and NAcc in supporting optimism, and points to brain-personality mechanisms promoting enhanced well-being as well as protecting against reduced well-being.

Negative Bias. Another important aspect of understanding the neural correlates of well-being is clarifying the links between individual differences in *affective biases* that influence well-being. Positive affective biases tend to be observed in optimistic individuals and are associated with indicators of improved well-being (Segerstrom, 2001), whereas negative affective biases tend to be observed in individuals with emotional disorders and are associated with indicators of reduced well-being (Cisler et al., 2009; Eysenck et al., 2007; Gotlib et al., 2004). Negative affective biases are often expressed as enhanced sensitivity to negative or threatening information (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007), and likely reflect compromised executive control of attention (Cisler et al., 2009) and impairment of the ability to inhibit prepotent responses and to resist interference to task-irrelevant distracters.

Negative attentional biases can be captured by tasks like the Affective Go/No-Go, in which participants are asked to respond to target stimuli and withhold from responding to distracter stimuli, while targets and distracters differ in affective valence. A negative affective bias can be detected by an increased speed and/or accuracy in participant responses when attending to negatively (vs. positively) valenced information (Schulz et al., 2007). This pattern is typically shown by patients with affective disorders, whereas the opposite pattern is typically shown by healthy participants (Erickson et al., 2005). Together, these results support the idea that negative biases in attention can be targeted to clarify potential links between impaired control mechanisms and affective disorders. Structural and functional imaging evidence has linked the IFC with performance in Go/No-Go tasks (Brown et al., 2015; Brown et al., 2012; Liddle, Kiehl, & Smith, 2001; Swick, Ashley, & Turken, 2008, 2011). Structural damage to the IFC is associated with higher error rates (Swick et al., 2008), and greater IFC activity has been seen in no-go trials (Liddle et al., 2001), particularly for negative emotional contexts (Brown et al., 2012), consistent with the idea that IFC helps to inhibit prepotent responses and is differentially engaged by emotional stimuli. Furthermore, the IFC responses to affective stimuli seem to be modulated by trait anxiety (Fales, Becerril, Luking, & Barch, 2010). More specifically, Fales et al. (2010) showed that higher anxiety was associated with greater activation within the left IFC in response to fearful (vs. neutral) targets, while lower anxiety was associated with greater activation to happy (vs. neutral) targets. Extending these previous findings, a recent study (Hu & Dolcos, 2017) showed that trait anxiety was negatively correlated with left IFC volume, and positively correlated with a negative bias in reaction time. Furthermore, trait anxiety mediated the negative association between the IFC volume and the negative bias measure, thus demonstrating that decreased volume in this brain region is linked to negative affective bias through anxiety.

Overall, extant evidence highlights the influence of negative affective bias in attention, and points to the IFC as a region both structurally and functionally associated with executive control. Available evidence shows that negative affective bias tends to be associated with enhanced sensitivity to negative or threatening information, possibly linked to compromised executive control of attention, and subserved by alterations of underlying brain mechanisms. In turn, negative affective bias plays a key role in understanding the neurophysiological substrates of well-being.

Self-Esteem is another important factor that has been shown to greatly predict well-being (Diener, 2009). Self-esteem typically refers to one's global attitudes about oneself (Rosenberg, 1965). Interestingly, evidence suggests that when happiness decreases, self-esteem decreases as well (Laxer, 1964; Wessman & Ricks, 1966), suggesting that the relation between these factors might be bidirectional (Diener, 2009).

At a neural level, self-esteem has been shown to be associated with both the structure and function of the brain. Structurally, self-esteem has been linked to greater HC volume, in both younger and older adults, suggesting a potential protective role against challenges such as stress (Pruessner et al., 2005). Self-esteem is also associated with the structural connections between regions, such as the white matter integrity between the mPFC and the ventral striatum (Chavez & Heatherton, 2015), consistent with the role of these brain regions in processing information about the self and positive affective processes such as reward, respectively. Functionally, self-esteem has been linked to modulation of brain activity both at rest and during tasks. Greater self-esteem was associated with greater resting state functional connectivity between the ventral mPFC and the HC (and between the cuneus/lingual gyrus and right dorsolateral PFC and ACC) (Pan et al., 2016), consistent with the idea that brain networks supporting self-referential, memory, and cognitive control-related processes support self-esteem. Furthermore, tasks involving social exclusion or social feedback have shown that self-esteem modulates the engagement of ACC and mPFC responses (Onoda et al., 2010; Somerville, Kelley, & Heatherton, 2010). For instance, individuals with lower self-

esteem relative to a high self-esteem group reported greater social pain in response to social exclusion, and had both greater response in ACC and greater connectivity between ACC and PFC (Onoda et al., 2010). These findings are consistent with the idea that self-esteem influences brain mechanisms engaged for interpretation of social signals and can lead to differential outcomes relevant to well-being.

Together, extant evidence suggests that self-esteem and the associated neural correlates influence factors of well-being. Self-esteem appears to be greatly linked to indices such as happiness, and is supported by both the structure and function of the brain. Hence, continuing research on these relations will refine and improve understanding and promotion of well-being.

Big 5 Traits. Yet another important aspect of understanding individual differences and the brain regions subserving well-being is the role of *general* personality factors. The link between the brain and well-being is complex, and might be better understood if individual differences in general personality traits are also taken into account. Personality is commonly studied using the Big 5 model, which includes the dimensions of extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience (Costa & McCrae, 1992). Whereas the Big 5 have been shown to be linked to measures of well-being, most findings focus on extraversion and neuroticism, which are also the focus of this review (for details about agreeableness, conscientiousness, and openness to experience, see DeNeve & Cooper, 1998; Gutierrez, Moreno-Jimenez, Garrosa, & Puente, 2005; Hayes & Joseph, 2003). Extraversion is typically defined as a trait reflecting sensitivity to reward and positive affect, whereas neuroticism generally encompasses sensitivity to punishment and negative affect. Extraversion is linked to indicators of increased well-being, such as positive affect (DeNeve & Cooper, 1998; Gutierrez et al., 2005), enhanced recall of positive memories (Mayo, 1983; Rusting, 1999) and maintaining a positive mood after retrieval of positive personal memories (Denkova, Dolcos, & Dolcos, 2012). In contrast, neuroticism is associated with indicators of decreased well-being, such as negative affect, reduced life satisfaction, reduced happiness, and a tendency to recall negative information (Bradley & Mogg, 1994; DeNeve & Cooper, 1998; Gutierrez et al., 2005).

Available evidence links extraversion and neuroticism to the structure and function of the brain. For example, extraversion is positively associated with the medial OFC (DeYoung et al., 2010). Neuroticism is negatively linked to AMY volume (Hu et al., *in press*), and positively linked to the volume of regions engaged by sensitivity to punishment, negative emotion, and emotional dysregulation (mid-cingulate gyrus and caudate) (DeYoung et al., 2010). These traits have also been linked to other structural aspects such as cortical thickness (Riccelli, Toschi, Nigro, Terracciano, & Passamonti, 2017), and the structural connections between brain regions (i.e., white matter) (Xu & Potenza, 2012), as well as to the function of the brain. For instance, resting state functional connectivity measures have shown that extraversion and neuroticism are differentially associated with activity in networks of brain regions while at rest (Adelstein et al., 2011; Sampaio, Soares, Coutinho, Sousa, & Goncalves, 2014), consistent with the idea that these traits are linked to regions engaged in processes such as emotion regulation, self-evaluation, and reward (Adelstein et al., 2011; Andrews-Hanna, Reidler, Sepulcre, Poulin, & Buckner, 2010). Moreover, extraversion and neuroticism influence brain responses, especially in the AMY and HC, during tasks that involve emotional learning (Haas & Canli, 2008; Hooker, Verosky, Miyakawa, Knight, & D'Esposito, 2008). Overall, the reviewed evidence highlights the role of general personality factors as possible targets for better understanding susceptibility, and improving resilience, against emotional disturbances.

Successful Aging, the Brain, and Well-Being

Healthy aging is generally associated with improved emotional functioning and well-being (Carstensen et al., 2011; Mather, 2012; Scheibe & Carstensen, 2010). Brain imaging findings parallel this behavioral evidence, suggesting that healthy aging is associated with relatively preserved structural integrity in regions typically involved in the processing and valuation of emotional information (AMY, mPFC), whereas it is associated with marked anatomical (Fjell et al., 2009; Raz, Ghisletta, Rodrigue, Kennedy, & Lindenberger, 2010; Raz et al., 2005) and physiological (Fabiani, 2012; Reuter-Lorenz & Park, 2014) losses in specific brain structures typically involved in executive control and emotion regulation (lateral PFC). Of note, given that the mPFC is also involved in some forms of emotion regulation (Roy, Shohamy, & Wager, 2012) and does not seem to show significant age-related cortical volume loss, it is possible that older adults may rely more on this structure in controlling their emotional responses (Mather, 2016).

In the context of overall preserved emotional functioning and well-being in aging, considerable evidence supports the idea of an age-related *positivity effect* in emotional perception, attention, and memory, by which older adults tend to pay greater attention to and remember more positive information (Charles, Mather, & Carstensen, 2003; Isaacowitz, Wadlinger, Goren, & Wilson, 2006; Knight et al., 2007; Mather & Carstensen, 2003) and show reduced processing of negative information (Grühn, Scheibe, &

Baltes, 2007; Wood & Kisley, 2006), compared to younger adults (see also Mather, 2016; Reed & Carstensen, 2012; Reed, Chan, & Mikels, 2014). In order to explain this age-related positivity effect and its impact on well-being, a few models of emotional aging have been proposed. According to the *Socioemotional Selectivity Theory* (SST; Carstensen, Fung, & Charles, 2003), older adults' preference for positive over negative information is driven in part by their prioritization of more present-focused motivational goals related to emotional meaning and satisfaction, which in turn enhances their well-being. The SST model interprets the positivity effect as a consequence of enhanced top-down modulation by the PFC/ACC influencing AMY response (Dolcos, Katsumi, & Dixon, 2014; St. Jacques, Dolcos, & Cabeza, 2010), thus emphasizing the role of motivational goals in emotion regulation (Carstensen et al., 2003). Another influential model called the *Aging Brain Model* (ABM; Cacioppo, Berntson, Bechara, Tranel, & Hawkley, 2011) interprets it as a consequence of impaired bottom-up processing of negative arousing stimuli by the AMY in older adults, considering that its response to positive stimuli may be relatively unimpaired by advancing age (Cacioppo et al., 2011). It is important to note, however, that there is evidence identifying activation of overlapping areas of the AMY between younger and older adults in processing negative stimuli (Dolcos et al., 2014; St. Jacques et al., 2010). Therefore, it is unlikely that the age-related reduction in AMY activity can be explained by impaired functioning of this region, as posited by the ABM.

In addition to reduced processing of negative stimuli, available evidence points to the link between enhanced processing of positive/rewarding stimuli and increased psychological well-being in aging. For instance, among a sample of middle-aged and older adults, those who showed sustained activity in the striatum, which is typically involved in the processing of various types of reward, over time in response to viewing positive pictures also reported overall greater levels of well-being (Heller et al., 2013). Moreover, striatal activation related to the viewing of positive stimuli mediated the relationship between well-being and daily levels of the stress hormone cortisol. In particular, greater levels of well-being were associated with increased activation in the striatum during positive picture processing, which in turn was associated with decreased levels of cortisol (Heller et al., 2013). Overall, these findings suggest that sustained engagement of the striatum in positive emotion processing is a key factor associated with well-being and adaptive regulation of stress necessary for maintaining health (see also Ryff, Heller, Schaefer, Van Reekum, & Davidson, 2016).

Taken together, these findings suggest that healthy aging is associated with an age-related positivity effect in emotion processing, as reflected in reduced processing of negative stimuli and enhanced processing of positive stimuli. This age-related positivity effect appears to be subserved by brain regions involved in basic/bottom-up processing (e.g., AMY, striatum) and those involved in higher-order/top-down processing and control (e.g., PFC, ACC) of emotional information. Successful engagement of these regions may in turn lead to improved subjective well-being in older adults.

Social Relationships, the Brain, and Well-Being

Humans are fundamentally a social species, sharing a strong need to interact with others. Social relationships can provide enjoyment and can feel rewarding (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004). They give people access to the benefits of shared resources, security, and social support (Baumeister & Leary, 1995), and have a protective role, being associated with a variety of positive outcomes ranging from lower rates of mortality (House, Landis, & Umberson, 1988) and increased survival from heart attacks (Seeman, 1996) to physical (Holt-Lunstad, Smith, & Layton, 2010) and mental/subjective well-being across the lifespan. On the flip side, however, the perceived absence of social relationships, or loneliness, makes people feel more unsafe and threatened in social contexts (Cacioppo et al., 2011; Cacioppo & Patrick, 2008), and is associated with increased risk of depression (Cacioppo, Hawkley, & Thisted, 2010; Cacioppo, Hughes, Waite, Hawkley, & Thisted, 2006) and other negative outcomes.

Interactions with others are so critical for our survival that we developed larger brains and complex neural networks to be able to understand other people and to predict their intentions. Interestingly, when at rest, the brain's pattern of activity looks very similar to when people are thinking about others, oneself, and the relation of oneself to other people (Mars et al., 2012). This has led some scientists to believe that "our brains are built to practice thinking about the social world and our place in it" (Lieberman, 2013). As such, it should not be surprising that a lack of interactions with the social world, and especially perceived loneliness, has deleterious effects on health through its effects on the brain (Cacioppo & Hawkley, 2009). The neural substrates supporting social cognition/behavior consist of many cortical and subcortical regions, each involved in several distinct processes. Most of the structures that we have talked about as being important in processing emotions and rewards are also important for social behavior. These include the AMY, the OFC, and the ventral striatum (especially the NAcc, caudate nucleus, and the putamen). Additional brain regions are also involved in social relationships. The next paragraphs review structural and

functional changes in the brain associated with the involvement in dyadic or more extended social relationships (i.e., love and social networks), and the perceived absence of social relationships (i.e., loneliness).

Love is a complex and rewarding mental state involving cognitive and goal-directed behavioral components (Bianchi-Demicheli, Grafton, & Ortigue, 2006). The different kinds of love (e.g., passionate, maternal) are important predictors of positive emotions, happiness, and satisfaction (Myers, 1992). Evidence indicates both common and dissociable circuits for different kinds of love (e.g., romantic vs. maternal). Functional brain imaging evidence (Bartels & Zeki, 2000; Bartels & Zeki, 2004) shows that all types of love engage subcortical dopaminergic reward-related brain systems (involving dopamine and oxytocin receptors), which play an important role in goal-directed motivation, reward, and pair-bonding (Ortigue, Bianchi-Demicheli, Patel, Frum, & Lewis, 2010). However, the different types of love also involve distinct neural networks inside and outside the dopaminergic network (Bartels & Zeki, 2004; Fisher, Aron, & Brown, 2005). For instance, passionate love engages the ventral tegmental area (part of the brain's reward circuit, associated with the motivation to pursue rewards) and the caudate nucleus (associated with reward detection and expectation). Maternal love recruits similar brain areas, with a specific involvement of the periaqueductal gray matter, an area that receives direct connections from the limbic emotional system, and contains a high density of receptors (vasopressin) that are important in maternal bonding and in pain suppression during intense emotional experiences like childbirth.

Interestingly, the presence of a loved one is not only rewarding, but it may act as a buffer against pain or stress. Showing female participants pictures of a loved male while receiving painful stimulation was associated with reduced reported pain intensity (Master et al., 2009), and such an analgesic effect correlated with activity in the reward-related NAcc (Younger, Aron, Parke, Chatterjee, & Mackey, 2010). Holding a partner's hand, relative to holding the hand of a stranger or squeezing a ball, produced similar effects (Master et al., 2009). Moreover, love also reduces critical social assessment of others. For instance, when people look at their loved partners, the neural circuits that are normally associated with critical social assessment (AMY, temporo-parietal junction, and mPFC) of other people are suppressed, whereas regions involved in reward and attachment (caudate nucleus, putamen, medial insula, ACC) are activated (Bartels & Zeki, 2000). In sum, love facilitates positive emotions, by connecting the NAcc with the PFC, and reduces negative emotions, such as social judgment, by connecting the NAcc to the AMY.

Loneliness has been linked to a number of psychological states that contribute to morbidity and mortality, including increased depression (Booth, 2000; Cacioppo et al., 2010; VanderWeele, Hawkley, Thisted, & Cacioppo, 2011) and lower subjective well-being (Kong, Zhao, & You, 2013; VanderWeele, Hawkley, & Cacioppo, 2012). Loneliness also influences individuals' perception and appraisal of the world. There is behavioral and neural evidence that loneliness increases attention to potential threats from the social world (Cacioppo & Hawkley, 2009), and is associated with increased worry about being evaluated negatively, as well as with higher levels of perceived threat in social situations (even when there is no increased likelihood of being rejected; Jones, Freemon, & Goswick, 1981). Lonely people also tend to feel more unsafe, compared to non-lonely people. They tend to appraise other individuals as more threatening, and to isolate themselves when confronted with stressors, rather than actively looking for the help and support of others (Berscheid & Reis, 1998; Cacioppo & Hawkley, 2005).

Loneliness involves multiple brain mechanisms, and produces significant changes in both brain structure and function. Recent structural brain imaging studies have identified relationships between loneliness and the density of gray and white matter in different regions of the brain. Loneliness was negatively correlated with the gray matter density in the left posterior superior temporal sulcus (pSTS), an area involved in processing biological motion and social perception (Kanai et al., 2012); the pSTS size was also related to poorer performance in a social perception task. Loneliness has also been associated with widespread reduction in white matter density in areas related to self- and social-cognition (bilateral inferior parietal lobe, the right anterior insula, and left posterior temporo-parietal junction), as well as areas associated with empathy (the left pSTS and right lateral PFC) and self-efficacy (dorsomedial PFC) (Nakagawa et al., 2015). In addition to these structural changes, neuroimaging evidence also reveals functional changes associated with perceived loneliness in a number of brain regions involved in the detection of threat (AMY, ACC, the ventrolateral PFC, and the insula; Cacioppo et al., 2013; Eisenberger & Lieberman, 2005; Eisenberger, Lieberman, & Williams, 2003), and managing the demands of complex social contexts (OFC, mPFC, STS, temporo-parietal junction; Bickart, Hollenbeck, Barrett, & Dickerson, 2012; Cacioppo, Norris, Decety, Monteleone, & Nusbaum, 2009; Cacioppo et al., 2016; Eisenberger & Cole, 2012; Klumpp, Angstadt, & Phan, 2012).

Overall, the evidence reviewed in this section illustrates the essential role of social relationships for our happiness and well-being. Our brains are wired to be social, and this wiring of our brains motivates us to engage in relationships with others, which in turn, increases positive emotions, enjoyment, and feelings

of reward. The fact that by simply enhancing social connections in our everyday lives we can enhance our well-being highlights the need to develop interventions focused on educating the social brain.

Enhancing Well-Being through Brain Building Interventions

The brain is a dynamic system, which responds to environmental demands and generates goals and actions, and hence its anatomical structure and physiology continuously change throughout our life. This ability to physically change and to maintain this change is known as *neuroplasticity*. Neuroplasticity has fascinating implications for our well-being! A growing body of evidence suggests that neuroplasticity is associated with variations in brain activity, which might come from experience (May, 2011), training/learning (Draganski & May, 2008), clinical status (Cahn et al., 2002), or injury (Sidaros et al., 2009). Plasticity allows our brains incredible flexibility, and evidence shows that our experiences can make real changes in the structure and function of our brains. This means that we have the power to change our brains for the better. Although the mechanisms underlying neuroplasticity are still an area of active research, it may describe a result of Hebbian learning, which posits that repeated patterns of neuronal firing lead to increased synaptic connectivity (Hebb, 1949), and suggests that these alterations might lead to changes in brain structure, such as gray matter volume (Boyke, Driemeyer, Gaser, Buchel, & May, 2008; Draganski et al., 2004; Draganski et al., 2006) and white matter connections between brain regions (Tang, Lu, Fan, Yang, & Posner, 2012), as well as brain function (Dayan & Cohen, 2011). Notably, extant evidence points to the possibility that interventions can be performed to improve well-being and the underlying structure and function of the brain (Davidson & McEwen, 2012). This idea has led to new and emerging research targeting different forms of training interventions to improve well-being and the brain. Areas in this domain include physical training and mindfulness training.

Physical Activity, the Brain, and Well-Being

Physical activity has been consistently associated with profound benefits for brain structure and function, and overall well-being. Engaging in physical activity might be enjoyable, and is associated with increased positive mood (Steptoe, Kimbell, & Basford, 1998; Yeung, 1996) and decreased negative mood (McIntyre, Watson, & Cunningham, 1990; Raglin & Wilson, 1996; Steptoe, Kearsley, & Walters, 1993). More important than these transient effects on mood are the more enduring effects of physical exercise, reflected in reduced stress and symptoms of anxiety and depression (Blumenthal et al., 2007; Silveira et al., 2013), prevention of the onset of depression (Schuch et al., 2016), and overall improved well-being (Penedo & Dahn, 2005). How is physical activity relieving the detrimental effects of stress and improving mood and well-being? Physical exercise changes the way the brain processes the information, and even more importantly, it changes the brain, having a positive effect on the structure and function of a number of brain regions (Foster, 2015), including the HC and the PFC. Although the exact mechanisms underlying the beneficial effects of physical activity on the human brain and well-being are not clear, extant research attributes these advantageous effects to a number of factors, including changes in neurotransmitters and neurogenesis – that is, the capability to recruit, in some specific areas of the adult brain, more neurons, showing cellular and synaptic plasticity abilities (Garcia-Segura, 2009). We will review these effects in turn below.

A possible neurobiological mechanism underlying these beneficial effects of exercise is the increased synthesis and release of neurotransmitters and neurotrophins, which could result in neurogenesis and neuroplasticity (Dishman et al., 2006). A critical mechanism involved in depression seems to be the depletion of a category of neurotransmitters called monoamines, including serotonin and norepinephrine (López-Muñoz & Alamo, 2009). Animal models provide evidence that, similar to the effects of antidepressants, regular aerobic exercise increases serotonergic and noradrenergic levels in the brain (Chaouloff, 1989; de Coverley Veale, 1987; Meeusen & De Meirleir, 1995; Van Praag, 1982). For instance, treadmill training and wheel running have been linked to increased levels of norepinephrine in the HC and frontal cortex in rodents (Dishman, 1997; Dunn, Reigle, Youngstedt, Armstrong, & Dishman, 1996). Exercise has also been associated with increases in the synthesis of serotonin (Chaouloff, 1997; Dunn & Dishman, 1991; Meeusen & De Meirleir, 1995; Wilson & Marsden, 1996).

Accumulating evidence shows that physical exercise has a strong influence on inducing neuroplasticity (Voss et al., 2013), increasing the levels of the brain derived neurotrophic factor (BDNF). Research in rodents has shown that 20 days of voluntary wheel running increased BDNF levels in the HC and caudal neocortex (Meeusen & De Meirleir, 1995; Russo-Neustadt, Beard, & Cotman, 1999). The increase in BDNF increases functioning in the serotonergic system and may promote neuronal growth. Research in humans confirms the beneficial effects of physical exercise on neurogenesis. A 3-month fitness training (Pereira et al., 2007) study in a small group of middle-aged participants showed increases in measures of cerebral blood volume (CBV) in a region of the HC (i.e., the dentate gyrus). The location of the CBV changes in the dentate gyrus is interesting, given that previous animal evidence has shown

neurogenesis in these very specific regions.

Physical activity interventions have also been shown to have positive effects in children, producing changes in brain structure and function. Research shows that more active children have greater HC volume (Chaddock, Erickson, Prakash, Kim, et al., 2010), along with greater basal ganglia volume (Chaddock, Erickson, Prakash, VanPatter, et al., 2010), and greater white matter integrity (Schaeffer et al., 2014). In addition, they show increased and more efficient patterns of brain activity (Voss, Nagamatsu, Liu-Ambrose, & Kramer, 2011), and superior executive and cognitive control performance (Chaddock et al., 2012; Davis et al., 2011; Hillman et al., 2014).

Most studies on the effects of exercise in humans have been done in the elderly. These studies have demonstrated that exercise improves older adults' cognitive abilities in various domains (and the associated neural mechanisms), or more directly, subjective well-being (reviewed in Bamidis et al., 2014; Gajewski & Falkenstein, 2016; Hillman, Erickson, & Kramer, 2008; Kramer & Erickson, 2007). Greater physical activity and cardiorespiratory fitness have been associated with reduced age-related cognitive declines and a lower risk for dementia in older adults (Buchman et al., 2012; Sofi et al., 2011). Furthermore, mounting evidence suggests that aerobic exercise interventions, such as those involving walking or dancing, lead to enhanced cognitive abilities and subjective well-being in older adults (Awick et al., 2017; Awick et al., 2015; Colcombe & Kramer, 2003; Kattenstroth, Kalisch, Holt, Tegenthoff, & Dinse, 2013; Netz, Wu, Becker, & Tenenbaum, 2005). Recent brain imaging studies in this population have shown that physical exercise induces both structural and functional changes in a variety of brain regions. For instance, weekly aerobic walking was associated with increased volume of the anterior HC in older adults, which was in turn positively associated with improvements in spatial memory performance due to exercise (Erickson et al., 2011). Similar beneficial effects of exercise have also been identified with respect to neural functioning. In particular, older adults who had undergone aerobic training for six months showed increased activity in the lateral PFC and parietal cortex and decreased activity in the ACC during a challenging task involving conflict resolution and selective attention; these participants also showed improvements in behavioral performance on the task (Colcombe et al., 2004). Overall, these findings suggest that exercise interventions can enhance the ability of the aging brain to effectively allocate neural resources, which in turn leads to improved performance on a cognitively challenging task (see also Voss et al., 2011).

In summary, exercise has beneficial effects by increasing the production of neurotransmitters such as serotonin and noradrenaline, by stimulating the growth factor and blood flow, and by stimulating adult neurogenesis.

Mindfulness Training, the Brain, and Well-Being

In recent years, there has been growing interest in the use of mindfulness-based training and intervention programs to improve well-being and to identify the underlying brain mechanisms associated with such improvements (Chiesa & Serretti, 2010; Fox et al., 2014; Gotink, Meijboom, Vernooij, Smits, & Hunink, 2016; Lomas, Ivtzan, & Fu, 2015). Mindfulness generally refers to "the awareness that emerges through paying attention on purpose, in the present moment, and non-judgmentally to the unfolding of experience moment by moment" (Kabat-Zinn, 2003). Training programs focusing on mindfulness typically target skills aimed at reducing distressing symptoms, including those associated with psychological disorders and somatic conditions.

Behaviorally, mindfulness training tends to mediate improved indices of well-being, such as decreased stress, rumination, and trait anxiety, as well as increased positive states of mind, psychological well-being, quality of life, and self-compassion (Branstrom, Kvillemo, Brandberg, & Moskowitz, 2010; Carmody & Baer, 2008; Nyklicek & Kuijpers, 2008; Shapiro, Brown, & Biegel, 2007; reviewed in Visted, Vollestad, Nielsen, & Nielsen, 2015). Notably, mindfulness training has been targeted in many different populations. For example, mindfulness interventions have been tested in healthy and clinical populations (Chiesa & Serretti, 2010; Fox et al., 2014; Gotink et al., 2016; Lomas et al., 2015), including groups with psychological conditions such as anxiety (Vollestad, Nielsen, & Nielsen, 2012; Vollestad, Sivertsen, & Nielsen, 2011) and depression (Jain, Walsh, Eisendrath, Christensen, & Cahn, 2015; Kuyken et al., 2016; van der Velden et al., 2015). Mindfulness-based interventions have also been tested in different age groups, such as children and adolescents (Kallapiran, Koo, Kirubakaran, & Hancock, 2015), young and middle-aged adults (Fox et al., 2014), and older adults (Ehrenbrusthoff, Ryan, Schofield, & Martin, 2012). Although there is much heterogeneity of the practices and goals of mindfulness interventions when applied to these various groups, available evidence generally points to improvement in intervention outcomes (Quaglia, Braun, Freeman, McDaniel, & Brown, 2016; Visted et al., 2015).

At a neural level, mindfulness interventions have been shown to induce changes in both the structure and function of the brain. Structural studies have associated mindfulness training with increased gray matter volume or density in the cingulate cortex (Hölzel et al., 2011), insula (Murakami et al., 2012),

and HC (Hölzel et al., 2011). Evidence for structural changes in the AMY seems a bit less clear (Hölzel et al., 2010; Murakami et al., 2012; Pickut et al., 2013), and is perhaps influenced by other factors such as sample demographics. However, overall, available evidence appears consistent with the idea that mindfulness engages brain regions that are key for body awareness, memory, and emotion (Fox et al., 2014). Mindfulness and meditation practice have also been associated with modulation of structural connectivity between brain regions. For example, meditation practice has been linked to changes suggesting enhanced connectivity within and between hemispheres of the brain (Luders et al., 2012; Tang et al., 2010), which is consistent with the idea that mindfulness and meditation training can improve the underlying connections in the brain that support attentional self-regulation processes (Luders et al., 2012). At the functional level, mindfulness training was associated with changes in the resting state functional connectivity between the so-called default mode and salience networks (Doll, Hölzel, Boucard, Wohlschläger, & Sorg, 2015), consistent with the idea that interactions between brain networks support the ability to attend to current experience without judgment. Moreover, mindfulness training appears to also influence brain responses when engaged in tasks, such as paradigms that involve responding to, or regulating response to, emotional stimuli. A study by Creswell and colleagues (2007), for example, showed that when labeling emotions, the AMY was negatively associated with lateral PFC activation in more mindful individuals. This evidence seems consistent with the idea that mindfulness training modulates the neural mechanisms involved in emotional processes.

Although how mindfulness interventions alter brain structure is still an open question that is being investigated, a number of possible mechanisms have been proposed (reviewed in Tang, Hölzel, & Posner, 2015). An account referred to as "use-dependent plasticity" (Bütefisch et al., 2000; Kleim et al., 2002; Kleim, Barbay, & Nudo, 1998; Nudo, Milliken, Jenkins, & Merzenich, 1996; for reviews of relevant studies in humans see Draganski & May, 2008; May, 2011) suggests that there is a relation between the structure of the brain and its level of use. This account may describe a result of Hebbian learning as mentioned above (Hebb, 1949), and suggests that these structural changes might lead to alteration in brain structure (Draganski et al., 2006). Consistent with the Hebbian learning model, it is possible that repeated engagement in mindfulness affects brain structure through expansions of existing synapses and dendrites, or creation of new synapses. It is also possible that engaging in mindfulness induces the formation of new neurons or myelin sheaths that help insulate the connections between neurons. Another possibility is that mindfulness influences autonomic and immune activity, which might help preserve or restore neurons. Alterations in these mechanisms at the level of brain cells might contribute to overall changes in the volume of brain regions and the integrity of the connections between them.

In sum, extant evidence on mindfulness training and the brain suggests that mindfulness interventions can enhance well-being, and modulate the structure and function of the brain. Available evidence highlights the benefits of mindfulness training, and further research in this area will continue to refine understanding of the effective practices and underlying neural mechanisms, in order to better promote well-being.

Conclusion

Taken together, the diverse body of neuroscientific evidence reviewed in this chapter reveals that factors known to play critical roles in well-being, such as personality traits, age, and social relationships, are influenced by subtle differences in the volume, function, and connectivity of a network of emotion- and reward-related regions. Our mind is highly plastic, and what we think, feel, and do changes the physical structure of the brain, and the function of different brain circuits. Given that the brain circuits supporting positive emotions and rewards are remarkably malleable, we have the amazing ability to reshape our brains, to change our affective mindsets, and to improve our well-being. One way to enhance well-being is to address the rising tide of chronic stress, anxiety, and depression, conditions that have negative impacts on the life and well-being of an increasing number of people worldwide. Another way is to engage in activities that have positive impacts on our minds and bodies. Being physically active and engaging in mindfulness meditation are known to produce many physiological changes in our body, but they can also produce striking changes in the structure, function, and communication between the brain regions supporting well-being, helping us to lead happier and healthier lives. This suggests that well-being might be enhanced through training. Future research is needed to tap further into the enormous potential benefits of these training activities and to determine whether such training can produce changes with long-lasting consequences.

Endnotes

[1]It is important to consider the distinction between cortices and gyri when discussing neural correlates. Anatomically, cortex usually refers to gray matter in particular, while gyrus might refer to both gray and white matter. Depending on the goal of a study, the focus might be specifically on the gray matter of a

particular region, in which case it is referred to as cortex (e.g., inferior frontal cortex, IFC), or the focus might be on a region of interest that does not distinguish between gray and white matter, and thus it is referred to as gyrus (e.g., inferior frontal gyrus, IFG). Hence, in the text and Figure 1 both cortical and gyral terms appear.

[2]Current brain imaging techniques allow noninvasive mapping of the anatomical and functional connections among distant brain regions. Structural connectivity refers to the "integrity" of the anatomical connections linking sets of neuronal elements. These connections refer to the white matter fibers linking different areas of the brain, and are often measured using a special magnetic resonance imaging approach called diffusion tensor imaging, or DTI. Functional connectivity evaluates the interconnections between spatially separated brain regions that occur at rest (resting state functional connectivity), or when a subject is performing an explicit task.

Abstract

Typically, when we experience stress, our physiological and social resources allow us to regulate and adapt effectively, which tends to prevent maladaptive outcomes associated with those experiences. A complex network of stress response systems maintains physiological and behavioral allostasis, or stability through change in their activity. The social relationships we have, particularly those with attachment figures, allow us to maintain this balance even if the stress would otherwise be outside our regulatory capacity. This is particularly critical early in life when we cannot regulate on our own. When these social relationships are absent, inconsistent, or of low quality, chronic activation of stress response systems can result in dysregulated stress reactivity and regulation. This puts children at increased risk for poor physiological and psychological outcomes and overall lower well-being across the life span.

Keywords: Stress Response, Physiology, Social Relationships, Regulation, Development

The experience of stress is a normal part of life. Therefore, humans possess mechanisms both "under the skin" and in the environment that function to support processing, responding to, and recovering from stressors while preserving physical and psychological well-being. During development, these stress systems are adapted to our individual context based on personal characteristics, early experiences, and social relationships. When faced with chronic stressors, the body makes continuous adjustments that may come at a cost to future well-being. When stressors become too intense or overwhelming, or when one of these mechanisms breaks down and can no longer function properly, there can be detrimental effects on physiological, behavioral, and emotional health. Up to a point, it is not the presence of stressors in your life, but the capacity to regulate reactions to them, that influences their impact on physical and psychological well-being. These impacts vary over time as the stress systems develop from infancy into adulthood.

Throughout this chapter, the 'stress response' is defined as the body's network of physiological and behavioral processes that are activated in order to restore homeostasis following an encounter with a real or imagined threat to our well-being. Stress responses are moderated by actual and/or perceived controllability and predictability of the stressor, the presence of social support, and the extent to which the stressor threatens physiological or behavioral stability (Koolhaas et al., 2011). It is important to note that stress is neither always negative nor does it always have negative consequences. Stressors within the regulatory capacity of the individual that result in moderate activation of stress response systems can actually aid in learning (Lucas, Chen, & Richter-Levin, 2013). We experience stress at all stages of life, for example after separation from a caregiver, when there is a physical or emotional threat to the self, or during the anticipation of social evaluation. By mobilizing available physiological and social resources when necessary, humans have an incredible capacity to regulate in response to stress. In fact, even in the face of severe, chronic stress, a sizable portion of individuals show resilient functioning. This may be due in large part to the buffering effect of stable, high-quality caregiving and social relationships.

Physiological Building Blocks of Well-being

There is a complex array of physiological systems involved in the stress response. This neuro-symphony of stress mobilizes particular resources in order to deal with stressors. While these systems work in concert, they do not all respond the same way to the same stressors. Perhaps the most critical, and most frequently studied, system involved in the stress response is the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis response begins in the paraventricular nuclei (PVN) of the hypothalamus, a brain region that is a central regulator of a wide range of homeostatic, autonomic and neuroendocrine processes. Multiple neural signals regulate the activity of these PVN neurons according to signals from higher brain regions, including the amygdala, hippocampus and prefrontal cortex (PFC; Ulrich-Lai & Herman, 2009). The hypothalamus secretes corticotropin-releasing hormone (CRH) which activates the anterior pituitary to secrete adrenocorticotropic hormone (ACTH) into the bloodstream. ACTH travels to the adrenal cortex, which sends the HPA axis end-product cortisol throughout the body (Charmandari, Tsigos, & Chrousos, 2005). Circulating cortisol binds to its receptors that reside in most cells, facilitating its wide-ranging influence on multiple systems. Once bound to its receptor, this glucocorticoid hormone is transported to the

cell nucleus where it regulates protein synthesis for various genes. Peak cortisol levels are achieved 20-40 minutes after activation of the system. Cortisol operates by regulating the transcription of genes into protein, processes that take minutes to hours to be achieved and whose effects may last days (Kirschbaum & Hellhammer, 1994). The HPA axis is reliably activated by psychosocial stressors, but not necessarily to stimuli like exercise, which results in non-social homeostatic disruption (Ulrich-Lai & Herman, 2009).

Circulating cortisol is regulated by its own negative feedback loop, reducing activity at all levels of the HPA axis, to prevent excess amounts of cortisol that may have detrimental effects on physical and mental health (Chrousos, 2009). However, in the context of severe, prolonged stressors, activating signals override negative feedback and elevated levels of cortisol continue which may result in poorer well-being (Strüber, Strüber, & Roth, 2014). Even in healthy individuals, increases in cortisol production seen approximately 30 minutes following wake-up (cortisol awakening response), have been negatively associated with trait well-being when they get too large (Smyth et al., 2015). In some cases, after a long period of elevated cortisol, negative feedback mechanisms can overcompensate and result in lower than normal cortisol production (i.e. hypocortisolism), which is also associated with poorer health and behavior outcomes (Fries, Hesse, Hellhammer, & Hellhammer, 2005; Strüber et al., 2014).

The effects of the HPA axis are generally slow and long lasting. In contrast, the sympathetic-adrenomedullary (SAM) system responds rapidly and supports fight/flight. This system is a component of the sympathetic nervous system (SNS) and is more reliably activated by any (internal or external) environmental stimulus that disrupts the body's physiological homeostatic balance and, to a lesser extent, psychosocial stressors (Ulrich-Lai & Herman, 2009). The SAM system involves innervation of chromaffin tissue in the adrenal medulla via the splanchnic nerve, which then releases epinephrine (Epi) and some norepinephrine (NE) into circulation to act on systems throughout the body (Gunnar & Quevedo, 2007). SAM activity amplifies the effect of the SNS which releases NE at synapses on many of the same target organs (e.g. heart, lungs, pupils, blood vessels; Charmandari et al., 2005; Gunnar & Quevedo, 2007). In a matter of seconds, heart rate and respiration increase to prepare the body for an immediate stress response.

The SNS is also influenced by the opposing branch of the autonomic nervous system, the parasympathetic nervous system (PNS), which operates synergistically with the SNS and promotes 'rest and repair' functions like digestion and bodily maintenance. Typically, the PNS suppresses or inhibits the activity of organs involved in fight/flight, for example causing the heart to beat slower, or the pupils to be less dilated. Upon detection of a stressor, the PNS usually releases its influence (i.e., 'lifting the vagal brake'), allowing organs under tonic inhibition (e.g., the heart) to rapidly increase their activity. This is enhanced seconds later as the actions of the SNS take effect, resulting in large increases in heart rate and blood pressure (Porges, 2007). Epi and the CRH produced outside of the hypothalamus act as positive feedback mechanisms for the SNS (Chrousos, 2009); however, PNS activation dampens the effects of SNS activity and returns the body to its resting state (Quas et al., 2014). In the context of chronic stress, the SNS tends to be hyperreactive, and autonomic regulation shifts away from balanced activation of SNS and PNS to an SNS-dominant system (Del Giudice, Ellis, & Shirtcliff, 2011).

These peripheral systems have upstream influences by widespread brain regions involved in detecting and responding to real or imagined threats in the environment. The HPA axis is regulated by CRH released by the hypothalamus, which is in turn regulated by the PFC, hippocampus, and amygdala (McEwen, 2007; Ulrich-Lai & Herman, 2009). Given that the hypothalamus also plays a role in autonomic functioning (Porges, 2007), neural regulation of the hypothalamus can have wide-ranging effects on the stress response. Generally, the medial PFC and hippocampus have inhibitory effects on the hypothalamus and are involved in the reduction or termination of the stress response (Ulrich-Lai & Herman, 2009), while the amygdala has excitatory effects (McEwen, 2007). Cortisol alters the activity of the structures that regulate its own production and, in doing so, alters thresholds for perceiving and responding to threat. Large and/or chronic increases in cortisol reduce hippocampal and medial PFC functioning, weakening their ability to terminate the HPA axis stress response and inhibiting learning and memory. Chronic cortisol production also increases the activity of the amygdala, which may lower the threshold for responding to threats and increase HPA axis activation (McEwen, 2007; Ulrich-Lai & Herman, 2009). All of these consequences may result in impaired well-being across domains (Davidson & McEwen, 2012).

There are a number of hormones and neuropeptides that are neuromodulators of stress, beyond CRH and NE. Oxytocin tends to reduce the HPA stress response, potentially through reduced expression of hypothalamic CRH (Jurek et al., 2015; Zheng et al., 2010). CRH produced in the central nucleus of the amygdala has widespread influence on neural systems that orchestrate fear responses and fear learning (Gafford & Ressler, 2015). Serotonin has been shown to reduce the sensitivity of the adrenal cortex to ACTH (Chen & Miller, 2012). Similarly, direct activation of serotonin receptors (5-HT_{1A}) in the rat hypothalamus reduces the amount of corticosterone (the rodent equivalent of cortisol) produced in response

to restraint stress, a common rodent stressor that involves extended immobilization and restricted limb movement (Stamper et al., 2017). Additionally, serotonin transporters in the adrenal medulla function to reduce the SAM response in rats (Brindley, Bauer, Blakely, & Currie, 2017). These patterns may partially explain why selective-serotonin reuptake inhibitors are a common treatment for anxiety and depression (Hirschfeld, 2001). Dopamine may also be a critical modulator of the stress response. When activated, CRH receptors in the ventral tegmental area release dopamine throughout the brain (Wanat, Hopf, Stuber, Phillips, & Bonci, 2008). The ventral tegmental area has bidirectional connections with the PFC, and increased levels of circulating dopamine produced by the nucleus accumbens are seen following acute (i.e., short-lived) stressors. However, exposure to chronic stress in infancy has been found to downregulate dopamine expression (Gatzke-Kopp, 2011). Additionally, rats exposed to restraint stress showed an increase in prefrontal NE followed by an increase in dopamine in the nucleus accumbens and PFC that does not occur in the absence of increased NE (Pascucci, Ventura, Latagliata, Cabib, & Puglisi-Allegra, 2007).

Coordination Between Stress Systems

Clearly, these systems are highly interdependent and each system responds based on activity of other systems. Additionally, genes influence the rate and amount of production of neuromodulators, their receptors, and other molecules involved in the transmission of neural signals (Charmandari et al., 2005). Every person has two copies of each gene (termed 'alleles') that may be identical to or different from each other and those of another person. Particular alleles influence stress system regulation; for example, alleles of the glucocorticoid receptor gene *NR3C1* confer differential sensitivity to HPA axis negative feedback (McEwen, 2007). Similarly, allelic variation impacts psychiatric outcomes associated with these stress systems; for example, an allele of the monoamine oxidase A (*MAOA*) gene that produces inefficient MAOA functioning increases the risk for antisocial behavior following abuse (Caspi et al., 2002).

While the genes a person possesses are permanent, the capacity of genes in a specific cell to be transcribed into protein (i.e., gene expression) is subject to change via numerous processes, including epigenetic modifications. Epigenetic modifications are alterations to chromatin structure that do not change the DNA sequence, but still can influence gene expression. Chromatin is comprised of the genes and their packaging proteins (called 'histones'). The more tightly the histones "package" the genes, which is influenced by epigenetic modifications, the less likely that gene will be transcribed into protein. These modifications are a key mechanism through which the environment and experiences produce lasting changes on gene function (Boyce & Kobor, 2015). Rodent studies have found that epigenetic alterations of the glucocorticoid receptor gene, *NR3C1,* are a function of the quality of early maternal care, and mediates early care's impact on stress responsivity in adulthood (Zannas & West, 2014). In humans, epigenetic processes are mechanisms through which children who have experienced maltreatment are at higher risk for various types of psychopathology (Lutz & Turecki, 2014). While epigenetic changes can be long-lasting and even transgenerational, they can also be reversible (Boyce & Kobor, 2015). This is promising for the success of interventions and treatment following adverse early experiences.

Although there is a wide range of stress systems and neuromodulators that allow the body to respond to diverse challenges, they tend to overlap in their functions (Joëls & Baram, 2009). There is extensive cross-talk and coordination between systems, such that each system cannot truly be understood except in the context of the rest. Countless studies have explored the link between HPA and sympathetic activity in rodents, primates, and humans (for a review, see Schumacher, Kirschbaum, Fydrich, & Ströhle, 2013). Petrullo et al. (2016) found attenuated cortisol reactivity, but unchanged salivary a-amylase reactivity (a peripheral marker of SNS activity), in juvenile rhesus macaques exposed to maternal abuse. Gordis and colleagues (2006) found that attenuated cortisol reactivity was associated with increased aggressive behavior in the context of lower, but not higher, a-amylase reactivity. Thus, it seems that attenuated cortisol reactivity is associated with aggression; however, it is still unclear whether and how SNS activity plays a role in this association. More research into the biological mechanisms underlying these associations is also needed to investigate whether this is a causal relationship. Coordination between these systems may also be associated with subjective stress and anxiety when discussing a conflict with a romantic partner (Laurent, Powers, & Granger, 2013). Other studies have explored SNS/PNS activity patterns (Blechert, Michael, Grossman, Lajtman, & Wilhelm, 2007; Winzeler et al., 2016), and their relation to HPA activity (Quas et al., 2014). El-Sheikh and Erath (2011) found that coactivation or coinhibition of the SNS and PNS, diverging from their typical asymmetry, presents greater susceptibility to externalizing problems for children experiencing marital conflict. Rash et al. (2016) suggest that maternal stress response profiles of HPA, SNS, and PNS activity may predict their child's dysregulation of the same systems. They propose that children with asymmetrical SNS/PNS activity and SNS/HPA activity are at the lowest risk for behavioral problems and psychological well-being.

With the emergence of cross-system research, some have put forth theories that include activity of multiple systems (Del Giudice et al., 2011; Joëls & Baram, 2009; Korte, Koolhaas, Wingfield, & McEwen,

2005; Porges, 2007). However, many questions remain unanswered. These systems operate on different time scales, and thus it is difficult to assess multiple systems within the same study. Similarly, while we are often interested in brain activation of these systems, practical and technological limitations sometimes force us to measure peripheral endpoints in blood, saliva, or activity of downstream systems (i.e. heart rate, skin conductance). These measures may only be modestly correlated with activity of the brain regions orchestrating the stress response. Moreover, responses are highly context-dependent and small manipulations such as the presence of a caregiver can alter the stress response (Conner et al., 2012). Finally, many studies have sought to find linear relationships between stress response systems. However, some systems, the HPA axis in particular, have non-linear relationships with well-being, such that both too much and too little activity are associated with poor outcomes (Chrousos, 2009). There is also reason to believe that relationships between stress systems are non-linear. Future studies should address the coordination between multiple systems using the most direct measures as possible, and acknowledge that their interactions are likely complex and non-linear.

Developmental Processes in Well-being

In addition to interrelations between stress systems, there are many changes occurring with development. Again, the most studied stress system in this regard is the HPA axis. Beginning in the prenatal period, a child's HPA axis develops in the context of the mother's cortisol production which impacts activity in the placenta (Gunnar, Doom, & Esposito, 2015). While the majority of the mother's cortisol is broken down by the enzyme 11b-HSD2, some cortisol still reaches the fetus intact and this prenatal exposure may influence the child's future HPA axis regulation (Oberlander et al., 2008). Moreover, maternal cortisol stimulates the placenta to produce CRH which may activate the fetus' own HPA axis. Infants exposed to higher levels of cortisol *in utero* were less able to mount a sufficient cortisol response to the Strange Situation, a maternal separation stressor paradigm, which may signify that fetal programming of the HPA axis can have maladaptive effects on later stress regulation (O'Connor, Bergman, Sarkar, & Glover, 2013). In the first few months after birth, infants typically start to develop a stable diurnal rhythm. During the preschool period, with the end of regular daily naps, this rhythm starts to resemble an adult-like pattern (Gunnar & Quevedo, 2007). There is some evidence to suggest that the cortisol awakening response tends to increase across the entire lifespan (Miller et al., 2016).

The other stress response systems have much less research delineating normative developmental changes. There is some evidence that heart rate, a measure of SNS activity, decreases with age and vagal tone, a measure of PNS activity, increases with age (Alkon et al., 2003; Gunnar & Quevedo, 2007). An increase in PNS activity may be associated with the development of emotion regulation, via the increased ability to modulate physiological and behavioral responses to a stimulus (Gunnar & Quevedo, 2007). Neuromodulators like serotonin are present at relatively high levels very early in fetal development, and during this period serve as neurotrophic (i.e., nerve growth) factors that stimulate brain development. Serotonin levels remain high for the first two years of life before gradually declining in childhood (Whitaker-Azimitia, 2001). Further research should address developmental changes in all stress response systems and their interactions in more detail.

The normative development of stress regulatory systems may vary by sex. These differences, particularly in the HPA axis, tend not to be present until puberty (Doom & Gunnar, 2013). When differences are found, males tend to have lower diurnal cortisol levels compared to females of the same age (Miller et al., 2016). With puberty, differences in gonadal hormone production tends to facilitate differential neural and HPA axis regulation (Del Giudice et al., 2011; Ordaz & Luna, 2012). Adolescent females begin to have larger cortisol awakening responses that peak at 45, rather than 30, minutes following wake-up (Schlotz, Hellhammer, Schulz, & Stone, 2004). Males begin to react to stressors more strongly than females, however not all studies have found these sex differences (Doom, Hostinar, VanZomeren-Dohm, & Gunnar, 2015; Ordaz & Luna, 2012). This inconsistency may depend on the type of stressor (e.g. social evaluation, pain, performance, Del Giudice et al., 2011). Studies assessing sex differences in autonomic reactivity have not always shown consistent effects either (Kelly, Tyrka, Anderson, Price, & Carpenter, 2008); however, some studies have found that females tend to have increased autonomic reactivity (Ordaz & Luna, 2012). Cortisol reactivity patterns may be a mechanism through which females, particularly adolescents, are at heightened risk for depression and anxiety, however the direction of these effects has been inconsistent (Natsuaki et al., 2009; Powers, Laurent, Gunlicks-Stoessel, Balaban, & Bent, 2016). For males, on the other hand, suppressed HPA and autonomic reactivity may be associated with substance abuse (Fox et al., 2009).

Temperament is associated with stress regulation and reactivity and affects how children respond to stressors. Temperamental fearfulness is associated with increased HPA axis activity to unavoidable social challenges in non-human primates and preschool children (Kalin, Shelton, & Davidson, 2000; Talge, Donzella, & Gunnar, 2008). Talge et al. (2008) also examined associations between fearfulness and

autonomic activity but found no consistent relation. Infant surgency (low fearfulness, high impulsivity) is also associated with elevated HPA and sympathetic reactivity (Laurent, Ablow, & Measelle, 2012); however, this may be dependent on the social context (Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003). In fact, several studies have shown that associations between temperament and stress reactivity depend on the quality of the parent-child relationship or the child's attachment to their primary caregiver (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Smeekens, Riksen-Walraven, & Van Bakel, 2007) with similar patterns emerging when predicting behavioral and emotion regulation (Kim & Kochanska, 2012; Thomas et al., 2017). Interestingly, the effect seems to be bidirectional – one study found that low parent-child relationship quality predicted increases in negative emotionality across childhood but only when the child also exhibited higher cortisol reactivity (Kopala-Sibley et al., 2015).

Social Relationships and Well-being

The parental figure is a primary example of how powerfully social relationships regulate stress response systems. Better parenting quality has been consistently associated with healthier HPA axis regulation (Albers et al., 2008; Martin, Kim, Bruce, & Fisher, 2014) and parasympathetic tone (Hinnant, Erath, & El-Sheikh, 2015). Secure attachment relationships and higher quality parenting are effective buffers from maladaptive stress outcomes for young children experiencing a wide variety of adversities (poverty: Blair, Raver, Granger, Mills-Koonce, & Hibel, 2011; foster care, Fisher, Gunnar, Chamberlain, & Reid, 2000, Oosterman, De Schipper, Fisher, Dozier, & Schuengel, 2010; maltreatment, Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; international adoption, Pitula, DePasquale, Mliner, & Gunnar, *in press*). Parenting quality may sometimes moderate the association between physiological regulation and maladaptive behavioral outcomes, such that the poor outcomes only occur when the child also experiences lower quality parenting (Barrios, Bufferd, Klein, & Dougherty, 2017; Bubier, Drabick, & Breiner, 2009). Furthermore, the dysregulation of a parent's own stress response systems may hinder their ability to provide high quality parenting (Skowron, Cipriano-Essel, Benjamin, Pincus, & Van Ryzin, 2013).

The presence of a sensitive caregiver often reduces the reactivity of a child's stress response systems, particularly the HPA axis (i.e. parental social buffering, Gunnar & Quevedo, 2007). In rat pups, by about 10 days of age the stress-hyporesponsive period ends and their HPA axis responds to aversive stimuli, except (for approximately the next 10 days) in the presence of the mother (Sullivan & Perry, 2015). This is similar to the capacity of the parent to buffer HPA axis responses by the end of the first year of life in humans and is most prominent in secure attachment relationships (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996). Oxytocin, a critical neuromodulator involved in attachment and affiliative behavior, may play a role in this phenomenon (Strüber et al., 2014). In one study, children who completed the Trier Social Stress Test (TSST), a common social-evaluative stressor, and had full contact with their parent immediately after showed both the lowest cortisol reactivity and the highest spike in oxytocin (Seltzer, Ziegler, & Pollack, 2010). Even for adult males, having a best friend provide social support during TSST preparation resulted in a smaller cortisol response, a larger increase in oxytocin, and less subjective stress and anxiety (Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003).

Still, there are developmental changes in the social buffering of stress reactivity. Parents essentially block the entire stress response in infants (Gunnar et al., 1996). They are also more effective buffers for children compared to adolescents. The loss of parental effectiveness as a stress buffer likely corresponds to pubertal maturation (Gunnar & Hostinar, 2015). Who, then, takes over as the primary source of social support? It turns out, it is not friends – at least not for social-evaluative stressors (Doom, Doyle, & Gunnar, 2016). In this study by Doom and colleagues, adolescents ages 15-16 showed a larger cortisol response to the TSST when preparing with their caregiver compared to that of younger children ages 8-9. Adolescents showed an even larger response when preparing with their best friend. Whether friends can be social buffers under other conditions during this developmental period or whether the quality of the friendship matters is not yet known. Certainly, by adulthood social partners can be effective buffers (Heinrichs et al., 2003). The ability to utilize social partners to buffer the stress response in early development is likely important for healthy physiological and brain development. It is possible that the apparent loss of this ability in adolescence helps the body learn to independently self-regulate and develop more mature patterns of stress system activity, however more research is needed to directly test this claim. Additionally, a limitation to this body of research is the disproportionate use of decontextualized stressors. The TSST, while a reliable way to activate the HPA axis, is one of many laboratory stressors that may not reflect how a person would respond in the real world. Future research should delve further into the developmental patterns of parental social buffering in more naturalistic contexts.

Nevertheless, it seems clear that the presence of a sensitive caregiver at particular points in development is critically important for physical and psychological well-being. Positive parenting in childhood can influence future HPA axis regulation and how children react to stressors years later (Hagan et al., 2011; Shirtcliff, Skinner, Obasi, & Haggerty, 2017). Early parenting, over and above later parenting,

is especially important for healthy physiological development (Loman & Gunnar, 2010; Sroufe, 1979). During early development, rapid changes in neurological and physiological systems are the building blocks for healthy functioning. The environment a child experiences during this time of heightened plasticity is highly influential for how those systems develop (Luecken & Lemery, 2004). Early experiences set the stage for physical, physiological, and psychological well-being across the lifespan.

Impact of Absent, Low Quality, and Inconsistent Relationships

Because early caregiving relationships have the potential to be a strong positive influence on children's development, they can also cause great harm when those relationships are absent, of low quality, or inconsistent. The negative influence of early caregiving has been powerfully demonstrated in "natural experiments" where children were exposed to extremely stressful or deprived environments early in life but were later removed from those environments. For example, children who have been adopted from or fostered out of orphanages/institutions have typically experienced unstable, inadequate care. In institutional care children have multiple rotating caregivers with whom they have no real opportunity to form relationships and little developmentally appropriate stimulation (Gunnar, Bruce, & Grotevant, 2000). However, once adopted or fostered into families, their environments drastically change. Still, many post-institutionalized children have lingering physiological and behavioral deficits for several years following adoption (Koss, Mliner, Donzella, & Gunnar, 2016; McLaughlin et al., 2015) and these deficits increase their risk for psychopathological outcomes (Slopen, McLaughlin, Fox, Zeanah, & Nelson, 2012). Increased caregiving quality following institutionalization has been shown to improve outcomes, however, particularly in the HPA axis (DePasquale, Raby, Hoye, & Dozier, *under review*; McLaughlin et al., 2015).

Even in more typical circumstances, breakdowns in early caregiving are detrimental to a child's well-being. Children who have experienced maltreatment exhibit dysregulated HPA and autonomic stress response systems and poorer socioemotional outcomes (McLaughlin, Sheridan, Alves, & Mendes, 2014). Children in foster care, particularly those placed several times, also show HPA axis dysregulation (Fisher, Van Ryzin, & Gunnar, 2011). Maternal depression and cumulative risk associated with poverty have been associated with more negative parenting and thus dysregulated HPA axis and autonomic functioning (Evans & Kim, 2007; Oberlander et al., 2008; Zalewski, Lengua, Kiff, & Fisher, 2012). In all of these instances – maltreatment, foster care, and poverty – the very people who should be a child's primary source of support and positive experiences may become the source of extreme stress and neglect. This may enhance the maladaptive consequences of those experiences, and significantly impact children's ability to adapt effectively over time. What remains to be studied in sufficient detail are the bidirectional effects between the parent and child on child physiological development, and the dyad's relationship quality and physiological, behavioral, and emotional well-being over time.

Because of the powerful role of caregivers in children's development, it is not necessarily the presence of stressors, but the capacity of the parents to buffer and regulate stress that affects a child's physical and psychological well-being. Depending on the developmental time period, when buffering systems fail stressors can have profound impacts on the entire network of stress response systems, which drastically reduces a person's ability to effectively adapt despite adverse experiences. Some stressors, like early institutionalization, are powerful enough to offset the protective effect of a sensitive caregiver encountered after adoption or foster placement. Institutionalization also highlights the specific importance of experiences during the first few years of life when the stress response systems are developing rapidly. Caregivers can affect well-being for better or for worse, and there are critical neurobiological mediators involved in the experience of stress and the impact of caregiving throughout development. The timing and nature of caregiving influences and adverse experiences may affect how these factors impact physiological reactivity and regulation and, as a result, psychological well-being. While timing is central to understanding development, it is precisely this area where we lack definitive answers. The question of sensitive periods and periods of opportunity to recalibrate stress-responsive systems is at the cutting-edge of research on stress reactivity, regulation and well-being.

Abstract

In their everyday environments, people spend a lot of time experiencing and dealing with appetitive desires of all kinds, including those for foods, sex, and drugs. In this chapter, we review the concept of appetitive desire and spell out its multifaceted link with subjective well-being. Our main conclusions are that, oftentimes, appetitive desires are quite unproblematic and adaptive, and enacting them is typically a source for affective and cognitive well-being. However, desires sometimes conflict with important long-term goal or moral values, and their mere experience can be aversive. More importantly, the enactment of such unproblematic desires appears to result in diminished hedonic gains, and is related to reduced cognitive well-being. Having identified motivational conflict as the main source for the sometimes problematic nature of appetitive desire, we conclude by discussing various ways through which individuals faced with the dilemma of problematic desire may be able to optimize their subjective well-being.

Keywords: Desire, Self-Control, Well-Being, Motivational Conflict, Morality

Consider the last couple of hours before you started reading this chapter: Did you desire to consume or acquire something? Perhaps getting a good-looking donut when passing that bakery? Perhaps a coffee, if you are a regular coffee drinker, or a cigarette, if you are a smoker? Or did you desire to be close to someone, be it psychologically, or even physically? In their everyday environments, people spend a lot of time experiencing and dealing with appetitive desires of all kinds. These include innate desires such as for food, water, sex, and sleep, but also acquired desires such as for alcohol, cigarettes, and other (more or less harmful) drugs. Typically, such appetitive desires are quite unproblematic and adaptive. And so, enacting them is typically a source for short-term pleasure and happiness.

Things, however, can easily get more complicated: Sometimes a given desire conflicts with an important long-term goal or moral value. Consider the alcoholic spouse who is fully aware of the fact that giving in to the desire for another drink at the barbecue party will likely impair his ability to drive home safely (putting him/her and other people at danger), or make him/her more flirtatious (putting his/her spousal faithfulness to the test). The example illustrates that poor desire regulation may not only involve possible personal costs (e.g., being fined for drunk driving or getting divorced, respectively), but also costs to other people involved.

On an aggregate, societal scale, the consequences of poor desire regulation can be enormous. According to an influential study, 40% of deaths in the United States each year have been estimated to be attributable to behaviors that, directly, or indirectly, have to do with poor desire control, such as with regard to unhealthy foods, tobacco, alcohol, unprotected sex, aggressive urges, and illicit drugs (Schroeder, 2007). Therefore, it seems important to both gain a better understanding of the antecedents that contribute to successful and unsuccessful desire regulation, as well as of the consequences for health and well-being that result from the way people deal with their appetitive desires.

The present chapter, therefore, is centered on the concept of appetitive desire. We will begin with a brief definition of desire and desire regulation. In doing so, we will also touch on the neuropsychological literature on appetitive desires, as well as on some of the key antecedents of poor desire regulation. This will lead over to our main question in this chapter: how is the enactment or non-enactment of appetitive desires such as for food, sex, and drugs linked to well-being?

Desire: Definition, Neuropsychological Basis, Similarity to Emotion

In colloquial language, the term desire can refer to all kinds of wishes and wants. Therefore, it is important to more clearly define what we mean by desire in the context of this chapter: We use the term "desire" here to refer to the more narrow sense of *appetitive* desire. Appetitive desire can be defined as a "feeling of wanting that propels us to approach and consume objects or otherwise engage in activities that satisfy a need and, in doing so, yield a gain in immediate pleasure (or relief from discomfort)" (Hofmann &

Nordgren, 2015, p. 5). Typically, appetitive desires are based in physiological need states; However, they can also be acquired through processes of reinforcement learning as in the case of drugs, media addiction, spending urges, etc. (Martin-Soelch, Linthicum, & Ernst, 2007). Moreover, we use the term "craving" to refer to desires across domains that are particularly high-intensity (e.g., drug craving, food craving).

How are desires represented in the brain? From a neuroscientific perspective, an often-replicated finding is that the emergence of desire appears to be rooted in activity in largely subcortical neural regions in the limbic system of the brain. The key region that lights up in dozens of desire-related studies is commonly referred to as the reward center in the brain. The reward center is part of the so-called mesolimbic dopamine system (Kelley, Schiltz, & Landry, 2005). Of particular interest is the so-called nucleus accumbens (NAcc) in the ventral striatum. This structure seems to be implicated in the generation of wanting experiences (Berridge, Robinson, & Aldridge, 2009; Peciña & Berridge, 2005). For instance, one study connecting laboratory brain data and everyday life desire experiences, showed that individual differences in NAcc activity during exposure to food cues in the scanner were reliably related to the average strength of food desires in people's everyday environments, as measured via experience-sampling (Lopez, Hofmann, Wagner, Kelley, & Heatherton, 2014). Likewise, individual differences in NAcc responsivity to food and sexual pictures have been shown to be predictive of subsequent weight gain and sexual activity 6 months later (Demos, Heatherton, & Kelley, 2012).

In sum, appetitive desire experiences appear to have its roots in deep-seated structures in the brain that we share with most animals. However, the desire (i.e., reward-related) signals emanating from these structures are then integrated, cognitively enriched and regulated in higher-order, prefrontal structures in the brain, as the system needs to decide which course of action from the available options to take. This then becomes an issue of desire regulation which we will touch on below.

From a conceptual perspective, a parallel can be drawn between the concept of desire and the concept of an emotion (Hofmann & Kotabe, 2013). That is, like emotions, desires have an affective, motivational, and cognitive dimension. Regarding the affective dimension, both desires and emotions are accompanied a certain phenomenological feeling (the feeling of "wanting" in the case of desire). Regarding the motivational component, desires as well as emotions prepare and motivate behavior. Desiring something means wanting to have, consume, or do something that is expected to yield pleasure (or reduce discomfort).

Regarding the cognitive component, both desire and emotions are subject to appraisal processes and can thus be intricately linked to cognition (as reflected, for instance, in the affect-cognition debate of emotion). The most prominent theory linking desire to cognition is the so-called elaborated intrusion theory of desire (Kavanagh, Andrade, & May, 2005). According to this theory, desire is typically accompanied by intrusive thoughts (including fantasies) about the object of desire. Moreover, desire and cognition can reinforce each other in a dynamical way (see Hofmann & Van Dillen, 2012, for a related dynamical model of this process): As a person engages in more and more cognitive elaboration of a given desire, the strength of the desire typically increases. As the strength of desire increases, it captures more and more attention and thus more mental resources are allocated to it in working memory. This is one explanation for why desires can sometimes escalate to the point where, metaphorically, common sense goes out of the window. In other words, the sometimes all-consuming, highly ruminative nature of intense cravings makes it increasingly more difficult for conflicting goals and values to gain the upper hand in the struggle for limited working memory resources (Hofmann, Friese, Schmeichel, & Baddeley, 2011; Hofmann & Van Dillen, 2012; Kavanagh et al., 2005).

Desire Regulation (or, the Killjoy Society)

Whereas many desires are unproblematic and adaptive, more often than we may wish, desires conflict with important self-regulatory or moral standards, goals, and values. This notion of intra-psychological conflict turns a given desire into a special subclass, *temptation* (or problematic desire), defined as a desire that stands in conflict with an important higher-order goal, standard, or moral value. Examples include food (dieting; not eating animal food), sex (sexually transmitted diseases; remaining faithful), and drugs (health, doing something illegal). It is thus clear that "desire" and "temptation" are not synonymous terms (Hofmann & Kotabe, 2013; Hofmann & Van Dillen, 2012). Rather, "temptations" can be conceptualized as a subset of desires, namely those that conflict with an important higher-order goal or value. To put it in the words of philosopher Alfred Mele (2001), to say someone is "tempted" requires that the person *desires* to do X and simultaneously has a *good reason* not to do X. Whether a person has good reason not to do X will typically hinge on the "baggage" the person brings with him- or herself in terms of endorsed self-regulatory goals, internalized or introjected values, or other competing motives and goals (Kotabe & Hofmann, 2015).

At a general level, the unrestrained enactment of desire can either be self-harming or interfere with

the well-being of fellow citizens (or both). For instance, excessive alcohol consumption may not only harm one's own body, but also have a disintegrating effect on one's family members (e.g., impulsive acts of family violence, failing to maintain a job). The capacity to regulate desire can thus be regarded as an important prerequisite for participating in society. Ignoring this necessity can be quite costly. As Sigmund Freud (1930) has so aptly put it in his seminal essay, *Civilization and its Discontents*, "An unrestricted satisfaction of every need presents itself as the most enticing method of conducting one's life, but it means putting enjoyment before caution, and soon brings its own punishment." Societies everywhere have developed multiple mechanisms to deal with those who repeatedly fail at controlling desires. For instance, repeated sexual offenders are typically removed from free society and confined to prison.

It is thus clear, that most people, most of the time, harbor good reasons against enacting problematic desires. But where do these "good reasons" come from? Not surprisingly, many of these reasons have become institutionalized as norms of proper conduct. That is, legal, religious, and educational systems have always played an active part in the regulation of desires as these norms are passed onto (most) members of society and ultimately internalized through the process of socialization. Presumably, the ideal goal of such regulative attempts is to establish a consensual balance between individual liberty and collective interests, including public safety, order, and health, even if it comes at the cost of sacrificing some individual pleasures (see Freud, 1930, for a classic treatment of this tradeoff).

In fact, the regulative power of morality runs deep, even beyond institutionalized normative influence. According to the well-established moral foundations theory (Graham et al., 2013), morality is based on several core moral principles: *Care* (i.e., "don't harm other people"), *Fairness* (i.e., "don't pursue your own advantage in disproportionate ways"), *Loyalty* (i.e., "don't betray your in-group"); *Authority* (i.e., "don't disrespect laws, rules, and authority figures"), and *Sanctity* (i.e., "don't do something "impure" or "indecent"). Another, separable core moral principle may be Honesty (i.e., "don't manipulate the truth"; Hofmann, Wisneski, Brandt, & Skitka, 2014). Each of these principles can serve as a moral reason of desire regulation in the sense of a moral "ought" (i.e., proscriptive morality; Janoff-Bulman, Sheikh, & Hepp, 2009). Accordingly, self-control goals often appear to be moralized (e.g., Haidt & Hersh, 2001; Mooijman et al., in press; Rozin & Singh, 1999). For instance, it is easy to see how harm (e.g., rape), disloyalty (e.g., infidelity), disrespect of authority/law (e.g., sex with a minor), impurity/disgust (e.g., sex with a sibling), or dishonesty (e.g., pretending to be a star when you are not) can all serve as good reasons or moral principles for why (people think) a person should think twice about advancing and enacting a given sexual urge.

Appetitive Desire and Well-Being

Having thus laid the foundation for the concept of appetitive desire, as well as its tension with societal affordances that require the motivation and capacity for the control of certain desires, we now turn to the even more complex issue of how appetitive desires such as food, sex, and drugs relate to subjective well-being. To better understand this complex picture, and introduce some meaningful demarcations, we will distinguish between (a) *affective* (i.e., hedonic) well-being and *cognitive* well-being (i.e., life satisfaction), (b) the *experience* and the *enactment* of desire (and its consequences), and (c) between *unproblematic* and *problematic* desires (i.e., temptations). The resulting organizational scheme is presented in Table 1. In a nutshell, we distinguish between affective and cognitive well-being to acknowledge the well-established fact that these two facets of subjective well-being can be clearly separated, and have different predictors and consequences (Diener & Chan, 2011; Lucas, Diener, & Suh, 1996; Luhmann, Hofmann, Eid, & Lucas, 2012). This opens up the possibility that the two major dimensions of well-being may be differentially affected by appetitive desires and their regulation. We distinguish desire experience and enactment to suggest that even the experience of desire may, under certain conditions, be aversive and thus reduce affective well-being. And we distinguish unproblematic and problematic desire because problematic desires may pose quite different challenges for well-being than unproblematic ones.

Table 1. Organizational Scheme of the relationship between appetitive desire and well-being. The taxonomy distinguishes between desire experience and enactment, affective and cognitive well-being, and unproblematic and problematic desire. Parts printed in gray font are only briefly discussed in the present chapter.

	Desire Experience	Desire Enactment
Affective Well-Being	Unproblematic Desire	Unproblematic Desire
	Problematic Desire	Problematic Desire
Cognitive Well-Being	Unproblematic Desire	Unproblematic Desire

Experiencing Desire and Affective Well-Being: The Role of Ambivalence and Conflict

How does the experience of appetitive desires such as for food, sex, and alcohol relate to in-the-moment affective well-being? As mentioned above, desires are characterized by a phenomenological state of wanting. This state has often been described as ambivalent (Kavanagh et al., 2005): On the one hand, there is tantalizing enchantment from anticipating pleasure ("imaginary relish"). On the other, there is frustration from not (yet) having had the opportunity to consume the source of the desire ("exquisite torture"; Kavanagh et al., 2005). So, even in the case of an unproblematic desire, the combined effect of experiencing a given desire on affective well-being may depend on the relative strength of the positive and negative ingredients of this "mixed" (ambivalent) emotional state (Larsen, Coles, & Jordan, 2017). If the positive ingredient of the anticipated reward is relatively larger, desire is likely to be positive in tone. However, note that in the case of unproblematic desire, the ambivalence emerges entirely within one given motivational stream of action (e.g., "longing for one's partner").

In the case of problematic desire, however, the ambivalence is arguably much more intense. The reason is that a major source of additional negativity enters the psychological scene: As mentioned above, problematic desires imply intra-psychological conflict between *motives*. There is the literal struggle between "two souls" within oneself: One part wants something and pushes for action, but another part inside urges caution and voices "good reason" for why one should not (Hofmann, Friese, & Strack, 2009; Milkman, Rogers, & Bazerman, 2008). Such motivational conflict has consistently been shown to be an aversive, unpleasant affective experience in a large body of research (e.g., Emmons & King, 1988; Nordgren, Van Harreveld, & Van Der Pligt, 2006; van Harreveld, Nohlen, & Schneider, 2016). Further evidence comes from the literature on cognitive conflict and error-related brain activity which likewise suggests that experiencing motivational conflict is aversive in nature (see Inzlicht & Legault, 2014, for a review). In a related vein, of course, the literature on cognitive dissonance has long suggested that holding conflicting thoughts in mind is an affectively negative experience (Festinger, 1957; Proulx, Inzlicht, & Harmon-Jones, 2012). A paper from a large experience-sampling project on self-control (Hofmann, Baumeister, Förster, & Vohs, 2012) has directly compared momentary levels of affective well-being for (non-enacted) unproblematic desires and (non-enacted) problematic desires (Hofmann, Kotabe, & Luhmann, 2013). The study found that the no-enactment baseline for problematic temptations was substantially lower than the no-enactment baseline for unproblematic ones, suggesting that the fact of being in a tempting, conflicting situation was experienced as considerably more aversive than when self-control demands were absent.[1]

In summary, the relation between experiencing appetitive desire and momentary well-being may depend on how problematic the desire is, that is, how much motivational conflict it entails. The available evidence consistently suggests that the experience of a desires that conflict with important self-regulatory goals or values is accompanied by higher levels of ambivalence and, hence, reduced affective well-being as compared with the experience of unproblematic desires. It was recently hypothesized that motivational conflict in desire control may be a function of desire strength, opposing goal strength, and their degree of incompatibility (Kotabe & Hofmann, 2015). Future research manipulating these or other aspects of motivational conflict may arrive at a more fine-grained picture of this relation.

Throughout this section, we have avoided discussing the relationship between in-the-moment desire experiences and cognitive well-being/life satisfaction, a decision that was motivated by the absence of a substantial amount of literature that would speak to this possibly more remote connection. Perhaps the (repeated) mere experience of unwanted desire intruding into consciousness and sticking around may lower one's life satisfaction via self-attributions of low control and perceived helplessness as mediating mechanisms. Future research will have to clarify this largely unknown territory.

Enacting Appetitive Desire and Affective Well-Being

What is the effect of enacting appetitive desires on affective well-being? The standard answer from motivation science is that the pursuit of pleasure (and avoidance of pain) is one of the most fundamental principles of motivation (Carver & Scheier, 1990; Hull, 1943; Lewin, 1935). That is, humans generally experience a temporary gain in affective well-being by fulfilling millennium-old basic needs such as the need to eat, rest, and reproduce, or acquired appetitive desires such as those for drinking alcohol or receiving likes on facebook.[2] For instance, large surveys as well as daily diary studies from relationship research have consistently found a positive effect of sexual activity on indicators of affective well-being (Blanchflower & Oswald, 2004; Hofmann, Finkel, & Fitzsimons, 2015; Muise, Schimmack, & Impett,

2016). Using the daily diary method, Oishi, Schimmack, and Diener (2001) found that people felt happier on days when they fulfilled physical desires such as for food or sex compared to days when they did not. Likewise, across several thousand observations from more than a dozen desire domains sampled from everyday life, a positive enactment gain on in-the-moment affective well-being was obtained, corresponding to a large effect size of about d = .90 (Hofmann et al., 2013). With regard to unproblematic desire, the equation thus seems straightforward: enacting appetitive desire boosts affective well-being, at least in the short run.[3]

Concerning problematic desires, however, motivational conflict enters the scene, and a highly interesting question emerges: What gain in affective well-being does enacting problematic desire bring about? Scholarly and public opinions about the instant utility of giving in to temptation run deep among political, religious, and cultural divides (Veenhoven, 2003). Overall, four quite different "lay" hypotheses about the outcome of such a comparison can be found. Their respective predictions are summarized in Hofmann et al. (2013; see their Figure 1).

The *pure hedonism hypothesis* holds that the gain in affective well-being resulting from enacting a tempting desire would be no different from the gain in momentary happiness resulting from enacting a comparable unproblematic desire: A cake is a cake. Take two people, one harboring no dieting goal whatsoever, the other being hard-pressed to diet: in both cases, the basic principle of need satisfaction would predict that consuming the object of desire sets free the same amount of pleasure units (for cake, these are sometimes also referred to as "calories"). According to this view, temptations have their downside, or course, but these negative effects lie in the delayed and uncertain future.[4] The *forbidden fruit hypothesis* suggests that enacting problematic desires is accompanied by a special allure that may add an additional boost for affective well-being. In contrast, both the *spoiled pleasure hypothesis* and the *backfire hypothesis* predict that enacting problematic desire yields a *reduced* hedonic payoff when compared with the unproblematic desire case. This reduction may be due to the impact of self-conscious emotions: Humans are not only equipped with basic emotions but also subject to emotions of self-assessment, such as guilt, regret, and pride (Taylor, 1985; Tracy, Robins, & Tangney, 2007). Thus, according to this view, affective well-being results from the combination of primary, basic and secondary, self-conscious emotional experience. Yielding to temptation may thus be like a "mixed blessing" for affective well-being: a feeling of pleasure that adds to affective well-being, but *at the same time* a constellation of self-conscious emotions (e.g., heightened guilt) that subtracts from it. The resulting net effect differs for the spoiled pleasure and the backfire hypothesis. In the former, the pleasure derived from enactment still outweighs the effect of self-conscious emotions; in the latter, the net effect is negative (see Figure 1), hence, from a happiness-maximization perspective, temptations are not even worth it in the "here and now".

First empirical evidence seems to support the spoiled pleasure account (Hofmann et al., 2013). That is, enacting problematic desires resulted in a considerably smaller, but still positive, gain in affective well-being (only a small positive effect of d = .13) as compared to unproblematic desires. Furthermore, the effect was not moderated by whether the desire domain in question is generally assumed to be addictive or not (Hofmann et al., 2013).

In sum, whereas there is strong evidence for a general boost in affective well-being for desire enactment, this effect has mainly been researched without a clear distinction between unproblematic and problematic desires. Given that the majority of appetitive desires are rather unproblematic in nature (Hofmann et al., 2012), this general positive effect is not surprising. However, distinguishing among unproblematic, and problematic (i.e., motivationally conflicting) desires reveals a considerably reduced hedonic gain for the latter type of desire. This novel finding from the field challenges the long-standing assumption underlying the "pure hedonism" hypothesis, according to which giving in to temptation would produce similarly rewarding immediate hedonic payoffs as the fulfillment of unproblematic desires, and would thus incur only delayed costs. Future experimental research will have to more closely investigate this intriguing possibility.

Enacting Appetitive Desire and Cognitive Well-Being

The final question we want to address is how the enactment of appetitive desires relates to cognitive well-being. Cognitive well-being refers to global or domain-specific evaluations of life. The most central and important aspect is global life satisfaction ("life satisfaction" henceforth), a cognitive judgment about how well one's life is going in general. The concept of life satisfaction is thus very similar to the Aristotelian notion of eudaimonic well-being, a sense that one is leading the "good" life, that one's life is "well-lived." So, in contrast to affective well-being which is experiential in nature, cognitive well-being requires that people "take a step back" to view and evaluate the way they lead their life (over larger time-spans) and cognitively weigh and integrate various sources of information.

Because the frequent fulfillment of unproblematic needs and desires adds to affective well-being,

and since there is little reason to question whether enacting these desires is time and effort well spent, it is straightforward to assume that the evaluation of one's frequent rather than infrequent enactment of unproblematic desires would generally be positive and thus contribute as one (out of many) sources for life satisfaction. Accordingly, the above-mentioned diary study by Oishi and colleagues (2001) also found that the average pleasure from fulfilling basic, physical desires positively contributed to life satisfaction (see also Tay & Diener, 2011). Moreover, because what is judged to be good is ultimately a value judgment, it is possible, that the fulfillment of basic appetitive needs may receive a stronger relative weight in those who prioritize the value of hedonism over and above other values in life (such as, for example, security, power, or achievement; Schwartz & Bilsky, 1987). Some evidence for this conjecture comes from the finding that people high in sensation seeking showed a stronger relationship between physical pleasure fulfillment and daily social life satisfaction (Oishi et al., 2001). In plain terms, if you value the pleasures of life a lot, seeing yourself harvest many of them will generally give you the sense that you are living your life in an optimal, authentic way. The desire to experience pleasure and happiness is also one focus of consumer research: Hedonic consumption is defined as the purchase of products that fulfill fantasies and satisfy emotions (Hirschman & Holbrook, 1982). In contrast to utilitarian consumption, which is characterized by the purchase of functional and necessary products, hedonic consumption has the essential feature of simply bringing pleasure or fun (for a review, see Alba & Williams, 2013). Consuming hedonic products improves satisfaction with the relevant life domains, and thus, increases cognitive well-being, based on a longitudinal study (Zhong & Mitchell, 2010).

Again, since most desires are unproblematic, the above general findings may somewhat cloud what can be gleaned with regard to problematic desires. Note that, with regard to affective well-being, our conclusion was that enacting problematic desire results in spoiled pleasure, but still a *positive* gain in affective well-being. In contrast, there is converging evidence from multiple areas of research suggesting that things take on a more negative spin when it comes to the cognitive evaluation of one's life: First, as discussed in length above, problematic desires are problematic for a good reason, and their - repeated or just one-time - enactment may wreak considerable havoc such as serious or even lethal health problems due to overweight, sexually transmitted diseases, continuous substance abuse or drug overdoses, or other problems such as poor social integration (Moffitt et al., 2011; Mokdad, Marks, Stroup, & Gerberding, 2004; Schroeder, 2007; Shoda, Mischel, & Peake, 1990). One of the key insights from work on self-control and weakness of will is that lack of awareness of/knowledge about these negative consequences is often not the key issue – rather motivational and volitional problems are central (Kotabe & Hofmann, 2015); hence, it can be supposed that most people who are low in self-control, most of the time, are well aware of the fact that their giving in to temptation may have negative long-term consequences. Second, from the perspective of dual motive conflicts, temptations can be regarded as obstacles with regard to making progress on the competing long-term goal; Hence, overly frequent indulgence that goes beyond people's ideal balance between the two motives may go along with the perception of insufficient progress towards important goals and aspirations (Hofmann, Luhmann, Fisher, Vohs, & Baumeister, 2014a; Wiese et al., in press). Third, there is the social environment: People who overindulge in problematic desires may receive frequent negative feedback from close others, doctors and caretakers, observers, including negative moral judgment directed towards oneself (Nordgren, van der Pligt, & van Harreveld, 2007). And fourth, the repeated enactment of desires one better ought to control may give rise to the sense that one is lacking internal control of one's inner driving forces (i.e., desires) that instigate the problematic behavior. Lack of perceived control is a well-known negative correlate of life satisfaction (e.g., DeNeve & Cooper, 1998), and research in problem populations such as obese people (e.g., Greeno, Jackson, Williams, & Fortmann, 1998) or teenagers experimenting with cigarettes and alcohol (Adalbjarnardottir & Rafnsson, 2001) supports the role of perceived control as one possible mechanism.

In sum, knowledge about negative consequences, insufficient long-term goal progress, negative social feedback, and perceived lack of control over one's behavior may all contribute to a negative evaluation of the way one conducts one's life. Accordingly, there is strong and often replicated evidence that individuals who describe themselves as low in self-control, as typically measured via the brief trait self-control scale (Tangney, Baumeister, & Boone, 2004), score higher on life satisfaction than those who describe themselves as high in self-control (Hofmann et al., 2014a; Wiese et al., in press), and alternative measurement approaches in more specific domains such as obesity support this view (Stutzer & Meier, 2016).

Is the relationship between self-control and subjective well-being a monotonic, linear function, or can there be too much of a good thing? Recently, Wiese and colleagues (in press) have scrutinized the theoretical possibility that too much self-control may have harmful implications for subjective well-being which might be due to overregulation of cognition, emotion, and behavior or obsession with accomplishment of long-term goals at the expense of happiness; However, across multiple studies,

methods, and measures there was no support for an inverted-U effect of self-control on subjective well-being.

Summary and Outlook

In this chapter, we have reviewed the link between appetitive desires such as for food, alcohol, and sex on subjective well-being. We set out by noting the dilemma between the ubiquity of appetitive desires as internal driving forces and the necessity for the regulation of "problematic" desires both for individual (e.g., health-related) reasons and for societal welfare. How individuals solve this dilemma appears to have important implications for subjective well-being. Our review of the connection between desire and happiness was guided by our proposal that a fine-grained analysis of this link needs to distinguish, at minimum, between affective and cognitive well-being, unproblematic and problematic desires, and the experience and enactment of desire. Our main conclusions from surveying the available evidence are that (1) the experience of problematic (as compared to unproblematic) appetitive desire seems to be associated with a temporary drop in affective well-being, (2) the enactment of problematic (as compared to unproblematic) appetitive desire provides only "spoiled" pleasure, that is, a substantially reduced boost in momentary affective well-being, and (3) the frequent enactment of problematic (as compared to unproblematic) appetitive desire is associated with reduced cognitive well-being (i.e., life satisfaction). A lot of empirical effort is still needed, however, to better understand the mechanisms that give rise to these effects, such as the mechanisms that mediate between repeated self-control failures and low life satisfaction.

From a practical perspective, the present analysis identified problematic desire as the main culprit. This view suggests that happiness may be optimized by either becoming a master at inhibiting the enactment of problematic desires through interventive self-control or by avoiding or even eliminating problematic desire experiences as much as possible through preventive strategies of self-control which, ultimately, may be more successful. (Fujita, 2011; Hofmann & Kotabe, 2012). Note, however, that problematic desires may also be eliminated through changes to one's *mental landscape*, i.e., the types of goals, moral values, and viewpoints one endorses. Though existing ideologies and moral systems typically offer such viewpoints (for free), one need not necessarily buy into them. Luckily, as people keep questioning and reasoning about moral values, there is overall moral progress (Shermer, 2015). One of the major, continuing challenges of societies, therefore, is to identify and demarcate the truly morally problematic forms of desire enactment from those that may be in need of revision and, possibly, unmoralization. As the moral landscape changes, new and better equilibria for balancing individual happiness and societal welfare may emerge.

Footnotes

[1] As an aside, an interesting question, inspired by Buddhist philosophy, is whether, given the ambivalence of desire, a life with substantially reduced desire or even without experiencing desire at all may be the peak of happiness? We believe that the answer may depend on the type of desire experienced: Desiring something unproblematic and attainable may be associated with levels of momentary affect that may lie above the "Buddha" baseline of no desire experience; such a finding would also be consistent with research on the lack of motivational drive, or anhedonia (Treadway, 2015); However, experiencing a problematic desire (temptation) may lie below that baseline for the above reasons of introducing aversive intra-psychological conflict.

[2] Even though not the focus of the present chapter, this general principle also entails the satisfaction of basic *psychological* needs (Tay & Diener, 2011), as spelled out, for instance, by self-determination theory (Ryan & Deci, 2000).

[3] Of course, such effects are temporary, as inherent in the idea that desire (needs) and desire fulfillment (need satisfaction) are parts of the cycle of homeostatic regulation. There is some dearth of longitudinal studies involving substantially longer time spans which would allow drawing conclusions about the extent to which being able to regularly fulfill important basic, hedonic needs is causally linked to increased general levels of affective well-being.

[4] Note that this is the standard utilitarian explanation for why people (sometimes) yield to temptation: They expect the immediate reward resulting from temptation enactment to outweigh the (temporally discounted) long-term reward resulting from resistance (Ainslie, 2001; Thaler & Shefrin, 1981).

Abstract

The growing evidence that positive psychological functioning is linked to favorable health outcomes has led to a search for biological mechanisms that may underlie these salubrious effects. Although there is interest in biological processes that are uniquely related to positive psychological functioning, most work to this point has centered on those with known associations with adverse psychological experiences, such as stress and depression. This chapter reviews the existing literature on the ways in which psychological well-being (broadly defined) is linked to hormone systems in the body (endocrine and neuroendocrine). The chapter is structured by hormone system. Given the newness of the field, this literature is understandably limited, and conclusions about such links are consequently tentative. Nonetheless, the overall picture is promising, and links between hormone systems and psychological well-being should be a vibrant area of future research with critical implications for physical and mental health.

Keywords: well-being, optimism, HPA axis, cortisol, catecholamines, metabolic hormones, oxytocin, prolactin

Psychological well-being has been linked to a broad range of health outcomes, most notably reduced risk of diverse forms of morbidity and general mortality (Chida & Steptoe, 2008; Giltay, Geleijnse, Zitman, Hoekstra, & Schouten, 2004; Hill & Turiano, 2014; Pressman & Cohen, 2005), and there is a large and growing literature devoted to illuminating the biological mechanisms that may underlie these health effects. Although there is interest in identifying biological processes that may be unique to positive psychosocial functioning (Kubzansky, Boehm, & Segerstrom, 2015), the bulk of existing research has examined the ways in which well-being affects and is affected by well established biological responses to adversity, including those related to immune and endocrine function (Friedman, 2012; Steptoe, Dockray, & Wardle, 2009). The focus of this chapter is on connections between well-being and endocrine biology, including bi-directional influences.

The construct of well-being can be operationalized in a variety of different ways. There exists, for example, two broad categories of well-being measures – hedonic and eudaimonic – reflecting different ideas of what it means to lead a good life, a debate that stretches back to Greek philosophical disputes. While hedonic well-being comprises various elements of emotional life (such as positive and negative affect and satisfaction with life), eudaimonic well-being focuses more on the realization of individual potential through meaningful engagement (Ryan & Deci, 2001; Waterman, 1993). While the two are often correlated, they are distinct in a number of relevant ways, including how they change with age and how they relate to a range of outcomes, including health (Cole et al., 2015; Friedman, 2012; Ryff, 2014; Ryff & Keyes, 1995). There are additional indicators of positive psychological functioning, such as optimism, that do not fit neatly into one category. In this chapter we define well-being broadly and consider links between diverse endocrine systems and multiple aspects of well-being.

An important point to make at the outset is that this chapter focuses on research featuring explicit measures of well-being, not ill-being. That is, there is a large and long-standing body of research on the endocrine, neuroendocrine, and autonomic correlates of clinical and sub-clinical mental illness, chronic stress, and the like. But there is substantial evidence that well-being is not merely the absence of ill-being (Keyes, 2002; Pressman & Cohen, 2005; Ryff et al., 2006). For example, studies in which more advantageous profiles of endocrine function are observed in those with lower levels of stress or depression have not necessarily demonstrated the biological impact on well-being. For this reason, with only a few exceptions we constrain our review to research assessing indicators of well-being. See Table 1 for an overview of the hormones, their function, and a brief summary of evidence in relation to well-being.

Table 1
Hormone function and summary of associations with well-being

	Function	Summary

Adrenal hormones		
Cortisol	Elevates blood glucose levels; activates anti-stress and anti-inflammatory pathways.	Well-being is linked to optimal daily cortisol regulation and buffering of adverse experiences.
DHEA(S)*	Androgen; intermediate in sex steroid biosynthesis; binds to neurotropin receptors.	Supplementation in older adults increases well-being
Catecholamines	Initiates cascade of physiological changes, mobilization of resources in response to stressors.	Studies linking catecholamines and well-being are mixed and inconclusive.
Sex hormones		
Testosterone	Controls expression and maintenance of male-specific characteristics; regulates sexual differentiation and behavior.	Weak evidence linking testosterone to well-being in older adults. Studies lacking in younger adults.
Estrogen	Controls expression and maintenance of female-specific characteristics; regulates sexual differentiation and behavior.	Evidence linking estrogen to well-being is largely absent. Studies across wider age ranges are needed.
Metabolic hormones		
Insulin-like growth factor	Involved in neuronal survival, neurogenesis, angiogenesis, neurotransmission, regulation of food intake, and cognition.	Inversely associated with well-being; binding protein directly linked to well-being. Associations likely age- and sex-specific.
Insulin	Regulates macronutrient metabolism by promoting absorption of glucose into tissues.	Intranasal insulin improves mood and attenuates reactivity to social stress; association may be dependent on age and ethnicity.
Thyroid hormones	Regulates physiological functions, including growth and development, metabolism, body temperature, and heart rate.	Generally positively linked to well-being, but evidence is mixed; age, sex, and thyroid function contribute to these associations.
Other hormones		
Oxytocin	Facilitates labor during pregnancy; promotes maternal bonding, sexual behavior, and affiliation	Intranasal administration has inconsistent associations with mood; links to well-being appear to be moderated by receptor genotype.
Anti-diuretic hormone	Stimulates water retention and vasoconstriction; promotes pair-bonding behavior	Limited evidence suggests positive relationship to happiness; receptor type may influence associations in a sex-specific manner.

Prolactin	Regulates water and salt balance, breast milk production, cell proliferation and differentiation, T-cell immunity, pancreatic β cell function, hematopoiesis, and adipogenesis	Limited number of studies suggest sex-specific positive associations with well-being. Positive behavior patterns during conflict were also associated with higher levels among women.
*DHEA(S) – Dehydroepiandrosterone (sulfate)		

Adrenal Hormones

The adrenal glands, located above the kidneys, are composed of an inner medulla and an outer cortex that together produce a number of hormones, including cortisol, dehydroepiandrosterone (DHEA), epinephrine and norepinephrine, among others. These hormones play key regulatory roles across multiple physiological systems. Most notably, the hormones produced by the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic-adrenal-medullary (SAM) axis help coordinate whole-body adaptive responses to acute and chronic stressors and other environmental challenges encountered in daily life. For a more detailed treatment of the HPA axis, the SAM axis and their role in the stress response and well-being, see DePasquale and Gunnar in this volume (Chapter 22).

Dysregulated levels of adrenal hormones have marked negative consequences for diverse physiological functions, and numerous syndromes and disorders characterized by aberrant hormone production are well-documented (Charmandari, Nicolaides, & Chrousos, 2014; Lacroix, Feelders, Stratakis, & Nieman, 2015; Zografos, Perysinakis, & Vassilatou, 2014). Conversely, the maintenance of efficient regulation of these hormones, not only day-to-day but across the life course, corresponds to optimal functioning and health. In addition, steroid hormones such as cortisol and DHEA can cross the blood-brain barrier (Banks, 2012) where they have marked influences on both neurophysiology and subjective psychological experience; these influences are observed in the context of stressors and during normal daily activity. The ability of adrenal steroids to influence the brain directly highlights bidirectional influences that are relevant for this chapter: well-being affects the regulation of adrenal hormones, and circulating adrenal hormones can affect subjective experiences of well-being.

Cortisol. The steroid hormone cortisol is the main downstream effector of the HPA axis. Cortisol serves to elevate blood levels of glucose, by liberating existing stores or initiating glucose synthesis, to be used by muscles and the brain for daily activity and responses to environmental challenges. It also activates potent anti-stress and anti-inflammatory pathways.

Cortisol is present in diverse tissues, including blood, urine, saliva, and hair, and cortisol levels from these different sources provide information on different aspects of HPA function. To illustrate, cortisol levels in blood and saliva can change over the course of minutes and hours, providing a lens into acute changes in the physical and psychological state of the organism. Levels in urine and hair, in contrast, reflect longer-term accumulation, and analysis of cortisol in these tissues can inform about chronic patterns of HPA activity. Importantly, cortisol concentrations determined from different tissues within the same person often show weak inter-correlations, emphasizing the distinct aspects of HPA functioning that different modes of assessment provide (Rector, Tay, Wiese, & Friedman, unpublished data).

In general, cortisol has been used to study the impact of negative subjective experience (e.g. stress, depression) on health via dysregulated HPA axis activation. There are, however, associations between cortisol and well-being that are distinct from these links to ill-being. To this point, cortisol is the best-studied hormonal correlate of well-being.

A currently popular mode of assessing HPA regulation involves tracking fluctuations in cortisol across the day. Cortisol has a strong diurnal pattern, with a peak soon after awakening and a nadir right before the onset of sleep. To assess diurnal cortisol, 4 samples are typically collected: one upon awakening, a second 30 minutes later, a third before lunch, and the fourth before bedtime. The timing of these samples makes it possible to capture several important parameters of the diurnal cortisol rhythm: the waking value, the cortisol awakening response (CAR) – the rise from waking to 30 minutes later, during which cortisol concentrations increase by around 50% – the decline to mid-day, which is usually the steepest part of the daily decline, and the concentration approaching the typical nadir, which both allows for calculation of the cortisol slope, or rate of decline across the entire day, and the value of the nadir, which has been shown to be meaningful for mental health in itself. Cumulative cortisol production across the day can also be estimated as the cortisol area under the curve (AUC). Diurnal cortisol regulation is a particularly attractive focus for research as many of these parameters are stable across measurement occasions (i.e., trait-like) while also being sensitive to acute life challenges (i.e., state-like).

There are at least two major features of the diurnal cortisol profile that show distinct patterns in relation to positive psychosocial functioning: the CAR and the slope (of cortisol levels over the day). In a study of 80 healthy Chinese adults aged 19-55 years, greater positive affect was associated with a steeper diurnal slope, but was unrelated to the CAR (Lai et al., 2005). Conversely, a later study using participants from the Family Heart Study (mean age: 31 years) found that greater positive affect was associated with a less pronounced CAR, but was unrelated to the diurnal decline (Brummett, Boyle, Kuhn, Siegler, & Williams, 2009). Notably, the Chinese study used median splits to determine high and low positive affect, suggesting that the relationship between positive affect and diurnal cortisol slope may not be linear across all levels of positive affect. That is, associations with the cortisol slope within the high positive affect group may be stronger than in those in the low positive affect group. Moreover, positive affect comprises dimensions of both emotional valence and degree of arousal. Calm and excitement, for example, are both positive emotions, but the latter is associated with higher levels of arousal. Along these lines, Hoyt, Craske, Mineka, and Adam (2015) found that high but not low arousal positive affect was associated with a steeper cortisol slope (and lower bedtime cortisol levels) among adolescents. The steeper slope seems to have been in part a function of lower levels of bedtime cortisol in those with the highest levels of high arousal positive affect (Hoyt et al., 2015). These results suggest a multi-dimensional representation of positive affect, which captures both valance and arousal, may be critical for a precise account of the relationship between positive affect and cortisol, and possibly help to explain prior mixed results.

There are more consistent findings for dispositional optimism. For example, among 543 healthy adults aged 53-76 years from the Whitehall II cohort study, a more robust CAR – a larger increase in cortisol from waking to 30 minutes later – was associated with lower optimism, but not the diurnal decline (Endrighi, Hamer, & Steptoe, 2011). A similar pattern of associations between optimism and the CAR was reported in Chinese adults. However, this relationship may be sex- and/or ethnicity-specific, as some associations were found only among men in the Chinese sample (Lai et al., 2005).

Smyth and colleagues (2017) assessed the relationship between global life satisfaction, measured by a single item, momentary affect (from ecological momentary assessment), stress, and diurnal cortisol slopes among 115 working aged adults (aged 19-63). Multi-level models revealed a trend ($p<.10$) towards greater global life satisfaction and steeper slopes, indicating a stronger diurnal rhythm, on each of the 3 sampling days. Interestingly, after averaging the slopes across the days, life satisfaction was actually associated with flatter cortisol slopes (Smyth, Zawadzki, Juth, & Sciamanna, 2017). The authors note that the initial measurements of cortisol did not begin until a few hours after waking, and likely missed important information from the early hours of the day needed to adequately assess the daily slope. However, Ryff and associates (2006) also reported an association between flatter cortisol slope and higher scores on the eudaimonic well-being domains of personal growth and purpose in life in 52 women aged 75 and older. These authors note that upon further examination, those with higher personal growth and purpose in life started the day with lower levels of salivary cortisol and stayed lower across the day, compared to those with lower scores on these domains (Ryff et al., 2006). These observations underscore the importance of considering absolute levels of cortisol and diurnal slope in tandem; flat slopes may result in different absolute levels of cortisol exposure depending on waking levels. Thus, one should also consider interactions between components in associations with well-being.

Well-being has also been studied as a buffer against the impact of stress on HPA responses. For example, in 135 community-dwelling adults aged 61 or older, Jobin and colleagues (2014) assessed stress perceptions and four indicators of diurnal cortisol (AUC, awakening, afternoon/evening, and CAR levels) on 12 different days over six years. When considering absolute levels of stress across participants, optimism was associated with a reduced CAR among those experiencing high stress levels. Compared to pessimists, optimists were protected against elevations in cortisol AUC, awakening levels, and afternoon/evening levels on days they perceived higher-than-average stress levels (Jobin, Wrosch, & Scheier, 2014). Conversely, in a double-blind, randomized study, Koelsch et al. (2016) exposed 143 participants to a CO_2 stress test (inhalation of 35% CO_2) and measured the impact of positive mood-inducing music on cortisol recovery. They found that compared to a neutral music control group the music intervention was associated with more positive mood and stronger cortisol responses to the acute stressor. The authors suggest that the lower cortisol among those with more negative mood is associated with a suboptimal (i.e. less robust) stress response, similar to HPA hypoactivity observed in patients with depression (Koelsch et al., 2016). The differences in the results of these two studies also illustrate the nuances associated with different types of analyses. In the context of acute stressors, a robust response is often linked to favorable outcomes, whereas in the context of daily function higher levels of cortisol typically indicate greater ongoing stress and poorer outcomes.

Overall, cortisol is a sensitive biomarker of psychological experience. Although a relatively recent line of work, research on positive psychological functioning and cortisol suggests that cortisol regulation

may be one biological pathway by which well-being has its beneficial effects on health. This effect is seen in direct links between markers of positive psychological functioning (e.g. positive affect; optimism) and daily cortisol regulation. Well-being also buffers the impact of adverse experiences.

Dehydroepiandrosterone (DHEA). The steroid hormone DHEA (and its longer lived sulfated form, DHEA-S) is one of the most abundant circulating steroids. Like cortisol, the majority of DHEA is produced and secreted by the adrenal cortex under the control of adrenocorticotropic hormone (ACTH). In addition to functioning as a metabolic intermediate in the synthesis of sex steroids and as an androgen in its own right, DHEA binds to and activates receptors of neurotrophins like nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) with high affinity, and is thus capable of signaling neurons to survive, differentiate and grow (Lazaridis et al., 2011; Prough, Clark, & Klinge, 2016). DHEA levels begin to decline in the early thirties at a rate of about 5% per year – DHEA is sometimes referred to as the "anti-aging" hormone – although the decline is highly variable and is driven by unknown factors. The various negative effects of this age-related decline are particularly robust in women, since DHEA is their only source of sex steroids after menopause. Such a decrease in DHEA-derived sex steroid availability could be partially responsible for numerous symptoms of hormone deficiency observed after menopause, including vaginal atrophy, bone loss, fat accumulation, type 2 diabetes, skin atrophy, cognition problems, memory loss, and possibly Alzheimer's disease (Labrie, 2007, 2010).

Observational studies associating DHEA(S) levels with various measures of well-being have been conducted primarily among older adults (Berr, Lafont, Debuire, Dartigues, & Baulieu, 1996; Lebrun et al., 2006; Petros, Opacka-Juffry, & Huber, 2013). Along with other physiological outcomes, Berr and colleagues (1996) found that among 622 community-dwelling adults aged over 65 years, DHEA levels were significantly lower in females with depressive symptoms, poor subjective health, and poor life satisfaction. A later study involving 402 post-menopausal women aged 56-73 years found that none of the hormonal parameters measured, including DHEA and DHEA-S, were related to quality of life (Lebrun et al., 2006). In an opportunistic sample of 32 individuals (63% women; mean age 29), Petros and associates (2013) found that salivary DHEA-S and resilience were positively associated after adjustment for age and sex. However, well-being was not significantly correlated with DHEA-S, cortisol, or the DHEA-S/cortisol ratio (Petros et al., 2013). These studies suggest that lower levels of DHEA(S) may be indicative of lower levels of well-being, although the results to this point are limited and mixed.

The potential importance of DHEA to health in older age has led to a number of studies aimed at boosting DHEA levels by supplementation. These studies provide the opportunity to examine the consequences of the manipulation of DHEA for well-being. The duration of administration in most placebo-controlled supplementation studies range from 7 days to 4 months. A 3-month randomized, double-blind placebo cross-over DHEA replacement trial among 30 men and women (aged 40-70 years) resulted in restoration of DHEA levels to those of young adults, a 2-fold increase in androgens in women and a small rise in androstenedione for men. These were accompanied by increased perceptions of physical and psychological well-being in men (67%) and women (84%) after 12 weeks, including improved sleep quality, feeling more relaxed, and having increased energy to better handle stress, as reported in open-ended questions (Morales, Haubrich, Hwang, Asakura, & Yen, 1998). Another randomized double-blind cross-over trial in men aged 62-76 found no significant differences in well-being between treatment and control groups in a 13-week DHEA supplementation trial. However, correlation analyses showed that higher morning DHEA levels were associated with lower confusion, while higher evening levels were associated with lower anxiety and lower current negative mood in the morning (van Niekerk, Huppert, & Herbert, 2001). These are relatively short administration periods, and studies assessing the impact of DHEA supplementation across longer periods of time are rare. As part of a 1-year DHEA supplementation trial in 225 men and women aged 55-85, cognitive functioning, life satisfaction, and quality of life were measured at 3, 6, and 12 months. This study found increases in cognitive function in the treatment group compared to the placebo control. Depression scores also decreased in both men and women. Women additionally showed increases in life satisfaction (Kritz-Silverstein, von Muhlen, Laughlin, & Bettencourt, 2008).

DHEA supplementation also has effects on brain regions relevant for well-being. A study involving 24 healthy young men (aged between 18 and 40 years), examined the impact of 7 days of DHEA supplementation on episodic memory and assessed potential neural correlates for its effects, specifically event-related potentials (ERPs). DHEA administration led to reduced evening cortisol and improved mood and memory. The authors linked these results to neuronal recruitment in the steroid-sensitive anterior cingulate cortex (ACC) that may be involved in pre-hippocampal memory processing (Alhaj, Massey, & McAllister-Williams, 2006). This neuronal recruitment by DHEA may be of particular importance to the issue of well-being, as the ACC as well as the prefrontal cortex and insula have been implicated in the regulation of happiness and well-being (Berridge & Kringelbach, 2011; Lewis, Kanai, Rees, & Bates,

2014; Suardi, Sotgiu, Costa, Cauda, & Rusconi, 2016).

In addition to the direct effects of DHEA supplementation on well-being, researchers have also examined the role of DHEA supplementation as a buffer against the adverse effects of stress exposure. For example, in a study by Kudielka et al. (1998), 75 healthy older males and postmenopausal women participated in a 2-week double-blind, placebo-controlled study of DHEA supplementation. Afterwards, they underwent an acute psychosocial stressor, the Trier Social Stress Test (TSST). Women treated with DHEA showed similar ACTH stress responses to men, but they were significantly enhanced compared to women on the placebo. As noted above, robust responses to acute stressors are considered markers of health.

There may also be a 3-way association among stress, well-being, and DHEA-S. A recent study focusing on caregivers of individuals with dementia and use of adult daycare services examined salivary levels of DHEA-S and their relationships to positive mood and depressive symptoms in the caregivers. This study found that DHEA-S levels in caregivers were significantly higher on the days after the individuals for whom they were caring used daycare services. These results suggest potential restorative effects of a brief respite from providing care and thereby protection against the physiological effects associated with caregiving stress. Furthermore, DHEA-S levels co-varied with daily positive mood, but not with depressive symptoms (Zarit et al., 2014).

Overall, observational studies suggest that DHEA links specifically to well-being are more readily discernible among older adults than their younger counterparts. Randomized control trials involving DHEA supplementation generally suggest a positive impact of DHEA supplementation on well-being, although null findings have also been reported. One difficulty in comparing study results is variability in the experimental protocols used: DHEA dosage protocols and well-being measures assessed vary from study to study. Studies with comparable dosages of DHEA covering longer supplementation durations and wider age ranges may provide further information about age- and sex- and dose-specific associations. Likewise, a common set of well-being measures to compare across studies would be informative. Evidence also points to DHEA(S) acting as a buffer against acute stress or as a restorative agent during recovery from chronic stress, although the range of well-being measures assessed in these studies has been limited.

Catecholamines. Norepinephrine and epinephrine are the two main chemical messengers released from the adrenal medulla via sympathetic nervous system activation, and they are responsible for the so-called 'fight-or-flight' response to threatening environmental stimuli. [Note: While the adrenal medulla is the sole source of epinephrine in the periphery, norepinephrine is released in multiple other parts of the body from sympathetic neurons]. Generally their release initiates a cascade of physiological changes and mobilization of resources needed to respond to a stressor, including elevations in heart rate, cardiac output, blood pressure and blood glucose levels. Not surprisingly, given this role in the stress response, studies of links between well-being and catecholamines tend to focus on well-being as a modifier of hormonal reactivity and recovery following stressors.

A range of measures has been used to assess well-being in the context of autonomic function, the latter usually in response to an experimental stressor. For example, in participants of the Family Heart Study mentioned above, Brummett et al. (2009) found that during a sadness and anger recall protocol, positive affect was inversely related to the mean level of norepinephrine. However, positive affect was unrelated to reactivity or recovery after. The study of 90 newlywed couples focused on behaviors during a real-time marital conflict as predictors of epinephrine and norepinephrine responses, measured as the composite of hourly blood samples across the day. The tendency of husbands to withdraw from the conflict ('negative-withdrawal' pattern) was associated with higher norepinephrine levels in the wives, whereas more positive behaviors ('validation-facilitation' pattern) were associated with lower epinephrine levels (Kiecolt-Glaser et al., 1996). In the study by Koelsch and colleagues (2016), norepinephrine exhibited the fastest and strongest response to the CO_2 stress test. However, norepinephrine was not significantly different in the positive mood-inducing music stimulus group compared to the neutral control group. Further analyses, comparing those who increased and decreased mood in response to the stress, showed that positive mood did not affect norepinephrine response to or recovery from the CO_2 stress.

Cancer tumors are able to synthesize and release hormones, and one interesting area of study is the impact of the host environment on tumor hormone processes. In a clinical sample of 353 adult ovarian cancer patients, Davis et al. (2015) used latent factors to represent eudaimonic well-being (personal growth, purpose in life and self-acceptance), positive affect, and psychological distress, and assessed their relationship with norepinephrine levels in tumor samples. Increased eudaimonic well-being was related to reduced tumor norepinephrine levels (Davis et al., 2015).

Taken together, the studies associating epinephrine and norepinephrine with measures of well-

being are mixed, although there have been few such studies, and larger epidemiological studies that could provide information about broad, population-level patterns of association between circulating or experimentally-induced levels of catecholamines and diverse measures of well-being are lacking.

Sex Hormones

Steroidal sex hormones, also called gonadal hormones, are produced in the gonads, i.e. the testes and ovaries of males and females, respectively. Their synthesis is under the control of the hypothalamic-pituitary-gonadal (HPG) axis, and is crucial for the proper development and function of the body. Testosterone and estrogens, present at higher levels in males and females, respectively, control the expression and maintenance of secondary sex-specific characteristics, and regulate sexual differentiation and sexual behavior patterns.

Some studies have measured the psychological impact of testosterone replacement (usually to restore sexual function) in males with abnormally low levels of testosterone, for reasons of hypogonadism or marked declines with age (e.g. adrenopause). Such studies have documented increases in anger, hostility, and aggressive behavior, with variable effects (Bassil, Alkaade, & Morley, 2009). Among those with normal functioning (eugonadal) additional testosterone administration may have a minor impact on mood (O'Connor, Archer, & Wu, 2004). In females, the rise and fall of levels of estrogen with the menstrual cycle have been suggested to play a major role in the fluctuation of mood and emotions. Over the life cycle, the decline in estrogen levels among women (e.g. perimenopause and menopause) has been suspected to modulate the increased rate of depression and mood disorders, compared to men. While the underlying mechanisms are not known, evidence points to the neurological effects of estrogen, which are directly relevant to mood symptomotology (Wharton, Gleason, Olson, Carlsson, & Asthana, 2012). Varying levels of testosterone and estrogen are often examined in conjunction with sexually dimorphic phenomena. However, few studies have directly investigated their relationship with well-being. The following section discusses findings relevant to the correspondence of levels of these hormones and various measures of well-being.

Testosterone. Studies relating testosterone to well-being have focused on older adults, in part because there is a gradual, age-related decline of serum levels after age 30 (Bassil et al., 2009), and generally these studies have not found links between testosterone and well-being. Castanho et al. (2014), studying 120 Portuguese community-dwelling adults aged 51-87 years, identified four participant clusters based on performance in cognitive functioning (executive functioning, memory), depressive mood and well-being. These clusters were compared for their serum concentrations of various hormones, including testosterone. In males, higher testosterone was generally associated with lower odds of membership in the poorest performance cluster, characterized by poor cognitive functioning, low well-being, and high depression, although testosterone was not significantly associated with the well-being or quality of life measures for either sex (Castanho et al., 2014). An earlier study by Lebrun and associates (2006) among 402 post-menopausal women aged 56-73 years did not find an association between testosterone levels and health-related or general life satisfaction. Similarly, in 466 men aged 64-97 years from the Lieto Study, Eskelinen and associates (2007) found that total testosterone and free testosterone levels were associated with higher self-rated health after adjustment for age; however, these associations were no longer significant after further adjustment for body mass index (Eskelinen, Vahlberg, Isoaho, Kivela, et al., 2007).

In general, given the above studies, the evidence that testosterone is related to well-being among older adults is weak. Importantly though, there are relatively few studies of testosterone that have assessed well-being. There are also few studies involving younger samples (e.g. around the time when testosterone levels first begin their decline). Well-being might, for example, affect trajectories of changes in testosterone over time. In addition, other measures of well-being, such as eudaimonic well-being, positive affect, and optimism, have not been investigated thoroughly.

Estrogen. Changes in estrogen levels occur naturally throughout the life course, and fluctuations, sudden withdrawal, or sustained deficits in estrogen have been linked with significant mood disturbance. Studies specifically examining the link between estrogen and well-being are inconsistent and appear to implicate lower estrogen levels in the progression of negative mental health instead of improvements associated with higher levels.

In their study of Portuguese community-dwelling adults, Castanho and colleagues (2014) found that in males lower levels of estradiol (a major form of estrogen) predicted significantly higher odds of membership in the poorest performance cluster, characterized by poor cognitive functioning, low well-being, and high depression. In the individual linear regression analysis, estrogen was not significantly associated with the well-being or quality of life measures (Castanho et al., 2014). Lebrun and associates (2006) failed to find an association between estrogen and health-related or general life satisfaction in post-menopausal women. However, there was a negative relationship between estrogen and health, seen only in

the highest quintile of estrogen. This association was no longer significant after adjustment for fat mass (Lebrun et al., 2006).

Estrogen appears, at least in older adults, not to be directly related to well-being. There may a sex-dependent association, whereby males generally perform worse than females with lower levels of estradiol. However, this association does not appear to be specific to well-being, but more likely reflects an overall reduction in mental functioning. There have been few observational studies of estrogens that include measures of eudaimonic well-being, optimism, or positive affect; such efforts would complement existing findings and allow for meaningful comparisons across studies.

Metabolic Hormones

Metabolism refers to a complex network of continuous biochemical processes that allow for the efficient breakdown of food into energy for carrying out activities of daily life (catabolism) or for conversion into usable components for building and repairing the body (anabolism). In addition to age, sex, body composition, diet, and physical activity, metabolism is greatly influenced by hormone function. Metabolic hormones, such as growth hormone, insulin, insulin-like growth factor, and thyroid hormones, provide signals that regulate catabolic and anabolic processes within the body. The structure provided by anabolic processes supports the proper functioning of the body. Consequently, dysregulation of metabolism can be associated with a wide range of diseases and disorders. For example, abnormal cellular structure and function of neuronal circuits in the brain has been implicated in the development and progression of neuropsychiatric disorders, including neurodegenerative diseases like Alzheimer's. Importantly, these disorders frequently co-occur with metabolic disturbances, such as insulin resistance, diabetes, and obesity (McIntyre, Mancini, & Basile, 2001). Individuals with major mental illnesses, such as schizophrenia and bipolar disorder, also have an increased prevalence of metabolic syndrome (Newcomer, 2007). Although, associations among these populations may be due to non-disease-related factors such socioeconomic status or adverse metabolic side effects from medications. In non-clinical populations, these metabolic hormones are likewise suggested to have an impact on cognitive functioning and mood. These observations highlight the potential role of metabolism in general well-being.

Insulin-like growth factor 1 (IGF-I). Insulin-like growth factor is a hormone whose production is regulated by growth hormone, nutrition, and insulin. These insulin-like peptides are involved in a variety of biological activities, including neuronal survival, neurogenesis, angiogenesis, excitatory and inhibitory neurotransmission, regulation of food intake, and cognition (Werner & LeRoith, 2014). Across the life course, IGF-I follows an age-dependent pattern with serum levels peaking around puberty and declining thereafter with increasing age. Most IGF-I in the blood is produced by the liver (Roelfsema & Clark, 2001). The majority of studies involving IGF-I and well-being are among individuals with growth hormone deficiency undergoing growth hormone replacement therapy. The few studies in non-deficient populations suggest an association between IGF-I (and its binding proteins) and well-being.

In a study of individuals aged 20-74, Unden and associates (2002) measured several domains of well-being (social well-being, mental well-being, self-esteem, social support, and self-rated health) and found that they were positively correlated to IGF-I in those aged 20-44 years. Overall, age was found to account for 40% of the variation in IGF-I levels. In multivariate analyses controlling for this decline with age, social well-being was important in predicting IGF-I concentrations in the younger age group. In the older two age groups (i.e., 45-59 years and 60-74 years), associations were limited to physical factors, such as sex hormone binding globulin, low density lipoprotein, and lipoprotein(a), as well as education and physical health (Unden, Elofsson, Knox, Lewitt, & Brismar, 2002). These results suggest that in older adults age-related changes in health and physical function may dominate and diminish the potential links between psychosocial factors and IGF-I. Of note, these analyses were completed using stepwise selection of independent variables for the linear regression model. This variable selection method has since been found to have inherent reliability issues (Whittingham, Stephens, Bradbury, & Freckleton, 2006). However, this null association was also observed in the above study by Lebrun and colleagues (2006) that found no consistent associations of well-being with IGF-I, nor with two major binding proteins, among the post-menopausal women. More recently, Emeny et al. (2014) found that among 985 Cooperative Health Research in the Region Augsburg (KORA) study participants aged 64-93 years, IGF-I was inversely associated with well-being and directly linked to depressive symptoms in women. On the other hand, the binding protein IGFBP-3 was positively associated with well-being in women. IGFBP-3 serves to shuttle IGF-I around the body, but its affinity for the IGF receptor means that it may also act as an antagonist, preventing IGF from binding and causing changes within the cell (hence the opposing effects of IGF-I and IGFBP-3 in this study). There were similar trends in men, but not statistically significant (Emeny et al., 2014). This study suggests that the previous studies may have failed to observe an association in older adults because it may be sex-specific. Further studies using the quality of life instruments utilized in these earlier studies with stratification by sex would be needed to confirm this possibility.

Overall, these findings show that in older adults, IGF-I may be inversely associated with well-being, while levels of its binding protein (IGFBP-3) were directly related to well-being. Importantly, these associations may be limited to older females. The menopausal status of these women may also be an important discriminating factor for these associations.

Insulin. Insulin is a peptide hormone produced by beta (β) cells of the pancreatic islets. Insulin helps to regulate the metabolism of carbohydrates, fats, and protein by promoting the absorption of glucose from the blood into fat, liver, and skeletal muscle cells. Under normal physiological functioning, the release of insulin into the circulation is closely linked to glucose concentrations in the blood. High glucose concentrations stimulate β cells to secrete insulin. Conversely, low glucose levels inhibit the secretion of insulin (Sonksen & Sonksen, 2000). Like steroid hormones, insulin can cross the blood-brain barrier where it appears to play an important role in neuronal survival (Werner & LeRoith, 2014). Research linking insulin levels and well-being has largely investigated the effect of insulin therapy either directly on mood or as a buffer of stress. These studies have generally found that intranasal insulin improves mood and attenuates HPA reactivity to social stress (Lee, Zabolotny, Huang, Lee, & Kim, 2016).

Observational studies have generally reported inverse associations between insulin levels and well-being. Oreskovic and Goodman (2013) investigated the relationship between dispositional optimism and insulin levels measured 6-7 years later among adolescents aged 12-19 years. In bivariate analyses, insulin was negatively correlated to scores on optimism and positively correlated with scores on pessimism. In analyses adjusted for a range of potential confounders, an inverse association was found among non-Hispanic black, but not white adolescents, whereby a one unit increase in unidimensional optimism corresponded to 2.2% lower insulin levels (Oreskovic & Goodman, 2013). A study of 402 post-menopausal women found that insulin was not related to health-related life satisfaction. There were negative associations between insulin and life satisfaction which were present only in the highest quintile of insulin, but these were attenuated by adjustment for fat mass (Lebrun et al., 2006).

Lee et al. (2016) recently summarized the results of numerous experimental studies involving insulin administration to human and animal subjects. A set of four studies specifically examined the impact of intranasal insulin on well-being and psychological responses to stressors, including social evaluative stress. The studies have generally found that intranasal insulin improved mood and attenuated HPA reactivity to social stress (Lee et al., 2016).

Thyroid hormones ($TSH/T_4/T_3$). Thyroid stimulating hormone (TSH) is an integral part of the hypothalamic-pituitary-thyroid axis. Specifically, the hypothalamus releases thyrotropin-releasing hormone (TRH) to stimulate the anterior pituitary to produce TSH. TSH then stimulates the thyroid gland to produce thyroxine (T_4), which is in turn converted to active triiodothyronine (T_3). T_3 affects almost every physiological process in the body, including growth and development, metabolism, body temperature and heart rate. T_3 and T_4 levels provide negative feedback to the hypothalamus and pituitary gland to regulate the release of TRH and TSH, respectively.

Alterations in the levels of thyroid metabolites occur normally with age and are also present in conditions that often result in lower levels of thyroid hormones (hypothyroidism), such as Hashimoto's Thyroiditis, thyroidectomy, or other thyroid deficiency. In non-patient populations, subclinical hyperthyroidism is characterized by lower-than-normal TSH in the presence of normal levels of free thyroxine (fT_4). Subclinical hypothyroidism is characterized by elevated TSH in the presence of normal fT_4. Subclinical hypothyroidism is often accompanied by increased levels of thyroid autoantibodies (thyroid peroxidase; anti-TPO).

Thyroid hormone status has predominantly been studied in relation to depression. Whereas most of the patients with primary depression have normal thyroid function, some patients with hypothyroidism or hyperthyroidism manifest features of depression, the latter presenting with a wider spectrum of neuropsychiatric symptoms (Hage & Azar, 2012). However, some studies have investigated the relationship of thyroid hormones with health-related quality of life (HR-QOL) and well-being, though not all studies are in agreement. Comparing 93 Hashimoto's Thyroiditis patients with 31 euthyroid (normally functioning thyroid) controls, Yalcin et al. (2017) found that depression and anxiety scores were higher and scores on subscales of the SF-36 (physical functioning, general health, and mental health) were lower in the patients. Larger studies outside of clinical populations tend not to find any associations of TSH and T_4 levels with life satisfaction, self-rated health, and quality of life in healthy control populations, nor any differences in those with hypothyroidism undergoing thyroxine replacement therapy (Eskelinen, Vahlberg, Isoaho, Lopponen, et al., 2007; Kelderman-Bolk, Visser, Tijssen, & Berghout, 2015). In a large study of 9,491 individuals of the LifeLines Cohort Study aged 18-90 years old, Klaver et al. (2013) compared to

euthyroid individuals, there was no difference between those with elevated or suppressed TSH or fT_4 levels in HR-QOL. There was a sex-specific effect whereby women with suppressed TSH scored significantly lower on domains of 'physical functioning' and 'general health' compared to euthyroid women (Klaver et al., 2013). Similarly, a later study among 8,214 Danish General Suburban Population Study participants aged 20 or older (55 years on average) found no difference in well-being between subclinical hypothyroidism and euthyroid individuals with or without high levels of anti-TPO. One exception is that euthyroid women with high anti-TPO had better well-being than euthyroid women with anti-TPO in the reference range; although this association may have arisen by chance (Fjaellegaard, Kvetny, Allerup, Bech, & Ellervik, 2015).

The literature on links between thyroid hormones and well-being generally show associations in the expected directions, but as with catecholamines, more large-scale studies are needed to document population-level associations.

Other Hormones

The hormones discussed below include posterior pituitary hormones, oxytocin and vasopressin, and prolactin. These hormones are important messengers that potently influence inter-personal interactions, including in-group affiliation and out-group discrimination, mating preferences and pair-bonding, parental behavior, and pro-social behavior (Olff et al., 2013; Shamay-Tsoory & Abu-Akel, 2016; Sobrinho, 1991; Walum et al., 2008), and as such may have considerable bearing on social well-being. These hormones also coordinate a number of other processes important for physiological and mental health, such as pain perception, wound healing, and reward circuits in the brain. Thus, these hormones may work across multiple levels to impact the subjective experiences of the individual.

Oxytocin. Oxytocin is a neuropeptide produced by the hypothalamus and stored in the posterior pituitary where it is released into the circulation. It can also be released from specific neural projections to other structures in the brain where it modulates the activity of other neurochemical systems. In addition to its physiological role during pregnancy – increasing uterine tone, promoting uterine contractions, and inducing labor – oxytocin is also involved in maternal bonding, sexual behavior, and affiliation (Ishak, Kahloon, & Fakhry, 2011). Recently, oxytocin administration has gained increased attention for its ability to promote positive social behavior and stress regulation, and for its potential as a therapeutic intervention for alleviating symptoms of various psychiatric disorders. However, the observed effects are not uniformly beneficial. Accumulating evidence suggests that contextual and inter-individual factors, such as presence of a stranger versus a friend, sex, attachment style, or the presence of psychiatric symptoms, moderate the effects of oxytocin, as well as absolute levels in the periphery (Olff et al., 2013). Specifically, these factors are thought to interact with oxytocin to influence the salience of social and environmental cues. Depending on the context, oxytocin can induce pro-social, anti-social or even aggressive behavior (De Dreu, 2012; De Dreu, Greer, Van Kleef, Shalvi, & Handgraaf, 2011; Shamay-Tsoory & Abu-Akel, 2016). Thus, oxytocin effects are not uniformly pro-social, as has been thought (it has been popularly referred to as the "cuddle" hormone), but rather is highly sensitive to social context.

Studies specifically relating oxytocin to well-being are rare. Those that have been done have tended to focus on the potential beneficial effects of intranasal administration. There is also interest in the oxytocin receptor, which has a number of polymorphisms that may be linked to well-being to different degrees. Barraza et al. (2013) studied the impact of 10 daily doses of intranasal oxytocin on mood among 41 residentially housed older adults (mean age of 80) in a randomized, double-blind, placebo-controlled study. No changes in mood were observed across the 10-day period. However, dispositional gratitude improved in the treatment group compared to controls. Saphire-Bernstein and colleagues (2011) investigated the link between the oxytocin receptor genotypes (with or without the A allele) and psychosocial resources (optimism, mastery, self-esteem) among 344 university students and employees aged 18-36 years. This study found that carriers of the A allele had lower levels of these resources, compared to G/G homozygotes. These resources were also found to mediate the relationship between oxytocin receptor type and depression (Saphire-Bernstein, Way, Kim, Sherman, & Taylor, 2011). These findings are in line with an earlier study by Lucht et al. (2009) among 285 adults that found individuals with the oxytocin receptor A/A genotype had lower scores for positive affect. However, this effect was only observed in males (Lucht et al., 2009).

Oxytocin has also been suggested to predict positive affective responses to acute socio-evaluative stress. Using the TSST among 172 participants aged 18-35 years, Moons, Way, and Taylor (2014) found that post-stress oxytocin levels interacted with oxytocin receptor polymorphisms to predict positive affective responses to the stressor. This effect was sex-specific whereby higher levels of oxytocin in females with the G/G genotype had more positive affect compared to the carriers of the A allele (Moons et al., 2014).

Anti-diuretic hormone/arginine vasopressin (ADH/AVP). Vasopressin is a hormone released from the posterior pituitary gland. Release of vasopressin in the blood increases water retention in the body, and in higher concentrations, produces vasoconstriction. Vasopressin also acts on reward circuits in the brain to promote pair-bonding behavior during partner preference formation in prairie voles. Similar effects of vasopressin receptor activation have been found in studies of marital discord in men (Walum et al., 2008). Studying the impact of intranasal vasopressin administration on musical working memory, Granot and associates (2013) found that compared to those in the placebo group, those receiving vasopressin had higher scores on happiness (Granot, Uzefovsky, Bogopolsky, & Ebstein, 2013). Moons et al. (2014) found an interaction between vasopressin and its receptor in predicting anger responses to the TSST. This effect was gender-specific whereby men, but not women, with high post-stressor vasopressin levels who were also carriers of a particular vasopressin receptor polymorphism had more post-stressor anger compared to non-carriers (Moons et al., 2014).

Prolactin. Prolactin is a potent hormone secreted mainly from the anterior pituitary gland with a broad range of biological effects, including water and salt balance, breast milk production, cell proliferation and differentiation, T-cell immunity, pancreatic β cell function, hematopoiesis, and adipogenesis. It acts via binding to prolactin receptors and cytokine-like receptors located in many tissues throughout the body (Bole-Feysot, Goffin, Edery, Binart, & Kelly, 1998). Creative approaches have been used in the study of prolactin responses to stressors. In one study, for example, women with anger responses to hypnosis-evoked experiences of humiliation showed elevated prolactin (Sobrinho, 2003). Additionally, more passive coping mechanisms in real-life situations have been associated with chronic elevations in prolactin (Sobrinho, 1991, 2003).

Studies assessing levels of prolactin and measures of well-being are limited. Castanho et al. (2014) found sex-specific associations among 120 Portuguese participants aged 51-87 years. In males, higher prolactin was associated with higher odds of membership in the poorest performance cluster, characterized by poor cognitive function, higher depression and lower well-being, compared to the best performance cluster. Similarly, in males only, linear regression analyses showed that higher prolactin predicted less depressive mood and greater well-being (Castanho et al., 2014). Kiecolt-Glaser et al. (1996) also measured prolactin among 90 newlywed couples during marital conflict and found that the more positive 'validation-facilitation' behavior pattern, but not the 'negative-withdrawal' pattern, was associated with higher prolactin levels, in women only. No such associations between the behavior patterns and endocrine responses during marital conflict were observed in the men.

Conclusion

The existing literature points to associations of some, but not all, hormones with well-being that are not merely the mirror image to those of ill-being. There are some features of the current literature that limit the conclusions we can draw about the relationship between hormones and well-being. First, the measures of well-being used across the above studies are diverse – some focused on emotions, others on meaningful engagement with life pursuits, others on optimism – and not all are used in any single study. Null findings in particular are thus difficult to interpret: is there no association with well-being, or with the specific measure of well-being used in a specific study? Second, the impact of basic but influential characteristics, such as age and sex, has not been considered explicitly in most studies and may have marked consequences for the outcomes studied. Even if there is a robust association between a particular hormone and well-being, it may change with age, for example, along with normative changes in biological functioning. Moreover, for many of the hormones considered here there has been evidence of sex-specific associations that should be clarified and replicated in future studies. Third, there are still open questions regarding the nature of the hormones themselves. In particular, the complexity of diverse cortisol assessments (c.f. Clow, Hucklebridge, Stalder, Evans, & Thorn, 2010) necessitates the systematic testing of the links between positive functioning and these measures. It may not be reasonable to expect that all of these different measures of cortisol will be linked to the same aspects of well-being to the same degree. Lastly, this chapter has considered studies looking specifically at the association of single isolated hormones with well-being. It is well-known that these hormones all have some degree of stimulatory or inhibitory function in relation to other hormones. For example, testosterone has been found to enhance the effects of growth hormone (Meinhardt & Ho, 2006) and norepinephrine to strongly inhibit insulin release (Nakaki, Nakadate, & Kato, 1980). There are practical reasons that no studies have included measures of all these various hormones and investigated their interactive associations with well-being, but the existence of such complexity must be acknowledged and assessed wherever possible. The few studies that did assess multiple hormones in a single sample did not specifically investigate their interactions in predicting well-being, but the results nonetheless suggest that complex interactions may exist with sex-specific effects (Castanho et al., 2014; Kiecolt-Glaser et al., 1996; Lebrun et al., 2006).

In sum, research on the associations between hormones and well-being appears to be in its infancy

compared to the vast body of work characterizing hormone associations with ill-being (e.g., depression, stress). Thus, this represents a fertile area of research with great promise to illuminate the physiological pathways by which well-being affects physical and mental health.

A Lifespan Perspective on Subjective Well-Being

By Jennifer E. Lansford, Duke University

Citation
Lansford, J. E. (2018). A lifespan perspective on subjective well-being. In E. Diener, S. Oishi, & L. Tay (Eds.), *Handbook of well-being*. Salt Lake City, UT: DEF Publishers. DOI:nobascholar.com

Abstract

This chapter provides a lifespan perspective on subjective well-being. First, evidence for stability and change in subjective well-being across the lifespan is considered with attention to both set-point theory and evidence regarding whether life events and choices can alter individuals' well-being in the long-term. Next, the chapter describes mean levels of cognitive and affective components of well-being and considers predictors and consequences of well-being at different points in the lifespan, including gender, culture and country, and socioeconomic factors that are important for the understanding of well-being. The chapter then summarizes aspects of cognitive and social development that affect subjective well-being from infancy to childhood, adolescence, early adulthood, middle adulthood, and late adulthood. Finally, the chapter suggests directions for future research.

Keywords: Infancy, Childhood, Adolescence, Adulthood, Lifespan, Subjective Well-Being

Subjective well-being is often conceptualized as encompassing meaning and purpose in life; life satisfaction; and feelings of happiness, sadness, and other positive and negative emotions (Kahneman, Diener, & Schwarz, 1999). Together, these components capture both cognitive and affective aspects of well-being (Diener, Lucas, & Scollon, 2006). This chapter begins with an overview of evidence for stability and change in subjective well-being across the lifespan and then describes mean levels of different aspects of well-being during specific life stages. The chapter then summarizes predictors and consequences of well-being that are applicable across the lifespan as well as specific to particular developmental stages and attends to gender, country or culture, and socioeconomic status, which are important considerations in the study of well-being. Next, the chapter traces the development of well-being from infancy through early childhood, middle childhood, adolescence, early adulthood, and middle adulthood to late adulthood, with a particular focus on factors related to cognitive and social development in each life stage that have implications for subjective well-being. The chapter concludes by suggesting directions for future research.

Stability and Change in Subjective Well-Being across the Lifespan

Theory and empirical research suggest evidence for both stability and change in subjective well-being across the lifespan (Sheldon & Lucas, 2014). Stability is promoted by heritability and personality correlates such as neuroticism and extraversion, which have been found to be stable over long developmental periods, especially after age 30 (McCrae & Costa, 1994, but see Roberts, Walton, & Viechtbauer, 2006, for an alternative perspective). Furthermore, individuals' environments are also largely stable over time, promoting stability in well-being as well. Change can be brought about by environmental stressors or welcome events (Clark, Diener, Georgellis, & Lucas, 2008) in addition to choices about one's life goals and priorities, time spent working and in leisure, healthy lifestyle, social participation, religion, and intimate partners (Headey, Muffels, & Wagner, 2010).

On the one hand, set-point theories of well-being suggest that because of genetic (Lykken & Tellegen, 1996) and personality predispositional (Headey & Wearing, 1992) factors, subjective well-being is stable over the long term. There is some evidence for homeostatic adaptation, meaning that because of genetically programmed dispositions for a set level of happiness, individuals tend to bounce back to this preset level, even after major positive or negative life events (Cummins, 2010). Although transitory factors as minor as the weather might influence individuals' reports of subjective well-being (Schwarz & Strack, 1999, but see Lucas & Lawless, 2013, for evidence to the contrary with respect to reports of life satisfaction), well-being is influenced by temperament and personality in addition to life circumstances. In studies that have compared the stability of well-being in individuals going through major life changes such as divorce or widowhood (e.g., Costa, McCrae, & Zonderman, 1987) or increases or decreases in income (Diener, Sandvik, Seidlitz, & Diener, 1993), changes in well-being have been brought about temporarily by major life events but then return to a baseline level after a brief adjustment period. Stability characterizes reports of positive and negative affect in addition to life satisfaction and is found even when different people report on a target individual's affect at different time points (Costa & McCrae, 1988).

On the other hand, subjective well-being is less stable than personality over time (Fujita & Diener, 2005). In a 17-year longitudinal study, 24% of respondents experienced a significant change in life satisfaction from the first five years to the last five years of the study (Fujita & Diener, 2005). Even after several years, individuals do not always bounce back following major life events such as widowhood (Lucas, Clark, Georgellis, & Diener, 2003) and unemployment (Lucas, Clark, Georgellis, & Diener, 2004). Individuals may also differ in the extent to which they return to set points of well-being after positive or negative life events. For example, marriage increased the life satisfaction of a subgroup of individuals over the long-term but decreased the life satisfaction of a different subgroup of individuals over the long-term; attending just to population averages may falsely inflate the apparent stability of life satisfaction because individual differences would be masked (Lucas et al., 2003). In a longitudinal study of a nationally representative sample of German adults assessed annually from 1984 to 2008, personal and economic choices were related to long-term changes in life satisfaction, contradicting set-point theory (Headey et al., 2010).

Life satisfaction may be less stable than positive and negative affect over time to the extent that the former relies on cognitive evaluations of one's present circumstances, whereas affect may be more strongly related to personality traits such as neuroticism and extraversion. Support for the differential stability of these different aspects of well-being was found in a meta-analysis of longitudinal studies that examined both cognitive and affective well-being in relation to eight family and work related life events (marriage, divorce, bereavement, child birth, unemployment, reemployment, retirement, and relocation/migration; Luhmann, Hofmann, Eid, & Lucas, 2012). Affective well-being generally returned more quickly to baseline than did cognitive well-being, although the magnitude of the change and rate of adaptation depended on the specific event. Furthermore, there was more variability in the effects of life events on affective well-being than cognitive well-being (Luhmann et al., 2012), perhaps because affective well-being is more strongly related to personality, social support, coping strategies, and emotional regulation that may affect how individuals adapt to life events (Diener et al., 2006).

Mean Levels of Well-Being at Different Ages

In comparisons of well-being at different ages, a frequently described pattern is characterized by a U-shaped curve in which well-being is higher earlier and later in the lifespan than during mid-life, a pattern that holds for life satisfaction as well as positive emotions and lack of negative emotions (Stone, Schwartz, Broderick, & Deaton, 2010). The Gallup World Poll conducted in over 160 countries, however, suggests that this pattern is most common in high-income countries, with the nadir of well-being in the range of 45 to 54 years. By contrast, in sub-Saharan Africa, few mean differences in well-being are found at different ages, and in Latin America and Eastern Europe, well-being decreases progressively with age (Steptoe, Deaton, & Stone, 2015). Different components of well-being also show somewhat different patterns with age. For example, anger and stress decrease after early adulthood, and worry decreases after middle adulthood, so by later adulthood negative affect is low (Stone at al., 2010).

Mean level changes with age are not inconsistent with demonstrations of stability in well-being over the lifespan. Stability and change can come in different forms. For example, rank-order consistency refers to how individuals in a group compare to one another over time, whereas mean-level change refers to whether individuals, on average, increase or decrease on a particular dimension over time (Roberts et al., 2006). Thus, even if there are developmental patterns whereby adults during mid-life, on average, have lower well-being than they do at earlier or later points in the lifespan, the happiest children may remain the happiest teenagers and the happiest adults, reflecting rank-order consistency as well as normative developmental change. Test-retest stabilities in global self-reported well-being are approximately r = .70, .60, .50, and .35 over 1-, 2-, 5-, and 10-year intervals with a lower-bound of approximately .20 to .35 over longer intervals (Anusic & Schimmack, 2016; Schimmack & Oishi, 2005). Average changes in mean levels of well-being with age, of course, do not necessarily reflect the experience of everyone in the group. For example, although negative affect decreased from adolescence to early adulthood for most individuals, a subgroup increased in negative affect (Roberts, Caspi, & Moffitt, 2001).

Predictors of Well-Being

Many predictors of well-being are consistent across the lifespan. For example, material deprivation, living in a dangerous neighborhood, and interpersonal violence are related to lower subjective well-being, whereas supportive family relationships and friendships are related to better subjective well-being for children and adults alike (e.g., Currie et al., 2012; Siedlecki, Salthouse, Oishi, & Jeswani, 2014). In representative samples from 155 countries, having social relationships, having a sense of purpose, feeling pride, and being treated with respect predict well-being consistently from early to late adulthood (Morrison, Jebb, Tay, & Diener, 2017). For children, living in a higher-income (and safer) neighborhood is related to more opportunities to play outside (Carver, Timperio, & Crawford, 2008), access to positive adult role

models (Galster, 2014), and freedom from the chronic stressors associated with crime and violence (Finkelhor, Turner, Shattuck, Hamby, & Kracke, 2015), all of which contribute to indicators of better well-being in both the short- and long-term. In a randomized housing mobility study, low-income adults who were randomly assigned to move from a low-income to a higher-income neighborhood showed improvements in subjective well-being 10-15 years following the move, even though the move did not affect personal economic self-sufficiency (Ludwig et al., 2012).

Other predictors of well-being are more salient at specific points in the lifespan. For example, being bullied is a more common experience during childhood and adolescence than during adulthood and, therefore, a more salient contributor to lower well-being earlier in life (Olweus & Breivik, 2014), although bullying in the workplace does occur during adulthood, predicting worse well-being for adults as well (Verkuil, Atasayi, & Molendijk, 2015). By contrast, romantic partnerships do not become developmentally normative until adolescence, at which point experiences in romantic partnerships begin predicting well-being (Collins, 2003). Having a job is a more important predictor of well-being in middle adulthood than in early or later adulthood (Morrison et al., 2017). Generativity (An, Cooney, & An, 2006) and wisdom (Ardelt, 2016) are important contributors to subjective well-being during later life. The link between behaving prosocially and subjective well-being strengthens from early to late adulthood (Morrison et al., 2017). Thus, predictors of well-being are sometimes tied to temporally proximal, developmentally salient experiences.

However, some experiences continue to predict well-being even years later. For example, physical, emotional, and sexual abuse during childhood have long-lasting detrimental effects on subsequent development (e.g., Draper et al., 2008). Adults who were abused as children are at greater risk for depression, anxiety, and other psychiatric disorders; have higher suicide rates; and report being less satisfied with their lives than do adults who did not experience childhood abuse (e.g., Fergusson, McLeod, & Horwood, 2013). Other adverse childhood experiences such as exposure to substance abuse in the home or having a mentally ill or incarcerated family member also can have long-term detrimental effects on well-being that persist into adulthood (Nurius, Green, Logan-Greene, & Borja, 2015). By contrast, warm, sensitive, responsive caregivers promote secure attachment relationships with their children, which can have protective effects throughout childhood, adolescence, and into adulthood (Schoenmaker et al., 2015). Social connections during adolescence are better predictors of well-being in adulthood than are academic achievements (Olsson, McGee, Nada-Raja, & Williams, 2013). The extent to which specific life events are related to long-term changes in subjective well-being depends on the event in question. For example, individuals adapt more quickly to marriage (Lucas et al., 2003) than to divorce (Lucas, 2005) or unemployment (Lucas at el., 2004).

In addition to life experiences, one's own choices can have long-term effects on well-being. Headey et al. (2010) identified several types of choices and preferences that are related to long-term changes in life satisfaction. Marriage to a partner low in neuroticism improves well-being over time, above and beyond an individual's own low neuroticism (Headey et al., 2010). Placing relatively greater emphasis on altruistic goals (helping other people and being involved in social and political activities) and family goals (having good relationships with one's spouse and children) over goals related to material success and one's own career predicts increases in life satisfaction over time, whereas prioritizing goals related to career and material success predicts decreases (Headey et al., 2010). For women, having a partner who prioritizes family goals also contributes to an increase in life satisfaction over time (Headey et al., 2010). Long-term increases in life satisfaction also are predicted by regular church attendance, working the desired number of hours per week rather than being over- or under-worked (with being under-worked having worse consequences than being over-worked), social participation with friends, and regular exercise (Headey et al., 2010).

Consequences of Well-Being

Well-being is an important outcome in its own right. In surveys of what adults desire for their children's futures, happiness is highly ranked across diverse countries (Diener & Lucas, 2004). The importance of subjective well-being has been recognized by governments around the world and has been added as an indicator of how nations are faring, along with more traditional measures of gross domestic product, infant mortality, and the like (Helliwell, Layard, & Sachs, 2017). Happiness is now regarded as an indicator of social progress at a national level, in addition to a desired outcome at an individual level.

Subjective well-being is also related to several other desired outcomes. Individuals higher in subjective well-being maintain better physical health and even live longer than individuals lower in subjective well-being (Diener & Chan, 2011; Diener, Pressman, Hunter, & Chase, 2017). In addition, better subjective well-being is related longitudinally to better outcomes in several domains such as higher educational achievement, better performance at work, and less work-family conflict (De Neve, Diener,

Tay, & Xuereb, 2013; Matthews, Wayne, & Ford, 2014; Suldo, Gormley, DuPaul, & Anderson-Butcher, 2014). Associations between subjective well-being and other aspects of adjustment are bidirectional and transactional over time. For example, well-being in one year predicts more community participation in the next year, and more community participation in one year predicts better well-being in the next year, controlling for continuity in both well-being and community engagement as well as potential confounds (Ding, Berry, & O'Brien, 2015). Taken together, previous research supports the conclusion that better well-being predicts future adjustment in other areas, even after controlling for prior adjustment in those areas.

Several studies have investigated mechanisms through which well-being could affect other outcomes. For example, in the education domain, brain imaging studies have demonstrated that positive emotions are related to more effective cognitive processing (Hinton, Miyamoto, & Della-Chiesa, 2008), which promotes success in school. Positive emotions also are related to more critical and flexible thinking, which helps students handle academic challenges (Fredrickson, 2001). Negative emotions such as anxiety and depression, by contrast, interfere with memory and efficiency of learning (see Valiente, Swanson, & Eisenberg, 2012). The "Broaden and Build" theory (Fredrickson, 2001) suggests that positive emotions promote academic success by encouraging exploratory, broadening thoughts, whereas negative emotions narrow students' focus, making them less engaged in school (Reschly, Huebner, Appleton, & Antaramian, 2008).

Taken together, extant findings suggest that consequences of well-being are tied to developmentally salient outcomes at particular points in the lifespan. For example, links between well-being and academic achievement are more salient during childhood and adolescence, whereas links between well-being and less work-family conflict are more salient during adulthood. Because early development sets the stage for later development, consequences of well-being during early childhood may be especially important for setting in motion developmental cascades predicting future well-being and positive outcomes in other domains (Masten & Cicchetti, 2010). Indeed, prevention science has demonstrated greater returns on investments made in early childhood than in later childhood or subsequent developmental periods (Heckman, 2006).

Sociodemographic Considerations in Relation to Subjective Well-Being across the Lifespan

Gender

In the adult literature, common findings are that women report higher life satisfaction than men but also more negative affect, including anxiety and depression (Senik, 2015; for a detailed discussion of gender differences in subjective well-being, see Batz & Tay chapter in this volume). Gender differences appear more pronounced at some points in the lifespan than others. Prior to adolescence, boys and girls have similar levels of well-being, but with the onset of puberty, gender differences begin to emerge, especially marked by increases in anxiety and depression for girls (Hankin & Abramson, 2001). Gender differences in well-being also have been reported in late adulthood. A meta-analysis of 300 studies found that in later life, women reported lower life satisfaction and happiness than men; the magnitude of the effects was small, accounting for less than 1% of the variance, but remained significant after controlling for widowhood, socioeconomic status, and physical health (Pinquart & Sörensen, 2001). Biological factors may account for some of the documented gender differences, but environmental factors such as gender equality at a societal level also play a role (e.g., Meisenberg & Woodley, 2015).

Culture or Country

International research has demonstrated that countries differ in their average level of subjective well-being and that subjective well-being is related to country-level factors such as individualism, equality, human rights, and income (Diener, Diener, & Diener, 1995). According to surveys conducted in 135 countries in 2013, countries in Latin America fare the best, and countries in sub-Saharan Africa fare the worst on a number of indicators of subjective well-being (Standish & Witters, 2014). Some of these differences have been attributed to cultural factors such as focusing on the positives in life in Latin America, and others may result from dire living situations involving civil war and extreme poverty (Standish & Witters, 2014).

Using data from representative samples of over 1.2 million adults in 155 countries, life satisfaction and negative affect were found to be slightly higher whereas positive affect was slightly lower in older than younger age groups (Morrison et al., 2017). However, there were regional differences. Compared to older adults in regions with negative attitudes toward aging, older adults in East and Southeast Asia, where older adults are more respected, showed levels of well-being more comparable to those of younger adults.

Indicators of subjective well-being have become an important part of assessing how countries are faring with respect to a wide range of factors that historically included primarily economic and physical health considerations (Helliwell et al., 2017). Historically, assessments of well-being at a national level

were based on external observations (e.g., poverty, material deprivation), but individuals who are poor can still be happy. Asking individuals to report on their own well-being provides a different perspective that may or may not align with external indicators. Assessing the subjective well-being of children and adolescents has become a way to give young people a voice and promote their participation rights (Martorano, Natali, De Neubourg, & Bradshaw, 2013).

Socioeconomic Status

Poverty and severe economic deprivation are related to low subjective well-being (Howell & Howell, 2008). There has been debate regarding whether there is a certain level of financial security beyond which additional economic resources do not predict further increases in well-being (see Stevenson & Wolfers, 2013). At a national level, after gross domestic product per capita exceeds $10,000, some research has reported that no additional increases in life satisfaction are found (Layard, 2005). For a family with an annual income of $10,000, an additional $10,000 would constitute a doubling of the family's financial resources for the year and have more substantial benefits in terms of being able to provide food security and pay for basic necessities, whereas a family with an annual income of $100,000 may also enjoy an additional $10,000, but this amount represents a smaller percent increase and would likely be used for more discretionary purposes rather than basic necessities. However, other research has not found a satiation point beyond which subjective well-being ceases to improve with further increases in income (Stevenson & Wolfers, 2013). As individuals' income rises, so do their expectations and reference points (Wolbring, Keuschnigg, & Negele, 2013). On a day-to-day basis, higher income is associated with more anger, hostility, anxiety, and tension, but not with happiness (Schnall, Schwartz, Landsbergis, Warren, & Pickering, 1998), perhaps in part because higher income is related to spending more time at work and in compulsory non-work activities that are related to tension and stress, but not with time in leisure activities that are related to happiness (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2006). The relation between income and well-being is stronger for cognitive (life satisfaction) than for emotional (happiness) measures of well-being (Howell & Howell, 2008).

Subjective Well-Being during Different Life Stages

Infancy

Underlying positivity or negativity may be expressed in similar or different ways at different ages. During infancy, negativity is generally reflected in descriptions of fussy or difficult temperaments, whereas positivity is reflected in descriptions of easy temperaments (Bates, Schermerhorn, & Petersen, 2014). Temperamental differences during infancy can persist into adulthood (Schwartz, Wright, Shin, Kagan, & Rauch, 2003). In the first year of life, infants do not yet have internal representations of mental states that are the foundation of cognitive aspects of subjective well-being (e.g., judgments regarding life satisfaction; Siegler, 2017). However, infants experience positive affect, as expressed through smiles, laughter, and positive vocalizations such as cooing, as well as negative affect as expressed through crying and fussing. Social smiles that begin in response to someone else's smile emerge between the age of four to eight weeks, and laughs begin by three to four months, increasing in frequency when interacting with familiar people by about six months (Gerber, Wilks, & Erdie-Lalena, 2010).

At this young age, caregivers play a more central role in emotion regulation than will be the case later in development. Sensitive caregivers will anticipate infants' needs to promote positive affect and will respond quickly to reduce negative affect. Through these interactions with caregivers, infants develop internal working models of relationships that set the stage for future interpersonal interactions (Bretherton & Munholland, 2008). Infants who have sensitive, responsive caregivers come to expect that their needs will be met by others and regard the world as a caring and reliable place; being securely attached to caregivers during infancy then predicts the development of more trusting social relationships in later developmental periods, including through late adulthood (Consedine & Magai, 2006). In contrast, infants whose emotional needs are not met by caregivers develop internal working models of relationships characterized by distrust, foreshadowing problems in future social relationships and decreasing well-being (Bretherton & Munholland, 2008).

Childhood

Cognitive developments during early childhood lead to the emergence of more sophisticated forms of subjective well-being as children become increasingly able to understand their own and other people's mental states. Theory of mind, which refers to the understanding that other people have thoughts and beliefs that can differ from one's own, typically emerges between the ages of three and four years. Although the development of theory of mind has advantages in terms of promoting children's perspective taking and ability to show empathy and provide support to others, the development of theory of mind is also associated with a decrease in self-esteem (Chaplin & Norton, 2015). Between early and middle childhood, children become increasingly self-critical as they develop a more nuanced perspective on their

own strengths and weaknesses relative to other people (Markus & Nurius, 1984).

During middle childhood, self-concept, self-esteem, self-efficacy, and self-worth emerge as increasingly important constructs (Harter, 2012), all of which are related to subjective well-being. These developing conceptions of the self all relate to cognitive aspects of well-being as children become more reflective and able to evaluate how they regard themselves and their lives. Play also has an important role in subjective well-being during childhood. Pretend play characterized by more emotion has been found to predict more subsequent life satisfaction and positive affect in real life, perhaps because through pretend play children are able to practice expressing and regulating emotions and coping flexibly (Fiorelli & Russ, 2012).

Beyond these cognitive and emotional developments, children who have positive relationships with family members and peers are also more satisfied with their lives and happier. As in infancy, parent-child relationships are among the most important predictors of well-being during childhood (Khaleque & Rohner, 2002). Dyadic friendships as well as acceptance (as opposed to rejection) by larger peer groups are important sources of fun and positive affect (e.g., Holder & Coleman, 2015). Thus, social relationships during childhood are directly associated with well-being because they provide opportunities for moment-to-moment enjoyment and positive affect as well as indirectly associated with well-being through mediators such as a sense of belonging and self-worth that enhance children's satisfaction with life. Social relationships continue to be importantly related to subjective well-being in adolescence and adulthood.

Adolescence

The onset of puberty marks the beginning of adolescence and a turning point in some aspects of subjective well-being. During adolescence, girls begin experiencing more negative affect than boys, which manifests in higher rates of internalizing disorders such as depression and anxiety that begin to emerge at this time and persist into adulthood (Nolen-Hoeksema & Girgus, 1994). As in childhood, relationships with parents and peers are related to well-being during adolescence, with friends becoming increasingly important confidantes (Markiewicz & Doyle, 2012). In addition, individuals often form their first romantic partnerships during this developmental period, with attendant risks and benefits for well-being (Collins, 2003).

Early theories and empirical studies focused on adolescence emphasized "storm and stress" characterized by conflict and negative emotions (for a review, see Arnett, 1999). However, the more recent positive youth development movement attends to more positive aspects of adjustment. For example, the Five Cs model focuses on caring/compassion, competence, character, connection, and confidence (Lerner, Almerigi, Theokas, & Lerner, 2005). During adolescence, character strengths that build connections to other people (e.g., teamwork, kindness) and that contribute to a sense of purpose beyond the self (e.g., love, meaning) are related to an increase in subjective well-being over time, including an increase in life satisfaction and a decrease in depressive symptoms (Gillham et al., 2011).

Early Adulthood

Early adulthood is characterized by major changes in family relationships as individuals transition from their families of origin to families of their own creation, yet relationships with parents continue to be related to well-being during early adulthood (Trzcinski & Holst, 2008). Intimate partnerships become increasingly important in early adulthood. A widely replicated finding is that men and women who are married are happier and more satisfied with life than non-married men and women (e.g., Waite & Lehrer, 2003). Even with marked demographic changes in the average age of marriage and the proportion of adults choosing to remain unmarried (e.g., Settersten & Ray, 2010), married individuals show better well-being than unmarried individuals in both low- and high-income countries, although the marriage benefit appears to be shrinking for men, particularly in high-income countries, as the life satisfaction of unmarried men has increased over time from 1981 to 2009 (Mikucka, 2016). Furthermore, despite these demographic changes, marriage continues to confer benefits for well-being that exceed those of cohabitation, although the difference is smaller in countries that are more accepting of non-traditional family forms (Vanassche, Swicegood, & Matthijs, 2013).

In addition to intimate partnerships, family formation during early adulthood often involves the transition to parenthood. Conclusions about how parenthood is related to well-being have been inconsistent and appear to depend largely on how the analyses are conducted (e.g., with or without control variables that differentiate who becomes a parent in the first place) and on who the reference group is (comparing parents to non-parents or comparing an individual to him or herself before and after becoming a parent). A meta-analysis of prospective longitudinal studies found that the transition to parenthood is associated with a decline in life satisfaction (particularly tied to a decline in satisfaction with the intimate partnership) but an increase in positive affect (Luhmann et al., 2012). After this initial transition, controlling for marital status, religion, income, education, and health, some research has found that adults who live with a child are less

satisfied with life and have higher levels of both positive and negative affect (Deaton & Stone, 2014). Other findings suggest that compared to non-parents, parents have higher levels of life satisfaction, moment-to-moment happiness, and feel more positive when taking care of their children than their daily average of positive emotion (Nelson, Kushlev, English, Dunn, & Lyubomirsky, 2013). However, these findings are moderated by gender, with men who are parents generally reporting more happiness than men who are not parents but no differences in happiness for women (Nelson et al., 2013), which the authors suggest may reflect the greater burden of housework and childcare experienced by mothers than fathers (Nomaguchi & Milkie, 2003). In addition, the findings depend on the circumstances of parenthood with individuals who were younger and unpartnered at the time they became parents reporting less satisfaction and happiness (but more meaning in life) than their counterparts who are not parents (Nelson et al., 2013).

Early adulthood also is characterized by education and work transitions related to completing schooling and joining the workforce, tasks that have become more prolonged in recent years than in the past (Settersten & Ray, 2010). Having employment problems that necessitate moving back in with parents is related to more depressed affect in early adulthood (Copp, Giordano, Longmore, & Manning, in press). In support of a value-as-moderator model, there is evidence that activities that are valued by an individual exert greater influence on well-being than activities that the individual does not value as strongly (Oishi, Diener, Suh, & Lucas, 1999). For example, receiving good grades at school is related to life satisfaction more strongly for individuals who place high value on achievement than for those who do not (Oishi et al., 1999). These findings suggest that in early adulthood, psychological well-being will be associated with engaging in roles and activities that have personal value and meaning.

Middle Adulthood

Middle adulthood is the time of life that is at the nadir of subjective well-being for individuals from high-income countries (Stone et al., 2010). At this time of life, individuals juggle many family, work, and community roles, contributing to stress and fatigue that can take their toll on well-being (Scheibe & Zacher, 2013). This developmental period is sometimes known as the "sandwich generation" to refer to the period roughly between the ages of 45 and 65 years in which adults are sandwiched between demands of caring for children and aging parents while still working in the paid labor force (Burke, 2017). Women continue to provide the majority of care to both children and aging parents, and providing extensive care is related to more depression and lower subjective well-being (Hammer & Neal, 2008). Demographic changes with an increase in the proportion of adult children who return home to live with their parents might also contribute to stress during middle adulthood. Relationships between parents in middle adulthood and their young adult children are generally positive, but parents feel more ambivalent about these relationships when their adult children are not attaining autonomy milestones (Fingerman, Cheng, Tighe, Birditt, & Zarit, 2012).

Late Adulthood

Subjective well-being is related to health and longevity (Diener & Chan, 2011), considerations that become especially salient later in life. In longitudinal analyses with an average follow-up of 8.5 years, controlling for demographic factors as well as baseline measures of physical and mental health, 29% of individuals in the lowest quartile of well-being died during the follow-up period compared to only 9% of individuals in the highest quartile (Steptoe et al., 2015). Well-being has been found to remain relatively stable during late adulthood until shortly before death, when it drops precipitously (Gerstorf, Ram, Goebel, Schupp, Lindenberger, & Wagner, 2010). The drop in well-being is more pronounced for individuals who die after the age of 85 (about three times as steep a decline in the four years before death than prior to that point) than for those who die between the ages of 70 and 84 (about two times as steep a decline), perhaps because of the accumulation of health problems and the loss of loved ones over a longer period of time (Gerstorf, Ram, Röcke, Lindenberger, & Smith, 2008).

Socioemotional selectivity theory posits that as individuals age, they selectively prune their social networks to focus on a smaller group of family members and friends to whom they are emotionally close rather than larger groups of acquaintances or individuals with whom they have distant or contentious relationships (Carstensen, Isaacowitz, & Charles, 1999). The theory has garnered considerable empirical support (for a review see Charles & Carstensen, 2010). Early in life when individuals perceive themselves as having a long future, they prioritize goals related to meeting new people, gathering information, learning new things, and maximizing achievement, whereas in late adulthood when individuals perceive their futures to be shorter, they prioritize short-term goals related to positive emotions and activities that are meaningful to them (Carstensen, 2006). Taken together, this body of research suggests that higher well-being during late adulthood is related to this narrowing of the social network and focusing on goals that promote positive affect.

Future Directions

As the study of subjective well-being advances, three directions for future research might be

especially useful. First, future research in neuroscience offers the potential to understand brain mechanisms involved in subjective well-being across the lifespan (see biology chapters in this volume). Early research in this area provides some intriguing insights into structural and functional aspects of the brain that could help delineate the neural underpinnings of well-being. For example, compared to adults not in a romantic relationship, adults with a romantic partner not only report more happiness but also show less gray matter density in the right dorsal striatum, a region of the brain important in processing social rewards (Kawamichi et al., 2016), suggesting one mechanism through which social relationships could affect well-being. Better understanding the biological substrates of well-being also offers the potential to intervene in targeted ways to enhance the well-being of individuals who are at risk for a variety of reasons. For example, treating mothers at risk of postpartum depression with oxytocin, a neuroendocrine hormone that promotes adjustment to motherhood, shows promise both in reducing postpartum depression and in promoting mother-infant bonding (Kim et al., 2014).

Second, future research on genetic factors and gene x environment interactions that shape subjective well-being across the lifespan will be important for understanding stability, change, and individual differences in subjective well-being. Estimates vary depending on features such as study design and measures used, but a recent meta-analysis found that approximately 32% of the variability in life satisfaction can be accounted for by genetic factors (Bartels, 2015). However, environmental factors have been found to both weaken and strengthen genetic effects on well-being. For example, being married has been found to weaken heritability estimates (Nes, Røysamb, Harris, Czajkowski, & Tambs, 2010), whereas increasing income has been found to strengthen heritability estimates (Johnson & Krueger, 2006). Conceptual models have come to recognize that it is not just that particular genetic markers can serve as risk factors in the face of certain environments but that particular genetic markers can make individuals more susceptible to both positive and negative environments, either enhancing or limiting prospects for well-being (Ellis & Boyce, 2008).

Third, the most consistent predictor of better subjective well-being across the lifespan is positive social relationships (Siedlecki et al., 2014). New technology has brought about many changes in social relationships that might affect well-being for the better or worse. On the one hand, texting, Skype, and social networking make it possible to stay in touch with family and friends who are not in close geographical proximity, which might contribute to enhanced well-being (Grieve, Indian, Witteveen, Tolan, & Marrington, 2013). On the other hand, online communication may not confer the same benefits for well-being as spending time with friends and family in person, especially if the online communication is not with people to whom individuals have strong ties or if the communication involves general posts rather than personal, dyadic communication (Burke & Kraut, 2016). Early research suggested that within the first one to two years that families began using the Internet, their social networks narrowed, they communicated less with other members of the household, and their depression and loneliness increased (Kraut et al., 1998). More recent research has yielded mixed findings (e.g., Best, Manktelow, & Taylor, 2014, for a review). Future research will benefit from trying to elucidate the ways that subjective well-being is related to social relationships in new, ever-changing technological contexts.

Conclusions

Adopting a lifespan perspective on subjective well-being facilitates understanding of the development of well-being over time. A large body of research has demonstrated that well-being is fairly stable over time as well as that, on average, individuals have lower mean levels of well-being during middle adulthood than earlier or later in the lifespan (particularly in high-income countries). In every stage of development, family relationships are central to well-being. During infancy, secure attachment relationships with parents set the stage for trusting, supportive relationships throughout life. During childhood and adolescence, parents remain important, but peer relationships take on increased importance in relation to well-being. In adolescence and early adulthood, romantic partnerships become developmentally salient and important sources of well-being. With the transition to parenthood, relationships with children bring well-being full circle to the next generation. Cognitive development across the lifespan enables the emergence of a sense of self during infancy that supports cognitive aspects of well-being, and during adulthood a future orientation and perceptions of time remaining in life are related to selective narrowing of social networks in ways that promote positive affect and life satisfaction. Life events and life choices can have both short- and long-term effects on well-being. Subjective well-being is important throughout life both in its own right as an important outcome as well as because better subjective well-being predicts other desirable outcomes including longevity.

Abstract

Results regarding whether men and women differ in terms of their well-being levels have been highly inconsistent. To more conclusively understand the past research regarding on the relationship between gender and subjective well-being (i.e., life satisfaction, positive affect, and negative affect), we summarize the current body of the literature on the subject including both large, nationally representative empirical papers as well as past meta-analyses. Next, we review explanations behind the presence of gender differences in subjective well-being as well as explanations behind the lack of gender differences in subjective well-being. We conclude by addressing current limitations of the present research and propose important future directions to further disentangle the remaining questions regarding gender differences in subjective well-being

Keywords: Gender Differences, Sex Differences, Subjective Well-being, Affect

Pundits, policy-makers, and lay people alike are captivated by differences between men and women. Questions of gender differences inundate both the popular press and academic journals: *how*, are men and women different, and *why*? It is not uncommon to see gender comparisons as a main emphasis in research on different psychological characteristics or drawn on as a moderator of interest. The role of gender and gender differences in well-being has also been of longstanding interest. Intriguingly, results regarding well-being differences in gender have often been inconsistent. While at times research fails to find a significant difference between men and women's well-being (e.g., Okun & George, 1984), others demonstrate significant differences between the genders in opposing directions (e.g., Stevenson & Wolfers, 2009; Haring, Stock, & Okun, 1984; Fujita, Diener, & Sandvik, 1991). Complicating matters, there are different aspects of well-being (e.g., positive affect, negative affect) that one can make comparisons on and different sub-populations within which gender comparisons are made (e.g., age, nation) (e.g., Shmotkin, 1990). Given an ongoing interest in gender differences in well-being, and the inconsistent results found in the past, there is a need to synthesize the well-being literature and provide conceptual grounding for when we might see gender differences in well-being, when we may not, and why.

In this chapter, we summarize the present state of research on gender differences in well-being. Specifically, we focus on subjective well-being (SWB) among the different possible conceptualizations of well-being. We begin by reviewing past research on gender differences on the three components of SWB (e.g., life satisfaction, positive affect, and negative affect). Next, we will discuss the findings of several large-scale meta-analyses and samples on the different SWB components. After which, we present the conceptual underpinnings that have been proposed as to why we would, or would not, expect to find differences in well-being between men and women. Drawing on the above, we conclude with limitations of current research and future directions to help address remaining unanswered questions.

Past Research on Gender Differences in Subjective Well-being

Subjective Well-being

Given widespread interest in gender and well-being, gender differences in SWB has been repeatedly examined over time. In a landmark review of the SWB literature, Wilson (1967) concluded that one's sex was not associated with happiness – though this conclusion was based on only two studies. One study was commissioned by the US congress to examine the mental health of 2,460 American adults 21 years old and older (Gurin, Veroff, & Feld, 1960), and the second was a study that included data from 450 households from various social-economic statuses (Bradburn & Caplovitz, 1965). Since more research has been conducted on this issue, re-examining the initial conclusion of a lack of gender differences in SWB is necessary.

Across broader and larger samples, there have been mixed findings on whether there are gender differences in SWB. Whereas some research has found that men have significantly higher levels of SWB (e.g., Stevenson & Wolfers, 2009; Haring, Stock, & Okun, 1984), other studies have shown that women have significantly higher levels of SWB (e.g., Fujita et al., 1991). Complicating matters further, many studies have found no significant differences (Okun & George, 1984), particularly after controlling for

other relevant demographic factors (e.g., age, marital status) (e.g., White, 1992; Inglehart, 1990; Shmotkin, 1990; Warr & Payne, 1982; Larson, 1978).

It has been proposed that these inconsistent and conflicting reports are in part due to SWB being comprised of three components: (1) positive affect, (2) negative affect, and (3) life satisfaction (Diener, Lucas, & Oishi, 2002; Diener, 1984). The magnitude and direction of the gender differences diverge for each component and conflating them in the analysis may reduce any observed differences – or it may lead to empirical confusion when not distinguished conceptually (Diener, Suh, Lucas, & Smith, 1999; Parker & Brotchie, 2010).

The idea that there are differences within these components has been supported by several studies that have examined the components of SWB independently. For instance, a large-scale international study by Lucas and Gohm (2000) found that in most of the nations examined, women experienced more negative affect than men. Other studies have reported similar findings that negative affect is more prevalent among women (Nolen-Hoeksema & Rusting, 2003). This is supported by research within the clinical domain that has found women experience greater levels of depression, anxiety, and mood disorders than men (Eaton et al., 2012; Grant & Weissman, 2007). Furthering the support of this explanation is the fact that women are also reported to experience higher levels of positive affect, or happiness, than men (Wood, Rhodes, & Whelan, 1989; Lee, Seccombe, & Shehan, 1991). Therefore, it is likely that the inconsistent findings may be in part attributable to conflating different dimensions of SWB – such as positive and negative affect. To avoid this potential pitfall, we will review past research on life satisfaction, positive affect, and negative affect separately.

Additionally, apart from conflating the different components of SWB, there may also be sampling variability leading to differences in observed gender SWB differences. To minimize this potential, we focus our review drawing on large-scale nationally representative studies and previous meta-analyses.

Life Satisfaction. Broadly, large-scale, nationally representative studies on life satisfaction have found somewhat mixed results on gender differences in life satisfaction. An early study by Clemente and Sauer (1976) found no significant differences between men and women on life satisfaction in representative sample of over 1,000 individuals from the United States. A study by Inglehart (2002) in using data from the World Values Survey that spanned more than 60 nations found that the direction of the gender difference was dependent upon on the age group, whereas younger (e.g., 18-44) women had higher levels life satisfaction than younger men, but older women (e.g., 44-65+) had lower levels of levels of life satisfaction than older men. A later study by Blanchflower and Oswald (2004) that compared over 20,000 individuals from both the United States and Great Britain, cited a small effect with women reporting higher levels of life satisfaction than men in both Great Britain and the United States. The most recent study by Tay, Ng, Kuykendall, and Diener (2014) used the Gallup dataset to examine this question for full-time workers across the United States and over 150 other countries. For the United States, they found very small effect size differences, but found larger differences across other included nations in which full-time working women had higher life satisfaction than full-time working men (Tay et al., 2014).

Table 1.
Summary of Large Scale, Nationally Representative Studies on Life Satisfaction

Study	Sample Characteristics (Number of Nations)	Sample Size	Findings
Clemente & Sauer (1976)	US representative sample (1)	1,347	No significant gender difference in life satisfaction
Inglehart (2002)	International representative sample (65)	~150,000	Young women have higher levels of life satisfaction than young men; Older women have lower levels of life satisfaction than older men.
Blanchflower & Oswald (2004)	US and UK representative samples (2)	94,574	Women have higher levels of life satisfaction than men.

Tay, Ng, Kuykendall, & Diener (2014)	International representative sample (156)	172,949	Women have higher levels of life satisfaction than men.

Notes. US= United States; UK = United Kingdom; ~ = approximate as reported by author

Consistent with large-scale representative samples, past meta-analyses have also been conducted on the question of gender differences in life satisfaction and have resulted in mixed findings as well. One of the first large scale reviews conducted on the subject was done by Haring, Stock, and Okun in 1984. Haring and colleagues (1984) looked at empirical studies from the US that examined gender and social class as predictors of subjective well-being. The studies included were conducted prior to 1980 and had to include "life satisfaction, happiness, morale, quality of life, and subjective well-being" as keywords. Based on the studies that met the above criteria, their results showed that men had slightly higher levels of subjective well-being, which included life satisfaction, than women, but the magnitude of this difference was small (r = .03; d = .06).

A few years later, Wood, Rhodes, and Whelan (1989) conducted another meta-analysis on sex differences in positive well-being with attention paid to marital status and emotional style. They drew upon 85 studies from both US and international samples that provided a comparison between men and women on measures of life satisfaction, happiness, morale, positive affect, or general well-being. In terms of life satisfaction, it was found that men had lower levels of life satisfaction than women (d = - .03).

Another meta-analysis conducted by Pinquart and Sörensen (2001) investigated differences between men and women over the age of 55 in psychological well-being. They included 174 studies from the developmental and gerontological literature that looked at gender differences in life satisfaction. They found that older men, as compared to older women, reported slightly higher levels of life satisfaction (g = .08; d = .08).

Most recently, Batz, Tay, Kuykendall, and Cheung (under review) conducted a meta-analysis that examines gender differences in life satisfaction and the influence of gender inequality on the size of this difference. Across the 281 included samples, which included over a million individuals, Batz and colleagues (under review) found that, after accounting for publication bias, men and women significantly differed in their levels of life satisfaction such that men report higher levels of life satisfaction than women (d = .03).

Table 2.

Summary of Meta-Analyses on Gender Differences in Life Satisfaction

Meta-Analysis	Sample Characteristics	Sample Size	Findings	Effect Size**
Haring, Stock, & Okun (1984)	US samples (k=146)	52	Men have higher levels of life satisfaction.	.06
Wood, Rhodes, & Whelan (1989)	US and international samples (k= 85)	1,505*	Women have higher levels of life satisfaction than men.	-.03
Pinquart and Sörensen (2001)	US sample; Over age 55 (k= 174)	27,186	Men have higher levels of life satisfaction.	.08
Batz, Tay, Kuykendall, & Cheung (under review)	US and international samples (k= 281)	1,001,802	Men have higher levels of life satisfaction.	.03

Notes. US = United States; k = number of samples; a positive effect size indicates men having greater life satisfaction; * = median number of participants among all included studies, total was not reported; ***All effect sizes converted to Cohen's d for interpretation*

Taken together, the majority of the results from meta-analyses on this subject favor the conclusion that men and women do significantly differ in life satisfaction, such that men have higher levels of life satisfaction than women, though the size of the difference is small.

Positive Affect. Across large, nationally representative samples, the discrete emotion of 'happy' or 'happiness' is often the operationalization of positive affect. An example of this is first seen in Inglehart's (2002) examination of the World Values Survey of individual from over 60 nations. Inglehart (2002) found that gender differences in happiness levels were dependent upon age, whereas young (18-44) women are happier than young men, middle aged (45-54) women and men do not differ in terms of happiness, but older (55+) women are less happy than older men. Another example of this is research by Easterlin (2003) who looked at gender differences in happiness using the internationally representative sample from the General Social Survey. Easterlin's results (2003) mirrored that of Inglehart (2002), finding that younger women are happier than younger men, while older women are less happy than older men. A more recent study Zuckerman, Li, and Diener (2017) examined gender differences in positive affect, measured by using a range of positive emotions beyond just happiness, using data from the Gallup World Poll, a globally representative data set of over 150 countries. Their results indicated that men and women did not statistically differ in terms of positive affect.

Table 3.
Summary of Large Scale, Nationally Representative Studies on Positive Affect

Study	Sample Characteristics (Number of Nations)	Sample Size	Findings
Inglehart (2002)	International representative sample (65)	~150,000	Young women have higher levels of happiness than young men; Middle aged women and men do not significantly differ in levels of happiness; Older women have lower levels of happiness than older men.
Easterlin (2003)	International representative sample (Not reported)	Not Reported	Young women have higher levels of happiness than young men; Older women have lower levels of happiness than older men.
Zuckerman, Li, & Diener (2017)	International representative sample (162)	455,104*	No significant difference between men and women.

Notes. US= United States; ~ = approximate as reported by author; * = total sample size for study overall

Meta-analyses have strived to summarize the rather large body of empirical studies that focus on both happiness and positive affect. For example, Wood, Rhodes, and Whelan (1989) conducted a meta-analysis based on 96 studies from both US and international samples. They found that women reported higher levels of happiness (d = -0.07), but that when examined more broadly, there was not a non-significant gender difference for positive affect overall. Another meta-analysis conducted by Pinquart and Sörensen (2001) used 58 studies to investigated differences between men and women over the age of 55 in happiness. They found that older women, as compared to older men, reported slightly lower levels of happiness (g = .06; d = .06).

Table 4.
Summary of Meta-Analyses on Gender Differences in Positive Affect

Meta-Analysis	Sample Characteristics	Sample Size	Findings	Effect Size**

Wood, Rhodes, & Whelan (1989)	International samples (*k*= 85)	1,505*	Women have higher levels of happiness than men; No gender difference in positive affect overall.	-.07; *n.s.*
Pinquart and Sörensen (2001)	US sample; Over age 55 (*k*= 58)	53,197	Men have higher levels of happiness.	.06

Notes. US = United States; *k* = number of samples; a positive effect size indicates men having greater life satisfaction; * = median number of participants among all included studies, total was not reported; ***All effect sizes converted to Cohen's d for easy interpretation*

Collectively, the results from meta-analyses on this subject come to different conclusions, whereas one finds that women report higher levels of happiness than men and the other finds the opposite to be true. One reason for this variation may be two very important differences in the studies themselves: the inclusion of international samples (Wood, Rhodes, & Whelan, 1989) versus the inclusion of samples only over the age of 55 years old (Pinquart & Sörensen, 2001). Additionally, the analyses were done over a decade apart. As such, one may conclude that the samples are so different that it is unfair to deem these results inconsistent with one another and instead address the question of gender differences in positive affect for different subsets of the population. Future work should examine this question further.

Negative Affect. Very few researchers have examined gender differences in negative affect on a large-scale or meta-analytically. This is likely due to the overwhelming interest in gender differences in mental health, particularly the experience of depression. Which, while related to negative affectivity, is viewed as a distinct concept from negative affect in the context of subjective well-being (Luhmann, Hofmann, Eid, & Lucas, 2012). However, one large-scale study by Zuckerman, Li, and Diener (2017) did examine gender differences in negative affect using data from the Gallup World Poll, a globally representative data set of over 150 countries. Their results indicated that men and women did significantly differ in negative affect, such that women had higher levels of negative affect than men.

Table 5.

Summary of Large Scale, Nationally Representative Studies on Negative Affect

Study	Sample Characteristics (Number of Nations)	Sample Size	Findings
Zuckerman, Li, & Diener (2017)	International representative sample (154)	455,104	Women have higher levels of negative affect than men.

Notes. * = total sample size for study overall

This large analysis conducted by Zuckerman and colleagues (2017) suggests that men and women significantly differ in negative affect, such that women have report higher levels of negative affect than men. While this study provides a baseline in which examine this question using a large and representative sample, one must avoid viewing this finding as conclusive. Future work must be done to examine this question further – including future meta-analyses that seek to examine this question across more samples to provide greater confidence in these results.

Reasons for Gender Differences in Overall Well-being

When attempting to explain gender differences in well-being, there are several themes that emerge from the literature, including structural factors (i.e., differences in institutional arrangements and opportunities between men and women), socio-cultural factors (i.e., differences in societal expectations and norms for men versus women), and biological differences (i.e., physical and physiological differences) (e.g., Stevenson & Wolfers, 2009; Wood et al., 1989; Tesch-Römer, Motel-Klingebiel, & Tomasik, 2008; Landers, 1988; Fujita et al., 1991; Russo & Green, 1993). These differences are summarized in Table 6. We recognize that there are likely complex interactions between these factors, but we seek to discuss them as main effects for parsimony.

Table 6.
Explanations for Gender Differences in Subjective Well-being

Category	Psychological/Physiological Mechanisms	Posited Outcome
Structural factors: Access to educational, economic, political, and social resources, opportunities, and power structures	Need fulfillment	Women have lowered SWB due to limited opportunities to fulfill basic and psychological needs from current structural inequalities between men and women
Social factors: Societal expectations and norms	Gender role fulfillment (prescription & description)	Violations of gender roles lead to lowered SWB where women seeking to move into the workplace or traditionally male-dominated industries have lower SWB. Emotional expressiveness is more acceptable for women rather than men meaning they are more willing to display and report higher levels of positive affect and negative affect than men.
Biological factors: Physiological	Hormones Genetics	Hormonal differences, both in the type and fluctuation, between men and women lead to variations in the experiences of both positive and negative emotions Genetic differences between men and women may led women to develop personality types that make them more susceptible to the experience of positive and negative affect.

Structural Factors: Gender Inequalities & Need Fulfillment

One potential key to undersanding gender differences in SWB is Need Fulfillment theory. This has often been implicitly, or explicitly, invoked in the examination of gender differences particularly for the evaluative components of SWB (e.g., Diener & Lucas, 2000; Tay & Diener, 2011). Substantively, this theory posits that SWB levels are dependent on the extent an individual's physical and psychological needs (e.g., autonomy, competence, relatedness) are fulfilled (Ryan & Deci, 2000; Ryff & Keyes, 1995; Maslow, 1943). This theory considers not only external, objective structural realities that influence the ability to meet one's needs, but also personal perceptions that physical and psychological needs are being met.

Based on this theory, gender differences in SWB may be understood in terms of the variation in men and women's experiences of global inequality within economic, educational, political, and social structures. More specifically, differences in access to opportunity structures (e.g., access to education), resources (e.g., income differences), and power systems (e.g., representation in government) for men and women would lead to difference in their respective perceptions of their ability to meet their needs. Such that women would not only be less able, but also feel less enabled to meet their needs as compared to men. Subsequently this would result in gender differences in SWB, but the size of this difference likely would be dependent upon the degree of inequality within these societal structures. Specifically, in nations and communities where there is equality within these structures (i.e., opportunity, resource, power) there will likely little to no difference in gender SWB but where inequality is high there will likely be greater differences between the sexes.

A substantial amount of research has shown support for the idea that a greater provision of human

rights (e.g., civil, political) and greater equality (e.g., education, income) is related to higher levels of SWB (Diener, Diener, & Diener, 1995; Oishi, Kesebir, & Diener, 2011; Oishi & Diener, 2014). Similarly, it has been found that in societies with greater gender equality, individuals have higher levels of overall happiness (e.g., Bjørnskov, Dreher, & Fischer, 2007; Inglehart & Welzel, 2005; Inglehart, Foa, Peterson, & Welzel, 2008; Jorm & Ryan, 2014; Ruth & Napier, 2014; Schyns, 1998). This prior work is supportive of the proposition that variations in the experiences of inequality may improve well-being for women and so enhance overall well-being nationally.

More direct evidence has been found in an empirical study that examined whether gender differences in life satisfaction were explained by variability in the experiences of gender inequality. The study, conducted by Tesch-Römer and colleagues (2008), examined the influence in differences of cultural inequality on the magnitude of gender differences in SWB in over 50 countries. They found that the greater societal gender inequality, the greater the difference between men and women on levels of SWB, but only in countries that valued gender equality.

However, some studies have found the opposite to be true to some degree. A study using data from over 90 countries by Meisenberg and Woodley (2015) found that although some indicators of gender equality and female status are related to higher life satisfaction for women, some indicators, including women's involvement in gainful employment and prolonged schooling, are negatively related to women's well-being. This may be explained by the fact that along with increases in opportunities and rights, women's aspirations and responsibilities have also increased, particularly in the workforce (Patten & Parker, 2012; Regan & Roland, 1982). These shifting standards and increased demands may cause gender differences in SWB to persist despite equality. The expansion of opportunities may have come at a cost for women, and ended up benefiting men more than women (Stevenson & Wolfers, 2009). This idea is consistent with work by Blanchflower & Oswald (2004) who found that women's happiness decreased over time in the United States and Britain despite women's rise in resources, opportunities, and power. Therefore, policies aimed at equality may have had an inadvertent negative impact on women's levels of SWB. Also, as women have taken on additional roles that were once reserved for only men, their comparison group may have expanded, and thus their perception of their relative success possesses a more negative connotation (Stevenson & Wolfers, 2009). Clearly, the relationship between culture, equality, and need fulfillment may be complex and will require future research to disentangle why we do not see vastly different effects despite these sometimes large disparities between men and women in terms of opportunities and resources

Social Factors: Societal Expectations and Norms

Social factors may also help explain gender differences in SWB via the differences in the norms and expectations for men and women, referred to in the literature as 'gender roles.' Gender roles are socially held, descriptive and/or prescriptive stereotypes regarding the characteristics of each sex as well as the subsequent acceptable, expected behaviors for men and women (Eagly & Karau, 2002). These expectations and norms in gender roles influence the perceptions regarding the appropriate occupations for men and women, the type of traits men and women should possess, and even the type of emotions that are acceptable to experience and demonstrate for men and women. Researchers have explored the consequences of violating gender role expectations and find that men and women who engage in behaviors counter to these expectations often face backlash from others, which can subsequently have a negative impact on both their successes and well-being (e.g., Eagly & Karau, 2002; Blazina & Watkins, 1996; Good & Wood, 1995). For instance, research has shown that women experience backlash that impacts their job satisfaction when they take on roles in organizations that are not traditionally feminine or require them to behave in traditionally masculine ways (Garcia-Retamero & López-Zafra, 2006).

A significant part of gender role expectations is that it is more acceptable for women than men to be emotionally expressive, which may also help explain why women report experiencing both positive and negative affect more often than men (e.g., Simon & Nath, 2004; Plant, Hyde, Keltner, & Devine, 2000). Men may be more reluctant than women to *report* the degree to which they feel specific positive and negative emotions, which may influence the self-report based findings on gender differences in positive and negative affect (Nolen-Hoeksema & Rusting, 2003). Moreover, these expectations may impact the degree to which men and women allow themselves to actually *feel* and express these emotions (Nolen-Hoeksema & Rusting, 2003).

Research by Grossman and Wood (1993) has supported this idea, finding that women report more extreme emotions than men without being prompted. However, when emotional responses were manipulated for a person to be either more, or less, emotionally expressive, no sex differences were obtained, which may be indicative of initial conformity to gender role expectations. Other research has examined this question and found that women engage in more non-verbal expressions of positive emotions

(e.g., smiling, laughing) than men particularly when gender was made more salient (LaFrance, Hecht, & Paluck, 2003). Similarly, a study by Fujita, Diener, and Sandvik (1991) examined the case for emotional intensity further, finding that gender alone accounted for less than 1% in the variance in the valence dimension of happiness-sadness, whereas gender accounted for approximately 13% of the variance on the emotional intensity dimension, suggesting that women are more open to intense emotional experiences than men.

Biological Factors: Hormones and Genetics

There has also been research done regarding biological factors, such as hormonal or genetic differences between men and women, that may contribute to men and women's differing levels of the affective components of SWB (e.g., Hyde, Mezulis, Abramson, 2008; McRae, Ochsner, Mauss, Gabrieli, & Gross, 2008).

First, this idea has been supported by studies that have looked at relationships between genetics and well-being. For example, a study by Weiss, Bates, and Luciano (2008) cited substantial evidence for a genetic component to well-being and happiness. Røysamb and colleagues (2002) conducted further exploration to test the hereditability of happiness. In this exploration, they used a classic twin-studies design with over 5,000 individuals. Results indicated a significant gender difference in the heritability of happiness. Further, they found that women have a greater genetic determination in their happiness level as compared to men (Røysamb, Harris, Magnus, Vittersø, & Tambs, 2002). Additionally, research has revealed that there might be different sets of genes that influence women's happiness as compared to men's happiness. Research has attempted to dive further into this by identifying specific genes, such as the monoamine oxidase A (MAOA) gene that is involved in mood regulation. Researchers postulate that the presence of this gene, via its impact on mood regulation, lead women to experience moods more intensely and lead to more frequent mood shifts than women with low expression of this gene, while the gene has no impact on men (e.g., Chen et al., 2013). This may lend some insight as to why women report greater levels of both positive and negative affect than men for instance However, when examined meta-analytically the results remain unclear as to whether there are gender differences in the genetic architecture of well-being (Bartels, 2015).

There is also some evidence that women's hormones, including estrogen and progesterone, may be tied to women's fluctuations in positive and negative affect, particularly around times which those hormones also fluctuate greatly such as their premenstrual period (Nolen-Hoeksema & Rusting, 2003). However, other studies have reported that these shifts in hormones around a woman's menstruation influence on negative affect levels is inconclusive (Golub & Harrington, 1981), though substantial work has shown that most women report mood shifts prior to menstruation (Johnson, 1987). Other work has looked at the influence of these gonadal hormone fluctuations across a woman's lifespan influence on their neurochemistry and their neuroendocrine system, which has a large impact on one's moods and mood regulation (Steiner, Dunn, & Born, 2003). The evidence from these studies support that gender differences in mood disorders, such as depression, are not as prevalent pre-puberty as they are post-puberty when these hormonal shifts are occurring and may lead to these affective differences in men and women (Kessler & Walters, 1998).

Additional work has looked at gender differences in the influence that well-being, including both affective and psychological, has on the physical and hormonal health outcomes of men and women. This line of works has found that there may be distinctive patterns of health-related outcomes from well-being in men and women, such that well-being leads to different outcomes in the male body versus female body (Steptoe, Demakakos, de Oliveira, & Wardle, 2012). For example, for men, well-being is associated with a smaller waist circumference, and women it led to fewer inflammatory markers in their body, yet both men and women had improved lung function (Steptoe et al., 2012).

Broadly, researchers conclude that while there is substantial evidence that men and women's anatomy and physiology differ, the implications of this on the experience well-being is not well-established (Savic-Berglund, 2010). So, while biological differences are commonly believed to be a contributing factor, more work needs to be done to provide greater supporting evidence.

Reasons for Lack of Gender Differences in Overall Well-being

We note that it is important to explain why we might *not* expect gender differences in SWB due to the number of large-scaled studies we reported with null effects. There is a line of research that proposes why we should not expect many, if any, differences between men and women based on the gender similarity hypothesis proposed by Hyde (2005). This hypothesis proposes that many gender differences are extremely small, if not totally non-existent. Hyde (2005) proposes than men and women are more similar than they are different. She bases this conclusion on a review of many meta-analyses on gender differences across a wide array of outcomes and characteristics. In this review, she finds that most mean difference

effect sizes are small, if not non-significant, on the outcomes of interest. She states that these overly endorsed claims harm men and women by propagating expectations of differences that can have detrimental impact on the lives of men and women, and as such people should be wary of making these conclusions (Hyde, 2005). We propose that it may not necessary be the case that these effects are inherently small, but rather are potentially minimized by other psychological processes that contribute to a rather static baseline of well-being and influence the evaluations one makes in determining their well-being levels. These psychological processes are summarized in Table 7.

Table 7.
Explanations for Lack of Gender Differences in Subjective Well-being

Category	Psychological/Physiological Mechanisms	Posited Outcome
Return to Baseline	Adaptation Habituation	Men and women adapt to their respective surroundings leading to little gender differences in well-being overall. Men and women are not impacted as greatly by aspects of life that become habitual in nature (e.g., inequality or stereotypes) leading to little gender differences in well-being overall.
Basis of Evaluation	In-Group Social Comparisons Values	Men and women may not consider one another part of their in-group and compare they life to others of their same sex leading to little gender differences in well-being overall. Men and women may value different aspects of life such leading to little gender differences in well-being overall.

Return to Baseline

Adaptation. Adaptation is another phenomenon difficult to address in our measurement of SWB that may contribute to seemingly null effects. Adaptation, also labeled the hedonic treadmill (Brickman & Campbell, 1971), is the theorized reason behind the lack of large, long-lasting influences of major life events (e.g., loss of a job, marriage, winning the lottery) on a person's levels of well-being (Luhmann, Hofmann, Eid, & Lucas, 2012; Brickman & Campbell, 1971). More specifically, researchers have found that despite major life events that intuitively one would suspect would have large, long-lasting impacts on one's well-being levels, it appears instead that individuals tend to adapt to their new-found situations and return to their original baseline levels of well-being (Luhmann, Hofmann, Eid, & Lucas, 2012; Brickman & Campbell, 1971). If men and women are not biologically predisposed to experience vastly different levels of SWB, this idea may be one reason behind why we do not see consistent or persistent differences in SWB between men and women in all samples we study. While in the moment stereotypes or restricted resources may impact women more negatively, decreasing their levels of SWB, relatively quickly – due to adaptation – women return to their baseline which may not be much different, if at all, from men's baseline levels of well-being.

Habituation. Habituation proposes that constant stimuli begin to fade into the background due to an evolutionary benefit of protecting our limited cognitive resources (Helson, 1948; 1964). This applies to the idea of well-being too, such that well-being is less dependent upon the desirability of the constant, ever-present circumstances (e.g., stereotypes, inequalities), but are more so reflective of changes in the *important* circumstances of life (Carver & Scheier, 1990). As such, once women become accustomed to life circumstances, such as inequalities, these circumstances may end up having less of an influence on their well-being levels. Thus, potentially diminishing differences between men and women in SWB that would have been present had this state not become habitual in nature.

Basis of Evaluation

In-group social comparison. Another challenge of self-reported well-being measures is the inability to determine the extent to which in-group versus out-group comparisons are being made. While some samples may find no difference between men and women, this may be due to women's in-group comparisons being comprised of only other women. Thus, it may be likely that they do not perceive themselves to be any worse off that other women, leading to relatively high levels of well-being. However, in some samples (e.g., working samples) where we do see gender differences in SWB, women's in-group social comparison may include men too, and then comparatively, due to inequalities or social expectations, they may have decreased levels of well-being from making this comparison. Unfortunately, current measures of SWB do not include a way for people to report when these sort of in-group comparisons are being made and how they go about defining their in-group members.

Values. Another critical issue that also needs to be considered in comparing the levels of SWB between men and women is that they may derive happiness from different sources. There has been substantial work on differences in what men and women value most in life and their sources of happiness. Past research has suggested that men and women's values differ (e.g., Beutel & Marini, 1995), which may influence the degree to which different aspects of life impact their respective levels of SWB. Work by Beutel and Marini (1995) found that women reported valuing the well-being of others and finding purpose and meaning in life more than men and value materialism and competition less than men. More specifically, some research has explored differences in perceived sources of happiness for men and women, reporting some differences among the sexes. While men reported sports, sexual activity, being liked, and having a quality social life significantly more influential on their happiness than women did. Women reported helping others, being close to family, and being loved as significantly more influential on their happiness levels than men (Crossley & Langdridge, 2005).

Some work has looked directly to differences between the sexes in terms of the influence of life factors have on their subsequent happiness. For example, in a meta-analysis by Pinquart and Sörenson (2001) found that income, education, and SES were more impactful on men's well-being levels as compared to women's, and that social networks were more impactful on women's well-being levels as compared to men's. Subsequently, women and men may go about basing their responses on SWB measures on different value structures, subsequently nullifying differences. If measures instead left less up for interpretation on what aspects of life one should be rating, or considering, in this evaluation, we may see greater gender differences in SWB.

Future Directions

While work addressing the question of gender differences in well-being is not rare, there are several limitations in current research that can be addressed by future work on this subject. As is true in most areas of research, there is a concern that the literature is inundated with only results that are significant, and those that are not significant are relegated to a "file-drawer" either literally or metaphorically (Rosenthal, 1979). While this is by no means a new problem, or an issue only relevant to the study of gender differences in well-being, it is an issue that should be paid particular attention to in an area of research most interested in differences by the very nature of the question being asked. Results that do not find significant differences should be equally valued if we are to have a balanced and complete perspective on this issue and significant results should be replicated to increase confidence in these findings (Pashler & Harris, 2012; Hyde, 2007).

Along these same lines, there is a need for further empirical work on specific theoretical reasons proposed for why gender differences exist rather than simply relying on secondary analyses to answer this question. Theory is critical in providing a foundation for research questions, and it is critical to then test the theory in an empirical manner to further develop an understanding of gender differences in well-being. This may include pinning two theoretical perspectives against one another in an attempt to empirically validate one over the other as has been done some previously (e.g., Mason, 1995). Additionally, research that is more causal in nature may be beneficial to further understand why and when environmental factors, such as inequality, contribute to gender differences in well-being. This may be done by manipulating situations of perceived inequality in a laboratory setting to provide some additional evidence of a cause and effect relationship rather than relying exclusively on correlational-based theory.

Other methods may also be beneficial to incorporate further to develop our understanding of well-being differences among the sexes such as longitudinal investigations. While presently there is work that compares gender differences across age groups (e.g., Pinquart & Sörenson, 2001; Diener, & Suh, 1997), variations in the magnitude of gender differences in well-being in these studies may be reflective of generational differences rather than differences across the lifespan. Past research has also suggested that longitudinal work may help to distinguish between the frequency by which men and women experience

positive and negative emotions versus the intensity that these emotions are experience by men and women respectively (Diener, Sandvik, & Larsen, 1985). There may be differences in well-being patterns overtime dependent upon whether one is interested in the frequency the emotions are experienced versus the intensity by which they respond to the same or similar emotional stimuli. As such, understanding the fluctuation across both the short-term and long-term using methods such as experience sampling method will provide additional insights that are critical to further understand well-being across time and help untangle the question of gender differences in well-being over time in ecological settings (Tay, Chan, & Diener, 2014).

Additionally, integrating both person-centered (e.g., looking at differences among clusters of individuals on outcomes) and variable-centered approaches in research on this subject may be beneficial to provide further insight as to why there are gender differences in well-being for some samples and not others. Integrating the adaption of a person-centric perspective on well-being will help to preserve the integrity of the person overall in order to understand the way that they shape, feel about, and understand their own well-being (Weiss & Rupp, 2011). This focus would emphasize the experience of the subjective states and experiences at both a momentary level (e.g, positive and negative affect) as well as more cumulative evaluations (e.g., life satisfaction). This would requires relying more heavily on both quantitative and qualitative methods such as gathering the histories and narratives individuals create about their lives.

In adopting these methods, we will likely have an increased understanding of gender's relationship to well-being and develop ways to enhance SWB for both men and women. Lyubomirsky (2001) proposed that the greater understanding of why some people, or sexes in this case, are happier may provide the foundation for interventions to increase happiness of the less happy group by drawing on the developable traits, behaviors, and environmental factors of the happier group. Because happiness has been shown to relate to and precede numerous important life outcomes (Lyubomirsky, King, & Diener, 2005), the ability to do this could subsequently improve the long-term success of both men and women in numerous areas of life.

Beyond understanding the causes of gender differences in well-being levels, it is also important to further explore the subsequent repercussions of these differences. Substantial amounts of research have examined the numerous positive outcomes that are believed to be a result of high SWB, but research has failed to examine if these outcomes differ for men and women. This would be important for understanding further the impact differences in well-being has on the lives of men and women. As such, we believe that exploring the differential validities of SWB for the outcomes of men and women separately may be beneficial to having a more complete picture of the impact of these differences in SWB.

Concluding Remarks

Despite the question's popularity in research and the work that has already been done, there is still substantial work that can, and should, continue on the subject in an effort to further our understanding of gender and well-being. While the question of whether men and women differ in levels of well-being is a seemingly straight-forward one, there are numerous complexities involved in answering it. First, it is important to consider the different types, and components, of well-being as a construct. Second, it is important to understand that depending on numerous biological, individual, and environmental factors the difference in SWB may be more or less apparent. Third, one must consider the present limitations in the research and act on the necessary future directions to provide further clarity and understanding. Thus, we hope that taken together these considerations paint a vivid picture of the complex nature of a seemingly simple question. Do men and women differ in levels of SWB? As cliché as it sounds, the answer appears to be, at least for now, "it depends."

Abstract

The purpose of this chapter is to clarify what is currently known about subjective well-being (SWB) for racial groups in the United States, with a focus on common racial struggles and resilience in people of color. We organize the chapter by first summarizing the between-group and within-group studies of culture and SWB. We then provide a Critical Race perspective on studying SWB across racial groups with particular attention to how we define race, followed by a comprehensive review of empirical literature on four common race and ethnic specific predictors related to SWB: racial-ethnic discrimination, racial-ethnic identity, acculturation and enculturation, and racial-ethnic socialization. We conclude with suggestions for future research to advance theory and methodology in the study of race and SWB.

Keywords: Race, Racism, Critical Race Theory, Subjective Well-being

Subjective well-being (SWB) describes how individuals feel and think about their own life (Diener, 2000). It has gained increased popularity in psychology, including growing interest and study across cultures and nations (Diener, 2000; Diener, Oishi, & Lucas, 2003). In the United States, understanding how race contributes to the experience of SWB seems pressing, as some of the major issues affecting minority communities today are tightly linked to race (e.g., Deferred Action for Childhood Arrivals program repeal, Charlottesville white supremacy march and murder of an anti-protester, anti-Muslim bans, Standing Rock, Black Lives Matter, Flint water crisis). How is SWB defined and maintained in these communities? How do they promote resilience and increased SWB in face of adversities? How is SWB shaped by history of race and racism in the United States?

The purpose of this chapter is to clarify what is currently known about SWB for racial groups in the US. We narrowly focus this review on race in the US as the construction of race informed by history operates differently within and across nations (Omi & Winant, 2014). We approach our review from a Critical Race theory perspective (Delgado & Stefancic, 2012), drawn from the interdisciplinary field of Ethnic Studies (Banks & Banks, 2009; Hu-DeHart, 1993), in order to *critically* advance the study of race and SWB. We organize the chapter by first briefly summarizing the between-group and within-group studies of culture and SWB. Second, we provide an Ethnic Studies perspective on studying SWB across racial groups with attention to how we define race, in particular. Third, we present a review of empirical literature of four common race and ethnic specific predictors related to SWB, including racial-ethnic discrimination, racial-ethnic identity, acculturation and enculturation, and racial-ethnic socialization. Finally, we conclude by providing suggestions for future research to advance theory and methodology in the study of race and SWB.

Between- and Within-Group Studies of Culture and SWB

Cross-cultural studies have primarily examined mean-level differences on SWB across many different proxies for culture, including country, income, wealth and other economic factors, and between individualistic and collectivistic societies (see Diener, 2000; Diener, Oishi, & Lucas, 2003; and Dolan, Peasgood, & White, 2008; for more detailed review). Many interpretations are provided for these differences including "tangible" resources (e.g., food, shelter), individual-level characteristics (e.g., approach and avoidance style, personality traits), measurement biases (e.g., self-serving biases), and broad cultural values (mainly focused on individualism and collectivism) (Diener, 2012; Diener & Diener, 1995; Kitayama, Markus, & Kurokawa, 2000; Suh, 2007). For instance, Dolan et al. (2008) reviewed economic factors contributing to SWB and found evidence that poor health, separation, unemployment, and lack of social contact are all strongly negatively associated with SWB. Diener et al. (2003) reported that differences in mean levels of SWB appear due to objective factors like wealth, to norms dictating appropriateness of feelings and importance of SWB, and to the relative approach versus avoidance tendencies of societies.

In particular, the role of individualistic and collectivistic values on thoughts, feelings, and behaviors associated with SWB has been extensively studied (e.g., Fulmer et al., 2010; Oishi & Diener, 2001; Oishi, Krochik, & Akimoto, 2010; Suh, 2007; Uchida & Kitayama, 2009); including, feeling and expressing positive emotions (Eid & Diener, 2001), differences in social support (Oishi & Schimmack, 2010), and differences in positivity (Diener, Scollon, Oishi, Dzokoto, & Suh, 2000). For instance, Diener and Diener (1995) investigated 31 countries and found that self-esteem is less strongly correlated with subjective well-being in those that were rated to be more collectivistic (e.g., East Asian) than in those rated to be more individualistic (e.g., European American).

When more closely examining racial group differences in the US (i.e., Asian American, Pacific Islander, Native American, African American, White, and Latinx) on SWB, there appear to be some group differences. For instance, Oishi and Diener (2001) found that European Americans were significantly more satisfied with their lives than Asian Americans. Crocker, Luhtanen, Blaine, and Broadnax (1994) found differential effects on the relationship between collective self-esteem components (private, public, membership, and identity) and well-being (personal self-esteem, life satisfaction, depression, and hopelessness) of African American, White, and Asian American college students. Some studies more broadly compare predictors and experience of SWB across White and "non-White" samples (e.g., Dush & Amato, 2005; Seder & Oishi, 2009).

There is growing literature and debate on interpreting racial group differences in self-esteem. Studies generally find African Americans tend to report higher levels of self-esteem than Whites. This has led some authors to raise doubts about the validity of the internalization of stigma perspective for racial minorities in the US (Gray-Little & Hafdahl, 2000). However, in a more thorough literature review of racial differences in self-esteem (including Latinx, Asian American, and Native American), Twenge and Crocker (2002) found levels of self-esteem differed widely between racial groups - varying by type of self-esteem measured, year of data collection and age, sex composition, and SES of the sample. Given this cross-racial group heterogeneity, they argued that future research should move away from asking *why* racial group differences exist, and instead ask *how* SWB is constructed within these different racial groups.

Overall, there is a wide range of cultural differences in the experiences and predictors of SWB. Causal interpretation of these differences, however, can be problematic for a number of reasons. For instance, in their review of economic factors associated with SWB, Dolan et al. (2008) cautioned against drawing firm conclusions about the causes of SWB. Their review identified contradictory evidence, a lack of certainty on the direction of causality, and concerns regarding the impact on findings of potentially unobserved variables.

Also, the level of cultural analysis (e.g., national, socioeconomic, income/wealth, race, ethnicity, general cultural values, etc.) is often either unclear or terms are used interchangeably in these studies. This is related in part to the complexity and challenge in finding agreed upon, operationalized, and differentiated meaning in terms broadly captured by culture (Giraldeau, Lefebvre, & Morand-Ferron, 2007). Still, this leads to a challenge in drawing any meaningful conclusion regarding cross-cultural differences on SWB. For instance, there is growing research on the role of broad cultural values on SWB. Many cross-cultural studies compare SWB between individualistic and collectivistic societies, often interchangeably using North American and East Asian countries, respectively. Not only does this hinge on outdated stereotypes (Matsumoto, 1999; Takano & Osaka, 1999), but it also ignores the evidence of greater heterogeneity within than between these national (rather than cultural) groups (Oyserman, Coon, & Kemmelmeier, 2002). It further limits our understanding of culture to individualism and collectivism (Hofstede's (2001) cultural dimensions additionally include instrumental and expressive, uncertainty avoidance and tolerance, for instance).

In addition, the group comparison in these studies often overemphasizes cross-cultural differences in SWB, ignoring heterogeneity of cultural and racial groups. For instance, although there are many studies that examine SWB across nations, there are few that examine differences within nations, including racial group differences within the US. An exception is a study conducted by Tay and colleagues (2014) that found racial differences in well-being among African American, White, Latinx, and Asian American in their workplace and in general (Tay, Ng, Kuykendall, & Diener, 2014). These racial differences in well-being measures, however, were not consistent. Further, studies that do assess SWB within nations often over-represent some racial groups and group comparisons (Whites, White and Asian, White and Black), while other groups and respective comparisons are under-represented (e.g., Native American, Latinx).

Finally, and most importantly, cross-cultural comparisons ignore the possibility that individual interpretations of SWB are unique to each culture, making it difficult to study across cultures. Cultural and indigenous psychology emphasize how all psychological phenomena (like SWB) are embedded within a particular cultural setting based on unique values, traditions, and history (Shweder, 1991). Further they are

critical of the *imposed etic* research approach where culture-specific ideas (such as SWB) may be wrongly imposed on and generalized to other cultures (Berry, 1989; Pike, 1967). Lastly, White and WEIRD samples (Western, Educated, Industrialized, Rich, and Democratic) are overly represented in viewpoint, cultural biases, and generalizability (Henrich, Heine, & Norenzayan, 2010). We therefore focus our review on the experience of SWB for separate racial minority groups and evaluate their common, uniquely racialized risks and resilience. Our focus is further framed by an analytical lens offered by Ethnic Studies that emphasizes complexity and agency of racialized groups.

Ethnic Studies and Critical Race Perspectives on SWB

Inspired by the 1960s U.S. Civil Rights movement, a joint coalition of Black, Latinx, Asian American, and Native American student groups led one of the longest student strikes in U.S. history in 1969 to demand fundamental changes in higher education (Banks & Banks, 2009). They challenged the prevailing academic power structure and the Eurocentric curricula of colleges and universities. They demanded for more scholarly programs, faculty, and staff who focused on the under-represented and under-studied histories and experiences of diverse racial minority groups, which led to the birth of Ethnic Studies (Maeda, 2009).

There are many ideas and debates of what Ethnic Studies is or should be, and conceptualizations can differ from campus to campus and change over time (Hu-DeHart, 1993). What is clear in its scholarship, however, is the specific or comparative focus on marginalized groups in America that often lacked equity, representation, and privilege. In particular, the field continually documents and emphasizes the self-determination, autonomy, and empowerment of racial minority groups, often in resistance and opposition to structural systems of oppression, colonialism, and inequity.

Today, Ethnic Studies pushes race-related scholarship, including more theories and methods to examine relations and intersections of power in race, class, gender, and sexuality (Hu-DeHart, 1993). It further expands across fields, level of education including K-12, and broadens the framework to include the effects of migration, assimilation, and accommodation of people moving between nations and borders. It considers new spaces, community, and identity forged by migrants across national boundaries (Basch, Glick-Schiller, & Szanton-Blanc, 1994).

Drawing on these principles, Critical Race theory can be helpful in clarifying and framing how race should be understood in the study of SWB. This theory developed in the early 1980s in response to the failure of critical legal studies to adequately address the impact of race and racism in the US jurisprudence. Legal scholars, including Derrick Bell, Richard Delgado, and Alan Freeman, initially helped contribute to advancing this theory. They critiqued the system of racial oppression and emphasized need for agency and activism; ultimately, the end goal focused on structural change and social justice (Bell, 1992; Delgado & Stafancic, 2012). Critical Race theory has now expanded across disciplines including history, women's studies, education, psychology, sociology, and political science. Central tenets of Critical Race theory include the significance of racism, racialization, intersectionality, and agency.

Racism. *Race* is a socio-political and legal construct based on perceived physical differences (e.g., skin color, facial features, and hair type), rather than inherent biological differences. It differs from *ethnicity*, which emphasizes the traditions, values, language, and history attached to a particular social group (Cokley, 2007). More importantly, race and racial differences were created and maintained to promote power and privilege attached to "whiteness." Whiteness is a racial ideology that is interchangeably used with what is normal, beautiful, and American (Devos & Banaji, 2005; Sue, 2005). It uses false narratives of biological and "cultural" inferiority of "non-Whites" to rationalize genocide, slavery, exclusion, and colonization of Black, Native, Pacific Islander, Latinx, and Asian Americans in the past (Miller & Garran, 2008; Takaki, 1993). Racism is systemic and maintains the racial status quo on an interpersonal, cultural, and institutional level, always seeking white supremacy and exclusion (Jones, 1997). Today, racial inequities continually persist as people of color are systematically disadvantaged compared to Whites across multiple domains of life, including health, education, work, and legal systems (Alvarez, Liang, & Neville, 2016; Lui, Robles, Leondar-Wright, Brewer & Adamson, 2006). Therefore, race and *racism—a* system of privilege and oppression based on racial hierarchy—are inextricably linked today and throughout history. Relevant to the study of SWB, racism raises questions, for instance, who gets to ask the questions? From what vantage point is the research conducted? Are studies of SWB comparably represented across racial groups? What groups are left out?

Racialization. Science has now debunked any notion of meaningful and distinct racial group differences, finding more within-group than between-group variations in phenotypic and biological characteristics (Betancourt & López, 1993; Carter & Pieterse, 2005; Smedley & Smedley, 2005). Nevertheless, invariably conceptualized within historical contexts, individuals are *racialized* as race shapes group membership, meaning, experiences, and treatment of others (Helms, 1990; Helms & Cook, 1999;

Omi & Winant, 2014). Further, the meaning and classification of race and racial groups is ever-changing, continually deconstructing and reconstructing to reinforce a power structure of systemic privilege that benefits Whites (Omi & Winant, 2014). For instance, the U.S. Supreme Court used varying definitions of race (e.g., biological vs. social) to deny citizenship to Asian Americans (e.g., regarding cases *Takao Ozawa v. US* and *Bhagat Singh Thind v. US;* López, 2006). Multiracials were classified and treated as non-Whites based on racist, legislative policies associated with the "one-drop rule" in efforts to maintain "racial purity" (Root, 2003). Irish, Italian, and Jewish immigrants were once considered racial "others" (non-White) and subjected to blatant forms of racism (Guglielmo & Salerno, 2003). However, their experiences were different compared to other racial minority groups in the US given their phenotypic proximity to whiteness. Further, these ethnic groups were later assimilated as part of whiteness. European immigrants of second and later generations subsequently had more opportunity to either choose or not choose to integrate their ethnicity into their daily lives without penalty (e.g., celebration of St. Patrick's Day), a privilege not afforded to people of color (Gans, 1979). With the end of World War II and the beginning of the U.S. Civil Rights movement in the 1960s, expressions of racism grew from "old-fashioned" blatant, overt, and intentional expressions of white racial superiority to include "modern" color-blind, subtle, ambiguous, and unintentional reinforcement of the racial hierarchy (Devine, 1989; Dovidio & Gaertner, 1986; Plous, 2003; Sue, 2005). Relevant to the study of SWB, racialization raises questions such as what are the unique racialized experiences of people of color that shape their experiences of SWB? How do roles of power and privilege, including structural inequities, influence how SWB is studied or interpreted with racial minority groups?

Intersectionality. *Intersectionality* highlights that oppressive systems–including but not limited to racism, sexism, classism, heterosexism, xenophobia, and ableism–are interconnected and not merely hierarchical or additive; as such, they should not be examined separately (Crenshaw, 1991). As a framework for understanding how multiple interlocking systems of oppression and privilege operate at a structural level, it has now been applied to understand individual-level processes and outcomes (Cole, 2009). Illustrating this framework, Le Espiritu (2008) uses an intersectional lens to analyze how roles of race, class, gender, and sexuality of Asian Americans have been used throughout US history to maintain racial hierarchy of Whites and to justify structural racism against Asian Americans. In particular, Asian men and women are often cast in contrasting images to help define and maintain White male heteronormativity. Over the course of U.S. history, Asian men have been racialized as both hypersexual and more recently asexual, while Asian women have been viewed as both masculine and more recently super-feminine (Le Espiritu, 2008; Sue, Bucceri, Lin, Nadal, & Torino, 2009; Takaki, 1989). Relevant to the study of SWB, intersectionality raises questions about how multiple identities are categorized and who is included. How do power and privilege shape multiple identities, their intersectionality, and what is their link to SWB?

Agency. Racism has been both intentionally and unintentionally violent towards racial minority groups both past and present (Alvarez et al., 2016; Lui et al., 2006). It is maintained by false beliefs in a natural order of biological and cultural differences, as Whites are assumed superior to people of color (Smedley & Smedley, 2005; Takaki, 1993). Despite the injustice, people of color have protested, resisted, and contributed to building a stronger, more equitable society in the US (Takaki, 1993). Critical Race points out that people of color are active agents creating their own personal narratives and directing their present and future lives (Lee, Kim, & Zhou, 2016). This theory proposes practices of counter-storytelling to reveal and contest the identity-infused base of everyday society. Relevant to the study of SWB, agency raises questions about whether cultural deficit models (including stereotype consistent models) are used to interpret racial differences. Do SWB studies include vantage points based on the unique perspectives and voices of racial minority groups? For people of color, what are unique forms of racialized resilience and their relation to SWB? How do critical consciousness and social activism relate to SWB?

Empirical Review of Race- and Ethnicity-Specific Predictors of SWB

Operationalized Definitions

There is a wide range of meaning in race and SWB in the psychological literature. Historically, scholars have differentiated race and ethnicity: *race* emphasizes a socio-political and legal construct based on perceived physical differences (e.g., skin color, facial features, and hair type) and *ethnicity* emphasizes the traditions, values, language, and history attached to a particular social group (Cokley, 2007). However, the use of these terms is often based on social convention rather than empirical definition. For instance, African American is typically thought of as racial while Latinx is typically thought of as ethnic - regardless of the context of the research question (Umaña-Taylor et al., 2014). Further, operationalization and measurement of racial and ethnic constructs often overlap such that they can be difficult to distinguish

(Cokley, 2007). Thus, we follow recent arguments for using the term "racial-ethnic" to capture this broad construct, and when possible, we use terms for specific aspects of each (Hughes et al., 2006; Umaña-Taylor et al., 2014). Similarly, there was a wide range of interpretation in operationally defining well-being, often using a broad collection of "positive" outcome measures including self-esteem, happiness, positive self-perceptions, life satisfaction, and positive and negative affect (e.g., Pascoe & Richman, 2009; Smith & Silva, 2011). Given many definitions of well-being, we focus our review on studies that used "positive" psychological adjustment outcomes such as those listed above. We also do not focus on broader negative outcome or mental distress (e.g., depression, anxiety, stress) measures in our review as they are extensively reviewed elsewhere (e.g., Lee & Ahn, 2011, 2012, 2013). Finally, from a Critical Race perspective, interpreting racial group differences may lead to essentializing racial groups or worse, to reinforcing racist conceptions of human behavior (Zuckerman, 1990). Emphasizing agency in people of color as they create personal narratives during both struggles and resistance, we focus our review on some of the most commonly studied racialized psychological risks and resilience that may affect their experience of SWB. These include: racial-ethnic discrimination, racial-ethnic identity, acculturation and enculturation, and racial-ethnic socialization. Our review provides a broad and brief summary of related definitions and theories, empirical review as it relates to SWB, and limitations for each construct.

Racial-Ethnic Discrimination

Racial-ethnic discrimination (RED) refers to the biased behavior and treatment of individuals based on their racial or ethnic background (Dovidio & Gaertner, 2010; Ong, Burrow, Fuller-Rowell, Ja, & Sue, 2013; Paradies, 2006). It is one of many ways in which racism occurs at the individual level, along with *racial stereotype* that emphasizes cognitive overgeneralizations and *racial prejudice* that emphasizes emotions attached to the overgeneralization (Fiske, 1998; Paradies, 2006). Racism also functions on a cultural and institutional level: cultural, institutional, and legal practices operate and are structured in ways to benefit the dominant group (Jones, 1997). Although many operationalized definitions and measures of racism are provided in the literature (Essed, 1991; Jones, 1997; Harrell, 2000), most emphasize the centrality of power and privilege attached to whiteness. The experiences of RED for people of color consequently are often chronic and wide ranging, including direct or indirect, intentional or unintentional, and subtle or blatant, to name a few (Harrell, 2000). The empirical work on the experience and impact of RED for people of color started after the 1960s U.S. Civil Rights movement (Winston, 2004), as psychology shifted from predominantly studying the perpetrator's experience of RED to including the target's experience as well (see Fiske, 1998, for review). There is now a large body of research that focuses on the perceptions and psychological correlates of RED for people of color.

RED has been theoretically and empirically linked to mental health and SWB for people of color. According to the racism-related stress theory, a popular and often cited framework in this area, perception and experience of racism can be stressful, taxing an individual's coping resources and consequently leading to higher distress and lower well-being (Harrell, 2000). This theory has been largely supported by empirical studies as multiple dimensions and domains of racism have been linked to a wide range of psychological distress and SWB outcomes. Although studied less frequently than maladjustment outcomes (Lee & Ahn, 2011, 2012, 2013), RED has been linked to a lower SWB (including lower self-esteem, life satisfaction, control and mastery, positive affect, and general well-being) for Asian, Latinx, and African heritage samples living the US and abroad. Similar results were found in one of the largest meta-analyses on the subject to date (293 studies from 333 articles) by Paradies et al. (2015) for African American (37%), Latinx (19%), Asian American (9%), and Native Americans, Arab Americans, or international students (less than 1% combined). Pieterse and colleagues (2012) also found this link in their meta-analyses focused on the SWB of African Americans. Finally, the RED-SWB link for people of color seems to vary considerably by the type of racism (e.g., subtle or blatant, Crocker, Voelkl, Testa, & Major, 1991; personal or group, Taylor, Wright, Moghaddam, & Lalonde, 1990), as well as a host of ecological factors (e.g., identity, family, school/work, society) (Bronfenbrenner, 1979; García Coll et al., 1996).

From a Critical Race perspective, there are few limitations and gaps that if addressed could strengthen this area of research. Most of the sample and related measures of RED focused on African Americans, and less was clear on the unique socio-political and historical circumstances of RED that shaped the SWB of other racial minorities, particularly Native Americans. Also, despite the theoretical importance of structural racism, most measures and research in this area focus on individual-level perceptions and outcomes of racism. More research is needed to evaluate the impact of objective cultural and institutional forms of racism, including anti-race policies. For instance, Gee (2002) found individual, self-perceived racism and institutional racism of segregation and redlining differentially related to health outcomes in a large community sample of Chinese Americans.

Racial-Ethnic Identity

Racial-ethnic identity (REI) is a broad construct associated with meaning, behaviors, and attachment towards a particular racial or ethnic group, although efforts to differentiate between the two are made (Helms, 2007). *Ethnic identity* is defined as the subjective sense of ethnic group membership that includes self-labeling, sense of belonging, knowledge, attitude, and group participation (Phinney, 1996). *Racial identity* is defined as the collective identity of any group of people socialized to think of themselves as a racial group (Helms & Cook, 1999). When researchers are interested in cultural beliefs, values, and behaviors on an individual, Cokley (2007) encourages the study of ethnic identity; when researchers are interested in response to an oppressive and highly racialized society, Cokley (2007) recommends the study of racial identity. Still, Umaña-Taylor et al. (2014) argued that the distinction between the *ethnic* and *racial* phrasing seems more artificial than intentional, and therefore a meta construct comprising both racial and ethnic identity should be used. REI is a multidimensional construct that taps into a variety of dimensions including, but not limited to, public regard, private regard, salience, pride, resolution, search, and participation (Lee & Yoo, 2004; Phinney, 1992; Roberts et al., 1999; Sellers, Rowley, Chavous, Shelton, & Smith, 1997; Umaña-Taylor, Yazedjian, & Bámaca-Gómez, 2004). Most common theories used to study REI and SWB include developmental models (Phinney, 1990), social identity theory (Tajfel & Turner, 1979), and schema models (Helms, 1990).

REI is believed to be important to the development and resilience of racial minorities in the US, a proposition supported by numerous empirical studies. In a meta-analysis on the link between REI and mental health for people of color in North America, Smith and Silva (2011) found a positive relation between REI and general well-being (r=.19; k=32), and mental health more broadly defined (r=.17; k=184). This finding is supported by Rivas-Drake et al.'s (2014) meta-analysis that found a positive relation between REI and well-being (r=.20; k=8), and positive adjustment more broadly (r=.26; k=27), including positive social functioning (6 studies), self-esteem (21 studies), and well-being (8 studies). Although fewer studies focus on "positive" outcomes in comparison to "negative" outcomes, REI seems comparably important to the SWB of people of color. Further, these findings held similarly across racial minority groups (i.e., African, Asian, Latinx, Native) in both reviews; one limitation is that half of the 51 sample studies focused on African Americans, roughly 15% on Asian Americans and Latinx, and only 6% on Native Americans (Rivas-Drake et al., 2014). Finally, although there is a wide range of racial and ethnic identity measures (Cokley, 2007), most studies reviewed here relied on the Multi-group Ethnic Identity Measure (MEIM; Phinney, 1992) and the Multidimensional Inventory of Black Identity (MIBI; Sellers et al., 1997).

From a Critical Race perspective, there are few limitations and gaps that if addressed could strengthen this area of research. Although there are a large number of studies that focused on African Americans, there are fewer that focused on other racial minority groups, particularly Native Americans. Consequently, little is known about the effects of REI on SWB for Native Americans, particularly the unique meaning attached to REI based on values, resilience, and history. Furthermore, there are limited measures of REI that focuses on uniquely racialized experiences of specific racial minority groups grounded in their history and interlocking oppression. An exception is the number of Black measures that consider these larger historic and system factors, including the MIBI (Sellers et al., 1997) that measures the salience of identity; the centrality of the identity; the ideology associated with the identity (including subscales: Nationalist, Assimilation, Minority, and Humanist); and the regard in which the person holds African Americans (including subscales: Private Regard and Public Regard).

Acculturation and Enculturation

Acculturation is a broad term that involves the process of one cultural group coming in contact with another cultural group and the associated change involved (Redfield, Linton, & Herskovits, 1936). However, in the field of psychology, for racial minorities and immigrants, *acculturation* is most often viewed as the process of adapting and learning about the dominant, mainstream culture. *Enculturation*, in contrast, is the process of retaining and learning about one's culture of origin (Yoon et al., 2013). The literature long debated whether the process and adaptive outcome of psychological acculturation was either unidimensional (i.e., individual reject their heritage culture to adapt to the host culture) or bidimensional (individuals reject/retain their heritage culture while also rejecting/retaining their host culture). Current evidence indicates that acculturation is bidimensional (Flannery, Reise, & Yu, 2001; Ryder, Alden, & Paulhus, 2000). Berry and colleagues further theorized and empirically supported four acculturation strategies that individuals engage in while negotiating between two cultures (Berry, 1997; Sam & Berry, 2010). They include *assimilation* (rejecting the heritage culture, adopting the host culture), *integration* (retaining the heritage culture, adopting the host culture), *separation* (retaining the heritage culture, rejecting the host culture), and *marginalization* (rejecting both the heritage and the host cultures). These strategies neither represent the totality of acculturation strategies, nor are they all equally valid across groups (for a more thorough review of the acculturation literature, see: Schwartz, Unger, Zamboanga, &

Szapocznik, 2010).

Acculturation and enculturation have been repeatedly linked with positive mental health outcomes. Yoon et al. (2013) examined unilinear measures of acculturation and enculturation, along with bilinear measures of acculturation in a meta-analysis of 325 individual studies. Unilinear measures of acculturation were unrelated to positive mental health, while bilinear measures of acculturation were positively related to positive mental health (r=.18; k=42). Further analyses found that only the integration strategy was related to positive mental health (r=.10; k=10), and that positive mental health was significantly better for the integration strategy than assimilation (d=.33; k=9) and marginalization (d=.92; k=9). Lastly, enculturation was positively related to positive mental health (r=.14; k=57). These findings are similar to Nguyen and Benet-Martínez's (2013) meta-analysis that suggested a positive relation between biculturalism (similar to the integration strategy) and psychological adjustment (high self-esteem and low anxiety; r=.11; k=52). Although these studies were conducted with different racial minority groups, no significant or meaningful group differences were found between acculturation/enculturation and SWB (e.g., Yoon et al., 2013). Furthermore, Latinx and Asian American populations were studied more often than African Americans and other minority groups (e.g., Middle-Eastern/Arab Americans).

Acculturation theory has made advances over the last few decades, such as the incorporation of bilinearity and an increased emphasis on context. Nevertheless, from a Critical Race perspective, limitations and gaps exist in the literature. While integration of two cultures is assumed to be most adaptive (Berry, 1997), it can be complicated and context dependent (e.g., proportion of similar racial in-group members in the community) (Nguyen and Benet-Martínez, 2013). Furthermore, future research should examine beyond individual-level factors (e.g., personality) that shape the relationship between acculturation/enculturation and SWB, focusing on broader social context and institutional factors (e.g., redlining, segregation, race-related policies). Solely focusing on an individual's acculturation strategies in relation to mental health and SWB can place undue responsibility and blame on individuals (Yoon et al., 2013).

Racial-Ethnic Socialization

In psychological and developmental literature, *parental racial-ethnic socialization (RES)* generally refers to the transmission of information from adults to children regarding race and ethnicity (Hughes et al., 2006). While the two aspects of "racial" (i.e., tapping into the racialized experiences of people of color) and "ethnic" (i.e., tapping into the dissemination of cultural knowledge) parental socialization have been well-studied for African American youth and families (Priest et al., 2014), scholars have only more recently begun to differentiate between racial and ethnic socialization processes for other racial minority families (Juang, Shen, Kim, & Wang, 2016). *Racial socialization* refers to the ways in which parents teach their children about the meaning that is associated with being from a certain race, for example, when one's racial group may be devalued in society, preparing children for challenges due to stereotyping and racism. *Ethnic socialization*, in contrast, refers to the preservation and transmission of cultural values, practices, traditions, language, and history. Hughes and Chen's (1997) most popular racial-ethnic socialization model and measure comprise of three dimensions that collectively describe the transmission of information regarding race and ethnicity. *Preparation for bias* emphasizes discussions about racism and how to cope with it. *Promotion of mistrust* emphasizes warning about interactions with racial out-group members. *Cultural socialization* emphasizes messages about the history, values, and pride of one's own racial and ethnic groups. Alternative terminologies have also been used for these RES strategies (Smith, Jacobson, & Juarez, 2011; Stevenson, Cameron, Herrero-Taylor, & Davis, 2002), which further complicates understanding and comparison of results between studies.

Research in this area emphasizes the importance of RES in developing SWB and preparing children to cope with barriers and inequalities present in American society (Hughes et al., 2006). Empirical studies, however, suggest the link between RES and SWB may be more complicated. It has been found to vary across a wide range of factors including the selected dimensions of RES and SWB, racial groups, agents of RES (e.g., parents, peers, mentors), and child characteristics (e.g., age, gender, skin color) (Hughes et al., 2006; Priest et al., 2014; Telzer & Vazquez Garcia, 2009). For instance, depending on domains of SWB measured, Constantine and Blackmon (2002) reported preparation for bias and cultural socialization were associated with higher family self-esteem, cultural socialization was associated with higher peer self-esteem, and mainstream socialization was associated with lower school self-esteem. Recent studies also found differential effects of RES dimensions on well-being for people of color. Cultural socialization for instance is generally positively related to well-being (Bynum, Burton, & Best, 2007; Juang et al., 2016; McHale et al., 2006; Rivas-Drake, 2011). Interestingly, preparation for bias seems to have a curvilinear relationship to adjustment, with low and high levels relating to poor adjustment and moderate levels relating to positive adjustment (Harris-Britt, Valrie, Kurtz-Costes, & Rowley, 2007; Seol, Yoo, Lee,

Park, & Kyeong, 2016). In other words, too little or too much discussion about racial bias may relate to poor well-being with moderate amounts being most adaptive.

There are several gaps and limitations in this research area. There is an inconsistent use of terminology referring to racial and ethnic socialization messages and behaviors. For instance, often "racial socialization" is used almost exclusively with African Americans, while "ethnic and cultural socialization" is used more often with Latinx and Asian Americans (Hughes et al., 2006). The inconsistent use of different terms and definitions make it challenging for researchers to tease apart specific psychological effects and integrate findings from past research. RES is also extensively studied and measured with African Americans, while less attention is given to other racial minority groups (Priest et al., 2014). Finally, more studies are needed to examine the multiple social and environmental factors (e.g., family, school, neighborhood) and multiple influential agents (e.g., parents, teachers, peers, online) that may influence RES and its relationship to SWB.

Conclusion and Recommendation for Future Research

Our review of the race and SWB literature (focusing on key predictors, racial-ethnic discrimination, racial-ethnic identity, acculturation and enculturation, and racial-ethnic socialization) highlights both the importance and challenges of studying this topic. Although at times, racial groups were compared with each other (e.g., comparing Latinx and Asian immigrants' experience of acculturation), the majority of these studies focused on a specific racial minority group. Even though this literature is smaller in comparison to that of key predictors related to negative mental health outcomes (see, Lee & Ahn, 2012, 2013), our review finds that these racial risks and resilience are important to the SWB of people of color. Furthermore, by going beyond simple racial group comparison–that may further reinforce stereotypes of racial minority groups living in an oppressive system of racism (Zuckerman, 1990)–these studies illustrate that the contribution of race to SWB is complicated and there are many important, uniquely racialized risks and resilience that are multidimensional. We conclude our review by providing suggestions for future research to advance theory and methodology in the study of race and SWB. Grounded in Critical Race theory, they focus on the significance of racism, racialization, intersectionality, and agency.

Significance of Racism

Given the system of racism that privileges Whites, our review narrowly focused on the racialized risks and resilience of racial minorities living in the US. That said, there were racial minority groups that were over-represented in some areas and under-represented in others. Research that focuses on "race" (including study of racial-ethnic discrimination, racial-ethnic identity, and racial-ethnic socialization) was conducted more frequently with African Americans while focus on "ethnicity" (including acculturation/enculturation) was studied more frequently with Latinx and Asian Americans. Native Americans, multiracials, and other marginalized minority groups (e.g., Arab Americans) were largely absent in this literature. Together, our review draws attention to these understudied groups and the accompanying stereotyped assumptions of significance in topic to specific racial minority groups (e.g., importance of race to primarily African Americans or ethnicity to Asian Americans or Latinx) that should be avoided.

Also, operationalization and measurement of racial and ethnic constructs often overlap, making it difficult to distinguish between them (Cokley, 2007) and easy to conflate results in regard to SWB. For instance, the same measures of identity and socialization may be defined as racial identity or racial socialization if studied with African Americans, but ethnic identity or ethnic socialization if studied with Latinx or Asian Americans (Juang et al., 2016; Umaña-Taylor et al., 2014). Therefore, research questions, measures, and sample selection should be based on whether researchers are interested in ethnic-related constructs that emphasize cultural beliefs, values, and behaviors or race-related constructs that emphasize response to an oppressive and highly racialized society (Cokley, 2007). Hence, a study might use a sample of Asian Americans when studying effects of racism-related stress, but specific Asian ethnic groups (e.g., Filipino American, Vietnamese, Asian Indian) when studying effects of acculturation gap. Similarly, operationalization and measurement of well-being was not consistent in this literature, often relying on a collection of "positive" psychological adjustment outcomes (e.g., self-esteem, positive affect). There is debate about whether there is a meaningful and measurable difference between SWB and psychological well-being (Chen, Jing, Hayes, & Lee, 2013); more importantly, few studies focused on understanding factor structure and invariance of SWB across racial groups or developing new theories and measures of SWB based on distinct racialized history and experiences of particular racial minority groups.

Finally, there are limited studies that investigate how the relationship between race-related risks/resilience and SWB is influenced by system-level factors (e.g., family, community, state). Most studies focused on individual-level factors (e.g., personality, coping strategy). Interestingly, many theories in this area of research (Bronfenbrenner, 1979; Garcia-Coll et al., 1996; Harrell, 2000; Phinney, 1990)

already emphasize the role of community and larger system factors (e.g., anti-race policies) on the individual. Incorporation of system-level factors in this area of research is needed to further understand how individuals and structures of oppression interact on SWB. Also, more studies are needed in understanding how race and SWB link relate to activism and ways that individuals engage in transforming a racist society (Klar & Kasser, 2009).

Significance of Racialization

Racial groups are distinctly categorized and their unique process of racialization leads to different trajectories in maintaining white racism (Omi & Winant, 2014). For instance, Asian Americans are simultaneously viewed as hard-working (i.e., model minority) but un-American (i.e., perpetual foreigner); in contrast, African Americans are viewed as lazy and aggressive but more American (Kim, 1999). This calls for more attention to studies focusing on uniquely racialized experience of each racial minority group, many of which were missing across the reviewed risks and resilience factors. Research on race and SWB should also provide more relevant, historical, and socio-political context of race-specific constructs (Lee et al., 2016). Also, absent from the literature were many other marginalized racial minority groups (e.g., multiracials, Arab Americans) and their unique racialization processes. For example, Shih and Sanchez (2009) point out that studies on multiracials in psychology often rely on a cultural-deficit view, despite the many ways they successfully navigate between multiple racial identities and racism (Yoo, Jackson, Guevarra, Miller, & Harrington, 2016). Lastly, as racism is ever-evolving to maintain power and privilege attached to whiteness, new roles of migration shaped by colonialism and imperialism need to be examined. For instance, studies often operationalize migration histories in terms of acculturation, generational differences, or immigration status, failing to account for alternative migration histories including transnationalism and diaspora (Huber, 2010; Lee et al., 2016).

Significance of Intersectionality

Research on the link between race and SWB would benefit from a broader framework that examines multiple and intersecting forms of oppression and identities (Cole, 2009; Crenshaw, 1991). Intersectionality is a lens that critique how multiple social systems interlock to produce and sustain complex inequalities (Crenshaw, 1991). In psychology, there is a growing interest and body of work using intersectionality lens to examine how multiple identities is associated with a wide range of psychological outcomes; although there is growing concern that psychological outcomes of multiple social identities are being examined without critiquing systems of inequality or ways in which oppression is challenged (Moradi, 2016; Shin et al., 2017). Other scholars have examined unique experiences of intersecting multiple identities and how they adaptively cope with discrimination. For instance, Seaton, Caldwell, Sellers, and Jackson (2010) examined how combinations of ethnicity, gender, and age moderated the relationship between perceived discrimination and psychological well-being (depressive symptoms, self-esteem, and life satisfaction) in a nationally representative sample of African American and Caribbean Black adolescents. Szymanski and Lewis (2016) applied intersectionality framework to study how African American women in an institution of higher education cope with gendered racism. There is also a growing number of empirically validated measures of unique experiences across multiple intersecting identities and oppression, such as the LGBT People of Color Microaggressions Scale (Balsam, Molina, Beadnell, Simoni, & Walters, 2011), Gendered Racial Microaggressions Scale for Black women (Lewis & Neville, 2015), and Foreigner Objectification Scale (Armenta, Lee, Pituc, Jung, Park, et al., 2013). Examining intersections of race, class, gender, and/or sexuality on SWB may also require methods that capture more nuanced relationships, including qualitative or mixed-method designs.

Significance of Agency

Critical Race theory emphasizes the role of people of color as active agents creating their own personal narratives within an interlocking, structural system of oppressions. The practice of counter-storytelling is encouraged to reveal and contest the identity-infused base of everyday society. Huber (2010), for example, uses the counter-storytelling method to explore intersectionality of race, gender, and migration on the educational experiences of undocumented Chicana college students. In addition, community-based participatory research designs (Minkler & Wallerstein, 2011) involve community members as part of the research team to help inform the study questions, designs, interpretation, and dissemination of research. This design allows for self-determination and safeguards against the imposition of dominant narratives. For instance, Okazaki, Kassem, and Tu (2014) argued how community-based participatory research with Asian Americans can counter the homogenized portrait of Asian American communities by disaggregating populations, increasing cultural competence in service providers, improving mental health literacy, and decreasing stigma.

Final Thoughts

Our review of race and SWB from a Critical Race perspective illustrates the significant and

dynamic relationships among unique racial challenges, racial resilience, and SWB of people of color. It is important to remember that this relationship is situated within the broader system of racism, as advantages attached to whiteness and disadvantages attached to being a person of color manifests on individual, cultural, and institutional levels (Harrell, 2000; Jones, 1997). Today, racial inequities continually persist as people of color are systematically disadvantaged compared to Whites across multiple domains of life, including health, education, work, and the legal system (Alvarez et al., 2016; Lui et al., 2006). Research and policies that promote SWB for racial minority groups should also emphasize the need to dismantle these systems of interlocking oppression. However, the burden of responsibility in deconstructing racism should not only weigh on people of color. Although not reviewed here, there is a simultaneously growing field of Critical White studies (Delgado & Stefancic, 1997) that examines how to deconstruct roles of power and privilege attached to whiteness by examining its mechanisms (e.g., color-blind racial attitude; Neville, Lilly, Duran, Lee, & Browne, 2000), evaluating emotional and behavioral costs of White racism (Spanierman & Heppner, 2004), developing critical consciousness, and helping deconstruct systems of interlocking oppression related to race, class, gender, and sexuality (Shin, Ezeofor, Smith, Welch, & Goodrich, 2016). Studies could examine how this awareness and engagement in developing a broader social justice identity for Whites may also contribute to their SWB (Klar & Kasser, 2009; Waters, 2010). Similarly, the study of race and SWB should not be a separate discipline from the general study of SWB. Rather, Ethnic Studies can provide multiple analytical frameworks (e.g., Critical Race theory) that can be applied to all research studying SWB–thereby, advancing the field of SWB with more rigorous and rich research that carefully examines the role of race.

Abstract

This chapter reviews the body of research investigating the effect of religion and religiosity on subjective well-being (SWB). First, we provide a broad overview of the relation between religiosity and SWB, with specific attention to cultural factors and circumstances that moderate this effect. Then, we review the research on four specific process variables that have been considered in the past as mediating the relation between religiosity and well-being. Meaning in life, coping, social support, and emotion regulation are considered in examining whether these variables can account for, and explain away, the effect of religiosity on SWB.

Keywords: Religion, Spirituality, Subjective Well-Being

Religion is a directed and active search for a sacred universal truth. The inclusion of the sacred is what makes religion different from other searches for universal truth (Pargament, 1999). The search – and the experiences, feelings, and beliefs that accompany the search – as well as the destination, are both part of the religious experience. For example, the search might include attendance at religious events, whereas destination might include experiences of the sacred. The sacred, in turn, has been defined broadly to include concepts about higher powers, the divine, and the transcendent. These beliefs about the sacred can be transferred to objects as well as people, thus turning ordinary objects, such as a bowl, a bead, or a statue, into sacred objects, and people into saints and other spiritual beings (Pargament, 2002). In addition, as an institution, religion includes not just the objects and edifices, such as codified texts, places of worship, methods of teaching and learning, but also the set of beliefs, values, norms, mores, and rituals that are observed, taught, and practiced. For the purposes of this chapter, we include all three of these aspects when we refer to religion or religiosity.

And it is through these institutions, practices, and experiences that religion can lift adherents to heights of ecstasy and serve as a bulwark against distress, anxiety, and loneliness – we examine the ways in which religion promotes well-being and lay out the research evidence linking religion and subjective well-being (SWB). Of course, this is not to say that religion has not served to justify heinous crimes and conflict. History is rife with such examples. However, the goal of this chapter is to examine the benefit of religion and evaluate the research evidence related to the intersection of religion and SWB.

Overall Findings about Religion and SWB

Much research supports the positive relationship between religion and SWB. In a nationally representative US Gallup poll, respondents were twice as likely to be in the "very happy" group if they had reported religious faith as being most important, as opposed to least important (Myers, 2000). Indeed, in their review, Koenig and Larson (2001) found that of the 100 studies that they considered, 79 found a positive relationship, including 10 of the 12 which included prospective cohort studies. When the criterion was depression, 60 of 93 found lower rates of depression and fewer symptoms (for a brief review, see also Seybold & Hill, 2001). In addition to broad reviews, several meta-analyses have also found support for this relationship. For example, Hackney and Sanders (2003) found an overall positive effect (r = 0.10) of religiosity on psychological adjustment. A more recent meta-analysis by Smith, McCullough & Poll (2003) also found similar results, in that they found a negative relation (r = -.096) between religiosity and depression. But as can be seen from the effect sizes, the impact at first glance appear to be small, at best. A closer look at the relationship, however, raises the possibility that the size of the effect may be slightly larger than that shown by overall means. Even though the overall effect found by Smith, McCullough & Poll (2003) in their meta-analysis was small, they also found that the strength of the relationship was stronger for those who were experiencing distress due to recent life events, such that those studies that considered severe life stress found weighted mean r = -.152, compared to minimal life stress (r = -.071). Similarly, Hackney and Sanders (2003) also found that depending on the operationalization of well-being and religiosity, average effect sizes varied from 0.11 to 0.32.

Of course, the above effects are still not large. However, what makes religion an important factor in

considering SWB is that this relation appears to hold across multiple situations, religions, and cultures. While much of the evidence supporting religion's role in SWB stems from research with Christians from Western and relatively wealthy and industrial nations, research examining the effect across different religions have similarly found that religion predicts SWB. For example, Abdel-Khalek (2006) found that for Kuwaiti Muslim undergraduate students, religiosity accounted for 15% of their variance on happiness. And for Kuwaiti participants, the predictive power of religiosity held even during and subsequent to Iraq's invasion of Kuwait (Figley, Chapman, Ashkanani, al-Naser, & Donnelly, 2010). Rosmarin, Pargament, & Mahoney (2009) found that trust in God was associated with greater happiness and lower levels of anxiety and depression for Jewish participants, and Krause, Ingersoll-Dayton, Liang, & Sugisawa (1999) found that for elderly Japanese participants, religiosity predicted better health. Ng & Fisher (2016) also found that religiosity predicted SWB for Hong Kong Christian Chinese participants. In addition to research that focuses on specific religions or populations, investigations that consider large multi-national samples have also found similar results. For example, Diener & Clifton (2002) found that religiosity was positively associated with positive feelings and negatively associated with negative feelings across Buddhism, Christianity, Hinduism and Islam, controlling for demographic variables of age, gender, and life circumstances at the individual and societal level.

A caveat, however, exists in that while religion might predict SWB, the strength of the predictive ability, as well as overall mean levels of SWB, do vary across religions as well as denominations within religions. For example, some research has found that adherents of more fundamentalist denominations compared to liberal denominations across different religions self-reported greater happiness, life satisfaction, as well as optimism (Ellison, Gay, & Glass, 1989; Green & Elliott, 2010; Sethi & Seligman, 1993). But the findings are mixed, with other research not finding such differences across different denominations (e.g., Diener & Clifton, 2002; Ellsworth & Ellsworth, 2010). And because it is not always possible to consider solely religious or denominational affiliation while eliminating the effect of other variables, such as individual and national wealth, majority vs. minority status, intra-individual changes in religiosity and value of religiosity, as well as other cultural values and beliefs, this research contains multiple confounds.

The culture-level variable that has garnered much research focus is whether the culture values religion or not. For example, Graham & Crown (2014) found an overall positive relation between religiosity and SWB using a large-scale dataset that includes about 160 nations. This relation was moderated by culture, specifically the religiosity of the culture itself. In cultures with high levels of religiosity, being religious had a greater impact on SWB, compared to cultures with low levels of religiosity. In addition, using the European and World Values Studies datasets, Stavrova, Fetchenhauer, & Schlosser (2013) found that the predictive power of religiosity on life satisfaction was greater in highly religious cultures, whereas the relation was negative in cultures that valued atheism (c.f. Pirutinsky, 2013, who replicated the main effect, but not the interaction of religiosity at the nation level, using European Social Survey). Lun & Bond (2013) also found that across nations, the impact of religiosity on well-being was further moderated by support for spiritual practice, as well as societal hostility towards religion. For nations with low support for socialization, spiritual practice and happiness were not related. Similary, Diener, Tay, & Myers (2011) found that while religiosity was associated with higher SWB generally, it was mediated by social support, feelings of respect, and meaning in life. These, in turn, were moderated by difficult life circumstances. That is, when life circumstances were difficult, greater religiosity predicted greater SWB, via greater social support and meaning in life. But if circumstances were not as difficult, religiosity did not provide much benefit to SWB.

Thus, it appears that overall, and generally, religiosity provides some benefits for SWB. The extent of the benefit varies, however, and are circumscribed by culture-level and individual-level variables. In addition, much of the effect appear to be mediated by third variables that may perhaps account for much, if not most, of the effect of religiosity on SWB.

Processes that Explain the Relation between Religion and SWB

What might explain the relationship between religiosity and SWB and further clarify the boundary conditions of this effect? Lewis and Cruise (2006) argue that by definition, religion provides "existential certainty," a meaning in life. They further argue that it provides mechanisms for social support, emphasizing the social implications of religious involvement (see also Myers, 2000). Indeed, much research have borne out this theory. In addition, others have noted that religion serves as a bulwark against distress by providing various ways of coping, whether it be through social services or through religious belief. Last, a growing body of research investigates the role of religion in emotion experiences and emotion regulation, both of which are implicated in SWB. Below, each of the process variables are discussed in turn and evaluated in terms of the research evidence.

Meaning in life. Religions, by definition, provide an explanation for the world and the rationale for existence within it. Most religions also provide a goal or a standard by which that existence should be measured. These edicts provide meaning and purpose to adherents, and research evidence bears out the importance of meaning in life as a mediator. For example, French & Joseph (1999) found that meaning in life fully mediated the relation between religiosity and happiness. Others have found similar results, even when meaning in life has been operationalized slightly differently as coherence or importance of meaning, or when religiosity was measured as attendance at religious service (e.g., Ellison, 1991; Yoon et al., 2015; see George, Ellison & Larson, 2002 for review of research on meaning as mediator for relation between religiosity and physical health). In addition, a prospective research study measuring adjustment and well-being pre- and post- a major natural disaster also found that sense of purpose, as well as optimism, mediated pre-disaster religiosity and post-disaster well-being (Chan, Rhodes & Perez, 2012). And as was the case for the body of research on religion and SWB in general, while much of the research is based on Christian adherents, the findings replicate across religions (i.e., Steger & Frazier, 2005; Vilchinsky & Kravetz, 2005).

Coping. Not all coping strategies, whether they be religious or non-religious, are effective. Similarly, not all religious coping strategies provide comfort. However, positive religious coping strategies, similar to positive coping strategies in general, provide access to heightened well-being. For example, Mickley, Pargament, Brant & Hipp (1998) found that for hospice caregivers, religious appraisals that were positive vs. negative (death as punishment from God vs. dying process as a benevolent act from God) predicted meaning in life, anxiety, depression, and spiritual well-being (see also Koenig, George & Siegler, 1988; Pargament et al., 1990). Indeed, a meta-analysis of 147 studies on the relation between religiosity and depressive symptoms found that while the overall strength of relation was r = -.09, when positive religious coping, intrinsic religious orientation and positive regard of God were separated from external religiosity and negative coping, the effect size was as high as r = -.20 (Smith, McCullough, & Poll, 2003). Similarly Ano and Vasconcelles (2005) found mean r = .33 for positive religious coping and positive psychological outcomes. Similar findings have been noted for Lebanese college students in Beirut (Moussa & Bates, 2011), and Muslim participants (Abu-Raiya, Pargament, & Mahoney, 2011). And while not as numerous as cross-sectional research, prospective studies have also confirmed the positive effect of positive religious coping on SWB. Chan & Rhodes (2013) found that positive religious coping predicted posttraumatic growth following a large-scale natural disaster, while negative religious coping predicted symptoms of post-traumatic stress disorder.

It is important to note, however, that much of the research on religious coping conflate several variables. For example, an often used positive religious coping strategy might be cognitive reappraisal, but also prevalent are forms of emotional and social support, such as seeking support from members of the religious congregation or religious leader (e.g., Pargament et al., 1994). Thus, below, we further investigate the different ways in which social support may be a crucial mediator in the relation between religiosity and SWB.

Social support. A robust body of research indicates that strong and close social relationships may be one of the most important predictors of SWB (for brief review, see Myers, 2000). For many religious traditions, regular attendance at religious services and/or membership in a congregation is a large component of adherence to the religion. A strong indication that social support may indeed account for much of the effect of religiosity lies in the fact that in many of the above research studies, religiosity has been operationalized as frequency of church attendance. When religiosity is measured in multiple ways, research have found that it is church attendance that best predicts well-being outcomes. For example, Strawbridge, Shema, Cohen, Roberts, & Kaplan (1998) measured private/individual religious acts and beliefs, such as prayer, importance of religion, as well as church attendance, and found that it was church attendance that best predicted well-being (see also Levin & Chatters, 1998).

Research indicates that frequent churchgoers not only have larger social networks, but also more frequent contact with members in the network, both in person and by telephone. Frequent attenders also received greater social support, and rate their social relationships as more favorable compared to those who do not attend religious congregations as frequently (Ellison & George, 1994). In addition, this relation held when personality variables, such as extraversion, were controlled for (Bradley, 1995).

The social support appears to provide benefits to adherents in two ways: As a buffer against adverse life events; and as source of social capital and status. For example, Williams, Larson, Buckler, Heckmann & Pyle (1991) found that religious attendance moderated the effect of stress on mental health, such that for low frequency attenders, stressful life events negatively impacted metal health, whereas high frequency attenders were less debilitated by negative life events (see also Ellison, Burr & McCall, 1997; Salsman, Brown, Brechting & Carlson, 2005). And in the aftermath of tragic events, such as the sudden death of an infant, parents who were frequent attenders received greater social support, and that social

support in turn predicted better adjustment three weeks later (McIntosh, Silver, & Wortman, 1993). As a source of social capital, Shkolnik, Weiner, Malik & Festinger (2001) found that religiosity predicted social status, which in turn led to social capital among elderly Jewish participants (see also King & Furrow, 2004).

The benefits of social support can also be discerned by holding the benefit of shared doctrine constant. Unitarian Universalism does not have a creed; instead, each member is responsible for seeking their own spiritual path, which means that the benefit of a cohesive principle or belief may be missing. Even in such cases, adherents benefited from social support of the congregation and derived strength and comfort (Elliott & Hayward, 2007). Researchers found, however, that the extent of benefit depended on whether being a Unitarian Universalist was central to their identity. The role of identity as a member of a religious group seems to be an important element of social support in other religions as well. Using a national probability sample, Greenfield & Marks (2007) found that social identity mediated the effect of church attendance on SWB. In addition, Hayward & Elliott (2009) found that degree of congruence with the congregation predicted having spiritual needs met, as well as help with daily living. Indeed, Hogg, Adelman and Blagg (2010) go as far as to posit religion as a social group, and religiosity as the extent to which one adheres to the norms, beliefs, and mores of that social group, with the difference between religions and other social groups being that religion's beliefs are existential.

But if social support mediates the effect of religiosity on SWB, and religion is yet another social group, then is religion necessary? That is, is religious social support something that provides benefits for the adherent above and beyond social support received from non-religious sources? Some research seems to indicate that while social support from non-religious sources also serves to buffer and provide social capital, religious social support provides unique benefits to well-being. For example, while church based emotional support appeared to buffer against the negative impact of financial stain, support from secular networks did not (Krause, 2006; see also Krause & Bastida, 2009). In addition, while spiritual support predicted positive religious coping in adherents, emotional support did not (Krause, Ellison, Shaw, Marcum, & Boardman, 2001).

And of course, one can be a strong adherent of a religion without being a member of a congregation. And in many religions, communal worship or membership in a congregation is not a codified part of religious adherence, or a valued aspect of religiosity. This was seen in Krause, Ingersoll-Dayton, Liang, & Sugisawa (1999), who found that for elderly Japanese participants, the aspect of religiosity that mattered was not attendance at religious functions, but daily at-home religious practices. Thus, while social support explains much of the link between religiosity and SWB, it cannot fully explain the effect of religiosity on SWB.

Emotion. In searching for additional processes that might explain the impact of religion on SWB, Fredrickson (2002) suggested positive emotions as a mediator. Indeed, emotions are an integral part of religion, such that religions provide guidelines for experiencing, or not experiencing, specific emotions (Kim-Prieto, 2014; Kim-Prieto & Diener, 2009). Thus, the experience of specific emotions, as well as regulation of that experience, might indeed help explain religion's impact on SWB.

A robust body of research indicates that religious emotions play a key role in promoting SWB. Religious services, prayer, sermons, reading religious texts, serve as triggers of positive religious emotions (Argyle & Hills, 2000). Emotions such as awe, gratitude, love and peace, as well as optimism, have been found to fully mediate religiosity and well-being (van Cappellen, Toth-Gauthier, Saroglou, & Fredrickson, 2016; Salsman et al., 2005). Religious people who practice forgiveness report lower stress, depression, and anxiety (Spilka, Hood, Hunsberger, & Gorsuch, 2003; Worthington, Berry, & Parrott, 2001), and those who practice Loving Kindness meditation, a Buddhist meditation practice, reported increased positive emotions, which in turn predicted increased social support (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008; see also Philippot, Chapelle & Blairy, 2002). In addition, even on social media platforms, presumed Christians showed greater use of positive emotions words compared to presumed atheists (Ritter, Preston, & Hernandez, 2013).

In addition to emotion elicitation, religious traditions regulate emotions in additional ways. Disclosure of emotion has been found have positive benefits for well-being, and religious practice often serves as a way by which trauma or negative experiences can be disclosed (described in Pizarro & Salovey, 2002). In the Roman Catholic tradition, for example, describing transgressions is expected to absolve sin, thus providing a way of ameliorating guilt. In addition, while prayer, meditation, and other similar rituals can serve to elicit positive emotions, they can also promote the regulation of other emotions. A growing body of research on mindfulness-based meditation, a Buddhist meditation technique, has established a robust set of evidence showing the benefits of meditation on emotion regulation (for review, see Lykins, 2014). For example, Goldin & Gross (2010) found that participants with social anxiety disorder who

participated in an 8-week mindfulness based stress reduction meditation session experienced reduction in anxiety, depression, and rumination.

Conclusion

Thus, as reviewed above, evidence points to religion as a factor in SWB. Much of the effect, however, is mediated by other intervening variables, such as meaning in life, coping, social support, and emotion regulation. While research evidence shows that some of these intervening variables fully mediate the effect of religiosity on SWB, additional evidence also indicates that some of these mediating factors may be unique to religion. In addition, some of these variables may also serve as moderators. For example, benefits of religious coping would accrue in response to distressful events, but not in the absence of such events. Last, additional context variables moderate the role of religion on SWB. For example, as reviewed above, the extent to which a culture values religiosity or provides supports for the practice of religion, along with the experiences of hardship at the individual and society level, impact the effect of religion on well-being.

Freud (1929) believed religion to be a form of neurosis. He considered religion to be an infantile search for bliss, merely an attempt to resolve the Oedipal complex and resolve feelings of helplessness. We have provided evidence that religion provides benefits to the individual and perhaps society. But we also cannot ignore the evidence that religion is not always beneficial. At the individual level, religiosity is linked with greater out-group hostility and prejudice, support for suicide attacks, unwillingness to forgive, and discrimination (e.g., Cohen, Malka, Rozin, & Cherfas, 2006; Ginges, Hansen & Norenzayan, 2009; Hunsberger & Jackson, 2005). Exline (2002) also points out that religion can serve as a source of interpersonal discord and strain, especially group-level violence. And when adherents struggle with disbelief, experiencing disappointment regarding the ineffectiveness of God, experiencing God as distant, or doubts about the existence of God, these experiences predict negative outcomes, with the impact being strongest for those who are most devout (Ellison, Fang, Flannelly, & Steckler, 2013; Exline, Yali, & Lobel, 1999; Exline, Yali, & Sanderson, 2000; Krause & Wulff, 2005; Pargament, 2002; Smith, McCullough, & Poll, 2003).

What are some other variables that might further bolster or attenuate the effect of religion on well-being? Are there specific types of religious activity that may be more or less beneficial than others? Additional research is needed on various mind-body practices, including yogic and other forms of posture based meditation, as well as other bodily practices, such as walking meditation and prayer, spiritual dance, or religious flagellation. And while the body of research investigating the effect in non-Christian and non-Western contexts is growing, additional research is needed to better understand whether some of the effects are merely the effects of those better-researched religions, or can be assumed to be generalizable to religions at large. In addition, while a few sets of research provide experimental data, where religion or religiosity have been experimentally manipulated or made salient (e.g., Kim-Prieto & Diener, 2009), most research are cross-sectional. More experimental research, as well as longitudinal investigations, would allow for stronger evidence of the causal direction of the impact of religion on SWB.

Abstract

As some of the most important relationships in people's lives, marriage and parenthood offer many opportunities for people to experience great joy or to suffer incredible disappointment. In the current chapter, I review current understanding of whether, how, and why marriage and parenthood are associated with well-being, drawing on evidence from cross-sectional, longitudinal, and daily experience studies. I also consider the implications of family structure for the associations between marriage and well-being, and parenthood and well-being, respectively. Current evidence provides relatively robust support for the association between marriage and well-being; however, the association between parenthood is much more complex. I conclude with a number of suggestions for future research.

Keywords: Family, Marriage, Parenthood, Well-Being, Happiness

For many people, getting married and having children represent the ideals of the American dream. Indeed, family relationships are some of the most important aspects of people's lives, influencing their day-to-day experiences, decisions, and broad evaluations of their lives (Gerson, Berman, & Morris, 1991). Not surprisingly, these relationships hold important implications for people's overall happiness and well-being (Nelson, Kushlev, & Lyubomirsky, 2014; Saphire-Bernstein & Taylor, 2013). Drawing on literature from psychology, economics, and sociology, this chapter focuses on how marriage and parenthood are associated with happiness and well-being, along with the psychological factors that magnify and minimize the happiness gained from these relationships.

What is Happiness?

The most common scientific approach to defining happiness (also referred to as subjective well-being) includes cognitive (high life satisfaction) and affective (frequent positive emotions and infrequent negative emotions) components (Diener, 1984; Diener, Suh, Lucas, & Smith, 1999). According to this definition, happy people evaluate their lives positively overall (i.e., high life satisfaction), and they experience frequent positive emotions (e.g., love, joy, contentment) and infrequent negative emotions (e.g., anger, frustration, sadness). Other researchers distinguish happiness from meaning in life, which is theorized to include three components—coherence (i.e., the evaluation that life makes sense), significance (i.e., belief in one's value, worth, and importance), and purpose (i.e., feeling that one has important goals and life direction; King, Heintzelman, & Ward, 2016; Martela & Steger, 2016). Despite these distinctions, however, happiness and meaning in life are highly correlated (Kashdan, Biswas-Diener, & King, 2008; King, Hicks, Krull, & Del Gaiso, 2006). Many studies also examine how family life is related to symptoms of psychological illnesses, such as anxiety or depression. In the current chapter, I focus primarily on studies that measure subjective well-being or one of its components (life satisfaction, positive emotions, or negative emotions) and meaning in life as they relate to family; however, I also draw on studies measuring symptoms of depression and anxiety, particularly when the well-being literature is sparse. I use the terms happiness and subjective well-being interchangeably but refer to specific constructs when discussing findings of individual studies.

Methodological Approaches to Studying Family and Well-Being

Studies of family relationships are remarkably interdisciplinary, drawing on multiple areas within psychology (e.g., developmental psychology, social psychology, clinical psychology), as well as economics and sociology. Moreover, because marriage and parenthood cannot be randomly assigned, drawing causal conclusions about their effects on well-being is difficult. In the absence of experimental approaches, three primary methodologies have been used to investigate the links between family and well-being—each with their own strengths and limitations.

Cross-Sectional Studies

First, research has investigated whether marriage and parenthood are associated with well-being by employing cross-sectional designs comparing the well-being of married participants with unmarried

participants (e.g., Diener, Gohm, Suh, & Oishi, 2000), or parents with nonparents (e.g., Nelson, Kushlev, English, Dunn, & Lyubomirsky, 2013; McLanahan & Adams, 1989; Umberson & Gove, 1989). These studies often rely on large, nationally representative surveys, thus avoiding potential sampling biases. In addition, these datasets often include respondents from young adulthood to very old age and provide in-depth demographic information on each respondent. These features allow researchers to thoroughly investigate the associations between family relationships and well-being across the lifespan and in light of a variety of demographic factors (e.g., gender).

Despite these strengths, studies relying on cross-sectional designs should be interpreted in light of a few limitations. Most notably, these studies cannot determine whether getting married or having children causes changes in well-being. Indeed, some evidence suggests that happiness precedes both getting married and having children (Kim & Hicks, 2016; Luhmann, Lucas, Eid, & Diener, 2013; Lyubomirsky, King, & Diener, 2005; Cetre, Clark, & Senik, 2016). In an effort to address this limitation and determine whether marriage and parenthood cause changes in well-being, some studies include many demographic factors (e.g., age, gender, income) as covariates in their analyses (e.g., Bhargava, Kassam & Loewenstein, 2014); however, few studies include similar covariates in their analyses, making it difficult to compare across studies, and causality is still impossible to determine in the absence of random assignment or time separation among variables. A more informative approach may be to examine these covariates as moderating variables that may alter the links between marriage or parenthood and well-being, respectively (for a full discussion of this issue as it relates to parenthood and well-being see Nelson, Kushlev, Dunn, & Lyubomirsky, 2014; Nelson, Kushlev, & Lyubomirsky, 2014).

Longitudinal Studies

Second, studies have examined whether well-being changes before and after getting married or having children using longitudinal designs (for a meta-analysis, see Luhmann, Hofmann, Eid, & Lucas, 2012). By relying on a within-person approach, these studies partially address selection biases (that happy people are more likely to get married and have children; Cetre et al., 2016; Kim & Hicks, 2016; Lyubomirsky et al., 2005). In addition, like the cross-sectional studies described above, many longitudinal studies examining the transition to marriage or parenthood rely on large, nationally representative samples (e.g., Dyrdal & Lucas, 2013; Lucas, Clark, Georgellis, & Diener, 2003).

These longitudinal studies are primarily limited by the timing of well-being assessments surrounding marriage and childbirth. A recent meta-analysis of the transition to parenthood, for example, revealed that the average timing of baseline well-being measurement was just 2 months prior to childbirth (Luhmann et al., 2012)—a time likely filled with excitement, anticipation, and celebration in preparation for a new child. Given evidence that well-being begins to change prior to experiencing major life events (Luhmann et al., 2012), these studies should be interpreted in light of when baseline well-being was measured. Furthermore, many couples have children within a few years of getting married (Claxton & Perry-Jenkins, 2008), and marriage itself is associated with a boost in happiness that typically lasts for 2 years (Lucas et al., 2003). Thus, changes in happiness in response to childbirth ought to be interpreted in the context of responses to other life events, such as marriage.

Daily Experience Studies

Finally, studies have investigated the links between family and well-being using methods to capture individuals' daily experiences—namely, by employing experience sampling methodology (Hektner, Schmidt, & Csikszentmihalyi, 2007), the Day Reconstruction Method (Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004), and other daily diary procedures (Bolger, Davis, & Rafaeli, 2003). In these studies, participants typically provide information about their daily activities and emotions, either in real-time (experience sampling), at the end of the day (daily diary), or the following day (Day Reconstruction Method). Using these approaches, studies could compare the daily experiences of married with unmarried participants, or parents with nonparents (e.g., Nelson et al., 2013, Study 2). Alternatively, some studies focus on within-person comparisons—for example, by contrasting parents' emotions during caregiving relative to their other daily activities (e.g., Nelson et al., 2013, Study 3; Nelson-Coffey, Borelli, & River, 2017), or by examining how daily behaviors (e.g., daily sacrifice) are related to relationship satisfaction and well-being (e.g., Impett, Gable, & Peplau, 2005). Thus, one benefit of this methodological approach is its flexibility to address a variety of research questions. In addition, daily experience studies can capture people's feelings while they are spending time with their spouse or children (in contrast to reports of global well-being, which may reflect feelings during other moments of the day). Finally, because these studies typically rely on in-the-moment reports of emotion, they may be less susceptible to response biases.

Notably, however, daily experience studies also have their limitations. Like the other methodological approaches discussed above, these studies do not provide information about the causal influence of getting married or having children on well-being. In addition, because these studies typically

capture reports of momentary emotions, they do not provide insight into how marriage and parenthood are related to global well-being; however, evidence suggests that emotions—especially positive emotions—are important predictors of global well-being (Kuppens, Realo, & Diener, 2008). Finally, daily experience studies may provide a limited portrait of marriage and parenthood, dependent on the type of activity or other influences on people's days.

Summary

In sum, a variety of methodological approaches have been implemented to better understand how family relationships—namely marriage and parenthood—are related to well-being. One of the great challenges in this line of work involves the desire to understand whether these relationships cause people to be happier. Although social scientists may not be able to directly answer the question of causality, they can draw on the methodological approaches described here to understand whether married people and parents are happier than unmarried people and nonparents, respectively, in a randomly selected group of people (cross-sectional studies); whether people become happier after getting married and having children, and for how long (longitudinal studies); and how marriage and parenthood are related to the emotions felt in daily life (daily experience studies). Furthermore, the strongest evidence supporting links between marriage or parenthood and well-being draws on multiple methodologies and demonstrates replicability. In the remainder of this chapter, I review the current literature on family relationships and happiness, turning first to the links between marriage and happiness and next to parenthood and happiness. In this review, I note areas of consensus and contradiction in the research findings and offer suggestions for future research.

Marriage

Is Marriage Associated with Happiness?

The majority of the evidence investigating the claim that marriage is associated with happiness comes from cross-sectional and longitudinal studies examining objective marital status and well-being. Cross-sectional studies indicate that married people tend to be happier than unmarried people (Coombs, 1991; Diener et al., 2000; Easterlin, 2003; Haring-Hidore, Stock, Okun, & Witter, 1985; Kamp Dush & Amato, 2005; Lee & Ono, 2012; Myers, 2000; Williams, 2003; Wood, Rhodes, & Whelan, 1989). These findings are robust and consistent across studies and cultures (Diener et al., 2000; Haring-Hidore et al., 1985; Lee & Ono, 2012). In one study, for example, the association between marriage and subjective well-being was examined in 42 nations. Across countries, married participants reported greater life satisfaction and positive emotions and lower levels of negative emotions, relative to both cohabiting and divorced participants (Diener et al., 2000). Additionally, in a meta-analysis of this literature, married respondents reported significantly higher levels of subjective well-being than unmarried respondents (average $r = .14$; Haring-Hidore et al., 1985).

An important consideration in evaluating cross-sectional studies examining the association between marriage and happiness is whether changes in happiness precede marriage. Evidence suggests that happy people have rich and satisfying social relationships (Diener & Seligman, 2002), which may increase their likelihood of getting married. In one classic study on this topic, women's positive emotional expression in their college yearbook photographs was associated with greater likelihood of being married at age 27 and greater marital satisfaction at age 52 (Harker & Keltner, 2001). Another study found that life satisfaction significantly predicted the likelihood of getting married within 5 years (Luhmann et al., 2013). Thus, the findings from cross-sectional studies may be partially explained by the fact that happier people are more likely to get married.

One way to address these selection biases is to examine whether and how happiness changes before and after getting married with longitudinal designs. Longitudinal research also suggests that getting married is associated with a boost in happiness, which diminishes over time. In one study drawing from the German Socioeconomic Panel, people reported their life satisfaction and a variety of demographic information annually for 15 years. Researchers were then able to track changes in respondents' life satisfaction after getting married. This study found that people reported an increase in life satisfaction the year they got married, which was followed by a return to their pre-marriage baseline happiness within 2 years (Lucas et al., 2003). In addition, a meta-analysis of this literature found that cognitive well-being (life satisfaction), but not affective well-being (positive and negative emotions), increased after marriage, followed by a subsequent decline (Luhmann et al., 2012). Thus, existing longitudinal evidence suggests that, on average, getting married is associated with a boost in well-being, which typically dissipates by a couple's second anniversary.

Another approach to understanding whether and how marriage is related to well-being is to consider how relationship quality predicts happiness, over and above objective marital status. These studies suggest that the quality of marriage is a more important predictor of happiness than simply being married. One study on this topic found that people who were in the happiest relationships—whether those were

marriages, cohabiting, or dating relationships—reported the highest levels of subjective well-being (Kamp Dush & Amato, 2005). Another study examined how changes in marital status and marital quality were related to changes in life satisfaction and symptoms of depression over 5 years. In this study, low marital quality (as indicated by high levels of marital stress and low levels of marital harmony) predicted decreases in life satisfaction and increases in depressive symptoms. In addition, this study found that people who remained in unhappy marriages reported lower levels of well-being than those who remained unmarried (Williams, 2003). Furthermore, in an examination of changes in marital quality and happiness over the life course, participants with the highest marital satisfaction also reported high levels of happiness over the course of 20 years (Kamp Dush, Taylor, & Kroeger, 2008). Thus, extant evidence—drawing on both cross-sectional and longitudinal designs—suggests that the quality of a person's relationship is an important predictor of well-being, perhaps more important than objective marital status. Indeed, a meta-analysis of 93 studies found that marital quality was significantly associated with well-being (average r = .37 for cross-sectional studies and average r = .25 for longitudinal studies; Proulx, Helms, & Buehler, 2007).

Individual differences. Marriage may be associated with greater well-being for some people than it is for others. Indeed, a number of demographic and psychological factors moderate the association between marriage and happiness. Although a full discussion of the many individual differences in the association between marriage and happiness is outside the scope of this chapter, below I consider two factors—gender and attachment style—that are important predictors of the association between marriage and happiness.

Gender. Some evidence suggests that the link between marriage and subjective well-being differs for men and women. In cross-sectional studies investigating the link between relationship status and well-being, marriage was more strongly associated with well-being for men than for women (Coombs, 1991; Haring-Hidore et al., 1985). Similarly, in one longitudinal study investigating gender differences in reactions to divorce, men experienced a greater drop in well-being following divorce than did women (Lucas, 2005). Notably, however, a meta-analysis of longitudinal studies examining reactions to getting married (rather than divorced) did not find any gender differences in reactions to marriage (Luhmann et al., 2012). One explanation for these gender differences suggests that men benefit more from the social support they receive from their spouses, whereas women—who tend to have stronger social ties outside of marriage—do not rely as heavily on social support from their spouse (Antonucci & Akiyama, 1987; Coombs, 1991; Gurung, Taylor, & Seeman, 2003).

Conversely, other studies have examined gender differences in the association between marriage and well-being by focusing on relationship quality rather than relationship status. In these studies, relationship quality tends to be more strongly associated with happiness for women than for men (Proulx et al., 2007; Saphire-Bernstein & Taylor, 2013). For example, in one study of older married couples, perceptions of social support from one's spouse was more strongly associated with greater marital satisfaction and well-being among women than men (Acitelli & Antonucci, 1994). Together, this evidence suggests that marriage is differentially associated with well-being for men and women. For men, simply being married seems to be sufficient to improve well-being; for women, however, being in a high quality marriage is associated with greater well-being.

Attachment. Attachment style is thought to develop based on individuals' early experiences receiving care from attachment figures (e.g., their parents) and shapes people's feelings, beliefs, and expectations about relationships across the lifespan (i.e., internal working models; Bowlby, 1969). Attachment styles are commonly measured along dimensions of anxiety and avoidance, with secure attachment characterized by low levels of both anxiety and avoidance (Mikulincer & Shaver, 2007). Attachment avoidance is characterized by distrust of relationship partners along with a desire for independence; attachment anxiety is characterized by fear of rejection and desire for extreme intimacy; and finally, secure attachment is characterized by trust, comfort, and ease in close relationships (Mikulincer & Shaver, 2007, 2016).

Investigations of attachment style and subjective well-being suggest that, relative to those with insecure attachment orientations (i.e., high attachment anxiety or high attachment avoidance), individuals with secure attachments experience greater subjective well-being overall and within their close relationships (Mikulincer & Shaver, 2013). For example, in one study, wives high in attachment anxiety and avoidance expressed fewer positive emotions after reuniting with their husbands following an extended separation (Medway, Davis, Cafferty, Chappell, & O'Hearn, 1995). Similarly, another study found that people high in attachment avoidance expressed fewer positive emotions when discussing positive aspects of their relationship with their partner (Tucker & Anders, 1998). Finally, in a daily experience study of attachment, relationship behaviors, and gratitude, people with secure attachments reported more gratitude in response to their partner's positive behaviors, whereas people high in attachment avoidance reported less gratitude in response to their partner's positive behaviors (Mikulincer, Shaver, & Slav, 2006). Although this

work does not directly test whether attachment style moderates the association between marriage and happiness, it suggests that individuals with secure attachment styles would experience the greatest happiness in response to marriage.

Why is Marriage Associated with Happiness?

Why is marriage associated with happiness? The bulk of research addressing this question focuses on the importance of relationships, and processes within those relationships, for happiness more generally, rather than the specific importance of marriage. From this perspective, theory suggests that human beings have a fundamental need to belong (Baumeister & Leary, 1995) and to feel connected to others (Ryan & Deci, 2000). Thus, marriage—especially highly satisfying marriages—may offer people opportunities to feel that they belong and that they are connected to others. In addition, a large body of research suggests that social support is beneficial for both physical health and subjective well-being (Cohen, 2004; Siedlecki, Salthouse, Oishi, & Jeswani, 2014). Indeed, receiving adequate support from one's spouse is associated with greater life satisfaction (Wan, Jaccard, & Ramey, 1996), as well as reduced depressive symptoms and perceived stress (Beach, Sandeen, & O'Leary, 1990; Brown, Andrews, Harris, Adler, & Bridge, 1986; Dehle, Larsen, & Landers, 2001).

To my knowledge, an integrated model explaining the association between marriage and happiness does not exist. Drawing on the substantial body of research demonstrating that relationships are beneficial for happiness, future researchers may wish to integrate this literature to develop a unifying theory explaining the links between marriage and happiness. Notably, such a model would help distinguish the extent to which marriage is associated with happiness due to selection effects (e.g., Luhmann et al., 2013), along with psychological processes beneficial to well-being after marriage, such as feelings of connectedness, social support, and others.

Family Structure and Changing Societal Norms

Notably, the majority of past research examining the association between marriage and happiness focused on comparing legally married, opposite-sex couples with those who were never married, divorced/separated, or cohabiting, with variations in comparison groups across studies. Understanding these distinctions is important, given rising rates of cohabitation (Bumpass & Lu, 2000; Lichter, Turner, & Sassler, 2010) and the legalization of same-sex marriage.

Cohabitation. In general, studies offer consistent evidence that being married is associated with benefits to well-being in comparison with those who have never been married (Easterlin, 2003; Lee & Ono, 2012; Myers, 2000; Williams, 2003), those who were divorced or separated (Diener et al., 2000; Myers, 2000; Williams, 2003) or those who were widowed (Haring-Hidore et al., 1985; Williams, 2003). The evidence comparing marriage with cohabitation, however, is mixed. Some studies found that marriage was associated with greater happiness relative to cohabitation (Diener et al., 2000; Lee & Ono, 2012), whereas others found no difference in happiness levels of married and cohabiting individuals (Kamp Dush & Amato, 2005). Furthermore, cross-cultural evidence suggests that marriage is associated with a larger boost in happiness relative to cohabitation in cultures with stronger religious and social norms against cohabitation (Lee & Ono, 2012; Soons & Kalmijn, 2009). In addition, a 1985 meta-analysis of the link between marriage and well-being found smaller effect sizes among more recent studies (Haring-Hidore et al., 1985)—a time also marked by increasing favorability towards cohabitation (Thornton & Young-DeMarco, 2001). To my knowledge, a more recent meta-analysis of the association between relationship status and well-being has not been conducted. An updated meta-analysis including studies from the last 30 years is warranted to determine if effect sizes have continued to shrink.

Other research has examined how cohabitation prior to marriage is related to relationship quality and stability after marriage. Early evidence suggested that premarital cohabitation was associated with lower marital quality and increased risk of divorce (Axinn & Thornton, 1992; Schoen, 1992; Thomson & Colella, 1992), but more recent work has suggested that this "cohabitation gap" is moderated in part by social context (e.g., gender climate and religious context; Lee & Ono, 2012; Soons & Kalmijn, 2009; Stavrova, Fetchenhauer, & Schlosser, 2012; Stavrova & Fetchenhauer, 2015). For example, in one study of 30 European countries, the cohabitation gap was larger in countries that were less accepting of cohabitation (Soons & Kalmijn, 2009). Additionally, another study found that women who cohabited only once prior to marriage (with their eventual spouse) did not demonstrate increased risk of divorce (Teachman, 2003), further pointing to inconsistency in the association between cohabitation and marital satisfaction.

Three explanations have been offered to clarify why cohabiters may be less happy and less satisfied in their relationships. First, studies finding that the size of the cohabitation gap depends in part on societal norms for cohabitation, gender, and religion (Lee & Ono, 2012; Soons & Kalmijn, 209; Stavrova et al., 2012; Stavrova & Fetchenhauer, 2015) suggest that people may be less happy due to their violation of these social norms. Second, people who choose to cohabit prior to marriage may be unique in ways that

undermine their happiness and relationship satisfaction. For example, cohabiters may have relatively less favorable attitudes towards marriage and more favorable attitudes towards divorce (Axinn & Thornton, 1992), which may increase their likelihood of divorce. Third, the experience of cohabiting may alter people's attitudes in ways that undermine marital quality. One study found that people were more accepting of divorce after cohabiting than they were prior to cohabiting (Axinn & Thornton, 1992), which in turn predicts declines in relationship quality (Amato & Rogers, 1999). Ultimately, research has supported each of these three possibilities, suggesting that they are not mutually exclusive.

Same-sex marriage and partnerships. Same-sex marriages are legally recognized in 23 countries worldwide (Pew Research Center, 2015). Notably, however, the majority of research on romantic relationships (marriage or otherwise) and well-being focus on opposite-sex partnerships. Evidence suggests that the factors that predict relationship quality in same-sex couples are the same as those that predict relationship quality in opposite-sex couples (e.g., trust, communication, conflict-resolution styles; Balsam, Beauchaine, Rothblum, & Solomon, 2008; Kurdek, 2005). In addition, one study compared lesbian, gay, and heterosexual couples on five domains expected to be indicative of relationship health: psychological adjustment (including life satisfaction), personality traits, relationship styles, conflict resolution, and social support. This study found no difference in reported life satisfaction between same-sex and opposite sex couples and that the only area in which same-sex couples fared worse than opposite-sex couples was in the amount of support they received for their relationships from others (Kurdek, 2004). More research incorporating same-sex couples in understanding the links between relationship status, relationship quality, and well-being is needed.

Summary

In sum, married people tend to be happier than single, divorced/separated, and widowed individuals, with the most consistent evidence from cross-sectional studies of opposite-sex couples. Longitudinal research suggests that getting married is associated with a boost in happiness that diminishes over time. Furthermore, despite these overarching trends in the association between marriage and happiness, little work has explained why marriage is associated with happiness.

Parenthood

Is Parenthood Associated with Happiness?

Is parenthood associated with happiness? This simple question assumes that there is a simple answer—parents are either happy or not. Notably, however, parenthood is a complex and dynamic role, involving multiple people (e.g., co-parent, one or more children) and many changes throughout the life course (e.g., parenting a toddler vs. a teenager). Accordingly, parenthood may be better understood as a fluid process that changes over time, and its association with well-being depends on many different factors (see Nelson et al., 2014 for a review).

Highlighting the complexity of parenthood, cross-sectional studies comparing the happiness levels of parents with nonparents have reached conflicting conclusions. Research has indicated that (a) parents report greater well-being than nonparents (Balbo & Arpino, 2016; Nelson et al., 2013); (b) parents report lower well-being than nonparents (Evenson & Simon, 2005; McLanahan & Adams, 1987, 1989); and (c) parents and nonparents do not differ in their reported well-being (Rothrauff & Cooney, 2008). Further adding to this confusion, another recent study found that parents reported both more positive emotion and more negative emotion than nonparents (Deaton & Stone, 2014).

Evidence regarding the association between parenthood and well-being from longitudinal studies appears to be more consistent than evidence from cross-sectional studies; however, this work also supports the idea that parenthood is complex and dynamic. Studies of the transition to parenthood have found that becoming a parent is associated with a rise in well-being followed by a decline (Dyrdal & Lucas, 2013; Margolis & Myrskyla, 2015). Moreover, this pattern is not consistent for all parents: Men and people with higher socioeconomic status (people with higher income, more education, and who are employed) have an easier transition to parenthood (Margolis & Myrskyla, 2015). Finally, a meta-analysis of this literature confirms the overarching trend—the transition to parenthood was associated with an initial rise in life satisfaction with a subsequent decline. This meta-analysis also revealed that parents reported greater positive emotion after their child was born than they did prior to becoming a parent (Luhmann et al., 2012).

These findings regarding positive emotion are also consistent with evidence from daily experience studies. In an experience sampling study comparing parents' and nonparents' emotions in their daily lives, parents reported significantly more positive emotion and meaningful moments than nonparents (Nelson et al., 2013). Providing a conceptual replication of these results, other work found that parents report more positive emotion and meaning in life during their time spent with children relative to their other daily

activities (Musick, Meier, & Flood, 2016; Nelson et al., 2013; Nelson-Coffey et al., 2017). These findings may seem contradictory to a classic finding that childcare ranks relatively low in positivity (Kahneman et al., 2004). In this study, a sample of working women (including both parents and nonparents) completed the Day Reconstruction Method, recording all of their activities and emotions for an entire day. When activities were rank-ordered by average positivity across the entire sample, childcare ranked close to the bottom—below having sex, relaxing, and watching TV, among others, but above housework, working, and commuting (Kahneman et al., 2004). Notably, however, this study included both parents and nonparents in their analysis and did not account for whether or not people actually engaged in each of the given activities. Thus, although this study provides preliminary insight regarding people's feelings during childcare, it does not provide conclusive evidence that childcare is significantly associated with lower emotional well-being among parents. In subsequent studies including only parents, their emotions during childcare were compared with their emotions during their other daily activities. In each of these studies, childcare was associated with elevated positive emotion and meaning in life (Musick et al., 2016; Nelson et al., 2013; Nelson-Coffey et al., 2017).

In sum, longitudinal and daily experience studies provide consistent support that parenthood could be associated with elevated well-being—albeit temporarily. Conversely, the evidence from cross-sectional studies is much less consistent. The conflicting evidence could be in part due to differences in statistical approaches and sample characteristics. Indeed, evidence suggests that the association between parenthood and well-being is moderated by a number of parent demographic (e.g., parent gender; Margolis & Myrskyla, 2015; Musick et al, 2016; Nelson et al., 2013) and psychological (e.g., attachment style; Nelson-Coffey et al., 2017) characteristics, which may shed light on these conflicting findings (see Nelson et al., 2014).

Individual differences. The happiness associated with parenthood depends in part on parents' age, gender, marital status, as well as their personality and attachment orientation. Indeed, a number of demographic (e.g., gender) and psychological (e.g., attachment style) factors moderate the association between parenthood and well-being. Although a full review of the many moderators of the association between parenthood and well-being is outside the scope of this chapter, in this section I consider gender and attachment style as important factors predicting parents' well-being.

Gender. Evidence suggests that parenthood is more strongly associated with greater well-being for fathers than for mothers. In one study of a nationally representative sample from the U.S., fathers were happier than men without children, but mothers were no more or less happy than women without children (Nelson et al., 2013). Consistent with these findings, other studies have found fatherhood to be associated with well-being (Keizer, Dykstra, & Poortman, 2010; Kohler, Behrman, & Skytthe, 2005). Conversely, studies comparing the relative well-being of mothers with women without children tend to find no differences or a relative well-being deficit among mothers. In one study of Norwegian mothers over the transition to parenthood, self-esteem decreased during pregnancy, increased around childbirth, followed by a gradual decline over the course of 3 years (van Scheppingen, Denissen, Chung, Tambs, & Bleidorn, in press).

One explanation for the gender differences in parents' well-being may involve the nature of mothers' and fathers' interactions with their children. Women tend to spend more time—and more time alone (i.e., solo parenting)—with their children (Musick et al., 2016; Nelson-Coffey et al., 2017). In addition, when mothers spend time with their children, they are relatively more likely to engage in basic childcare, childcare management, cooking, and cleaning with their children, whereas fathers are more likely to engage in play and leisure with their children (Musick et al., 2016). These gender differences in how parents spend time with their children have implications for happiness as well. In this study, for example, play (more common among fathers) was associated with the highest levels of well-being across activities, whereas basic childcare and solo parenting (more common among mothers) were associated with low levels of well-being (Musick et al., 2016). Other work suggests that mothers experience more guilt, particularly in juggling caregiving and employment (Borelli, Nelson, River, Birken, & Moss-Racusin, 2017; Borelli, Nelson-Coffey, River, Birken, & Moss-Racusin, in press), suggesting another potential pathway explaining mothers' relatively lower levels of well-being.

Attachment. In addition to shaping people's expectations and experiences in romantic relationships, attachment style also shapes people's experiences caring for their children (Jones, Cassidy, & Shaver, 2015; Mikulincer & Shaver, 2016). Attachment avoidance is associated with greater stress in the transition to parenthood (Rholes, Simpson, & Friedman, 2006), less reported closeness with children (Rholes, Simpson, & Blakeley, 1995; Wilson, Rholes, Simpson, & Tran, 2007), and lower parenting satisfaction (Cohen, Zerach, & Solomon, 2011; Rholes et al., 2011). Furthermore, two daily experience studies found that parents high in attachment avoidance reported fewer positive emotions while spending time with their adult (Impett, English, & John, 2011) and young (Nelson-Coffey et al., 2017) children.

Together, this work suggests that attachment avoidance would be associated with relatively lower levels of well-being among parents. In addition, attachment anxiety is associated with greater parent-child conflict (Selcuk et al., 2010), greater parenting stress (Fernandes, Muller, & Rodin, 2012), and greater negative emotion in parent-child interactions (River, Borelli, & Nelson-Coffey, 2016). Notably, however, in a daily experience study, attachment anxiety did not differentially predict positive emotion, negative emotion, or meaning during caregiving relative to parents' other daily activities (Nelson-Coffey et al., 2017). Thus, existing evidence more consistently indicates that parents' high in attachment avoidance may experience lower levels of well-being; however, more work is needed to disentangle the moderating role of attachment anxiety in parents' well-being.

Why is Parenthood Associated With Happiness (and Unhappiness)?

Drawing on evidence from cross-sectional, longitudinal, and daily experience studies, my colleagues and I developed a model of parents' well-being to illuminate the psychological factors that predict happiness and unhappiness among parents (Nelson et al., 2014). According to this model, parents report greater happiness when they experience elevated feelings of meaning in life, positive emotions, psychological need satisfaction (i.e., autonomy, competence, and connectedness), and fulfillment of social roles. Conversely, parents report less happiness when they experience elevated negative emotions, financial strain, sleep disturbance, and lower relationship satisfaction.

Notably, not all pieces of this model have been thoroughly tested. Supporting the path to parents' greater well-being, research reliably indicates that parents report elevated meaning in life (Nelson et al., 2013; Nelson-Coffey et al., 2017; Umberson & Gove, 1989) and positive emotion (Deaton & Stone, 2014; Musick et al., 2016; Nelson et al., 2013; Nelson-Coffey et al., 2017). Fewer studies have directly tested the links between parenthood and psychological need satisfaction and fulfillment of social roles, although indirect evidence supports that they would be important predictors of parents' well-being. For example, one study found that parenting efficacy, authenticity, and satisfaction with friendships and partner were correlated with life satisfaction among mothers (Luthar & Ciciolla, 2015), providing suggestive evidence for the importance of competence, autonomy, and connectedness, respectively. Furthermore, research suggests that holding more social roles (Barnett & Hyde, 2001; Thoits, 1992) and feeling called to fulfill those roles (Bellah, Madsen, Sullivan, Swidler, & Tipton, 1985) promotes well-being. Thus, parenthood may be associated with improved well-being by providing parents with an additional social role or calling to contribute to their identities.

Supporting the path to parents' lower levels of well-being, research consistently indicates that parents report relatively lower levels of relationship satisfaction (for meta-analyses see Luhmann et al., 2012; Twenge, Campbell, & Foster, 2003), along with greater financial strain (Bird, 1997; McLanahan & Adams, 1987; Ross & Van Willingen, 1996; Umberson & Gove, 1989; Zimmermann & Easterlin, 2006) and sleep disturbance and fatigue (Chalmers & Meyer, 1996; Gay, Lee, & Lee, 2004; Lee, Zaffke, & McEnany, 2000; Yamazaki, Lee, Kennedy, & Weiss, 2005). The evidence regarding parents' experiences of negative emotions, however, is somewhat inconsistent. Some evidence suggests that parents report greater stress (Deaton & Stone, 2014), anger and frustration (Ross & Van Willingen, 1996; Simon & Nath, 2004), and depression (Evenson & Simon, 2005) compared with nonparents; however, another recent study found that parents did not report greater negative emotion while they were spending time with their children relative to their other daily activities (Nelson-Coffey et al., 2017). Notably, more work is needed to better understand parents' experiences of negative emotions, as well as replication of this latter finding.

Furthermore, the parents' well-being model was developed based on a comprehensive review of the literature and has therefore not been tested extensively. Future work investigating the predictors of parents' happiness and unhappiness in a single study would be informative. In particular, such a study would illuminate whether some factors are more important for parents' happiness than others. For example, past research indicated that positive emotions more strongly predict long-term well-being than negative emotions (Coffey, Warren, & Gottfried, 2015; Cohn, Fredrickson, Brown, Mikels, & Conway, 2009; Kuppens et al., 2008; Nelson, Layous, Cole, & Lyubomirsky, 2016). Accordingly, understanding whether these patterns persist among parents is an important direction for future research.

Family Structure

Families come in all shapes and sizes, including biological, adoptive, and blended families, in addition to parents in opposite-sex or same-sex partnerships. Accordingly, it is important to consider the association between parenthood and well-being in light of the variety of family structures (Caballo, Lansford, Abbey, & Stewart, 2001).

Adoptive and blended families. Little research focuses on understanding how the well-being of adoptive and step-parents compares with parents in other family structures. Adoptive parents may be coping with infertility, managing intrusive adoption screening, and perhaps even coping with societal

discrimination and stigmatization (Bird, Peterson, & Miller, 2002; Caballo et al., 2001), which might predict lower levels of well-being among this group of parents. Notably, however, existing studies do not provide conclusive evidence for differences in the psychological well-being of adoptive and biological parents (Caballo et al., 2001; O'Brien & Zamostny, 2003). For example, one study compared a group of adopted children and their parents with a matched sample of biological children and parents from the National Survey of Families and Households. In this study, biological and adoptive parents did not differ in their reports of happiness or depressive symptoms (Borders, Black, & Pasley, 1998). In addition, other studies found no differences between biological and adoptive parents in stress, health, or self-esteem (Mainemer, Gilman, & Ames, 1998; Ternay, Willborn, & Day, 1985).

Research comparing stepparents to other family structures is similarly inconclusive. For example, one study found that stepparents reported lower parenting satisfaction than biological parents (Rogers & White, 1998), but another study found no differences between stepparents and biological parents in symptoms of depression, life satisfaction, and self-esteem (Lansford, Ceballo, Abbey, & Stewart, 2001). Finally, research comparing the well-being of biological, step-, and adoptive parents indicates that factors associated with family processes (e.g., family cohesion) are stronger predictors of well-being than objective family structure (Lansford et al., 2001).

Same-sex partnership. Most research on parents' sexual orientation has focused on child outcomes. These studies generally do not find any harmful consequences of being raised by parents in same-sex relationships in terms of children's gender behavior and preferences, sexual behavior and preferences, or mental health (Stacey & Biblarz, 2001). Very few studies have investigated the relative happiness of parents and nonparents in same-sex marriages or partnerships. Parents in same-sex partnerships may face stigmatization, difficult adoption proceedings, or other challenges in becoming parents that might indicate low levels of well-being. However, existing research suggests the reverse: Parents in same-sex partnerships tend to report relatively high levels of well-being. One review of this literature noted that lesbian mothers reported fewer depressive symptoms and greater self-esteem than heterosexual mothers (Stacey & Biblarz, 2001). Similarly, one study of fatherhood in Israel found that gay fathers reported higher levels of life satisfaction than heterosexual fathers (Erez & Shenkman, 2016). Another study found that the self-perceived parental role—which involves multiple aspects of parent identity, including investment, competence, integration with other life domains, and satisfaction—was associated with meaning in life among gay, but not heterosexual, fathers in Israel (Shenkman & Shmotkin, 2016). Finally, psychological need satisfaction within one's relationship was associated with greater levels of personal growth among lesbian mothers, but not heterosexual mothers (Shenkman, in press). These studies provide preliminary evidence that parents in same-sex relationships do not report reduced well-being, and may even experience elevated well-being in comparison to heterosexual parents. Notably, however, much of this research relied on Israeli samples (where same-sex marriage is not legally recognized and attitudes towards same-sex relationships may differ from other cultures). Accordingly, more work is needed to evaluate how sexual orientation is related to parents' well-being in other cultures.

Summary

In sum, researchers have drawn on a variety of methodological approaches to investigate the association between parenthood and well-being. Cross-sectional studies have reached conflicting conclusions about whether parents are more or less happy than nonparents, but longitudinal and daily experience studies have more consistently indicated a happiness benefit (albeit temporary) for parents. In addition, recent work has focused more on understanding why and for whom parenthood is associated with happiness (e.g., Nelson et al., 2014). Furthermore, despite changing trends in family structures, evidence does not suggest that parenting in the context of adoptive, blended, or same-sex partnerships is associated with detriments to parents' well-being.

Concluding Remarks

As some of the most important and significant aspects of people's lives, family relationships—particularly marriage and parenthood—have important implications for individuals' happiness. However, much remains to be learned about how and why marriage and parenthood are related to well-being. In this chapter, I suggested potential mechanisms linking marriage and parenthood to well-being, and provided suggestions for future research on these topics. In particular, studies aiming to understand how and why marriage is associated with happiness would be informative. Furthermore, an important direction for research on parenthood and well-being will be to consider parenthood as a dynamic process that unfolds over time, rather than a static identity. Finally, research considering strategies people can use to improve their marriages and relationships with their children, along with whether and how such strategies improve happiness, would be illuminating. Thus, nurturing one's family relationships may offer people opportunities to live happy and fulfilling lives.

LIFE DOMAINS

Work, the Work-Family Interface, and Subjective Well-being

By Michael Ford, Yi-Ren Wang, & Youjeong Huh, University of Alabama

Abstract

Work is a significant contributor to subjective well-being (SWB) among working people and their families. Chronic, structural work conditions and discrete emotionally-charged events have potential to influence SWB via job satisfaction, affective states experienced at work, and spillover of work into family life. In this chapter we review cumulative empirical findings on the relationship between SWB and a) characteristics of the work that people perform, b) social support and leadership at work, c) fairness and mistreatment at work, d) perceived characteristics of one's employing organization, and e) the work-family interface. Also considered are emerging research questions about the dynamics and causal directions among work and SWB, the integration of and recovery from work and other life roles (e.g., family), empirical findings taking a global perspective on work and SWB, and the role of precarious employment arrangements and unemployment in worker SWB. Empirical results indicate that factors from each of these areas correlate with SWB, although some are more predictive than others, and results vary across dimensions of SWB. Furthermore, questions remain about causal relationships and temporal dynamics among work and SWB and differences across cultures and regions of the world. As science continues to accumulate on SWB, the role of work will continue to be better understood alongside other life factors.

Working people spend the majority of their waking hours on the job, and the characteristics of their jobs and work situations vary in systematic ways that contribute to their quality of life and well-being. Work also tends to spill over into other areas of life, which has additional implications for well-being and functioning in family and other life domains. Relatedly, there is increasing pressure in many societies to sacrifice family and leisure in order to respond to work-related pressures. Thus, a complete understanding of subjective well-being needs to incorporate the experiences and chronic conditions that characterize work life. What are these experiences and working conditions that contribute to subjective well-being (SWB) and which are most important? And how are these structured and organized?

Fortunately, there is large literature with many replicable findings on the work-related factors that contribute to SWB. In this chapter we review major models and empirical findings on the relationship between work and SWB. We also consider the spillover of work into other areas of life, especially family. To be comprehensive, we will start by describing the structure of empirical models linking work to SWB. This will be followed by a discussion of specific findings on the relationship between SWB and job characteristics, the work context, and the work-family interface. Finally, empirical findings and unanswered questions on emerging topics will be considered.

The primary focus of our review across these topics will be on the effects of the work *situation* on SWB. With that said, there are many variables at the individual level such as personality traits, coping behaviors, and appraisal processes that may moderate the effects of work-related factors. These are covered extensively in other chapters within this handbook and can be applied to work as well as to other life domains. Because income and finances are covered in detail in other chapters within this volume, our chapter will focus mainly on nonfinancial factors, and will address financial factors only to the extent that they influence SWB via other mechanisms (e.g., perceived fairness, supportiveness, precarious employment). Finally, unless otherwise noted, the core sections of this review will focus on evidence that has accumulated over many studies and has been reported in meta-analyses. The section on new and emerging topics will also discuss a mixture of evidence from meta-analyses and individual studies.

Empirical Approaches to Work and Subjective Well-being

Before delving into the specific work-related factors in SWB, it is important to consider the general structure of these factors and linkages to more general models of SWB. As noted in other chapters of this Handbook, the basic structure of SWB includes overall summary evaluations of one's life, such as life satisfaction and satisfaction with specific life domains (e.g., health, work, family), as well as one's emotional experiences, such as positive and negative affective states (Diener, 2013). There is general support for the notion that these three dimensions, namely satisfaction, positive emotions, and negative emotions, are related but also distinct (Diener, 2013).

Similar to overall SWB, work-related SWB is structured into overall summary evaluations of one's job and emotional states experienced in response to work. Accordingly, the contributions of work to overall SWB are primarily through their influence on a) job satisfaction, and b) emotional experiences at work. Affective Events Theory (AET) (Weiss & Cropanzano, 1996) specifies this distinction and its implications for work-related antecedents. From the perspective of AET, structural work conditions that are relatively stable from day to day, such as one's job duties, organizational procedures, and pay and benefits, influence the stable component of one's job satisfaction. This stable component of job satisfaction tends to change primarily as a function of major changes to one's work situation, such as a pay raise, promotion, or a reorganization of one's job duties. On the other hand, there are discrete work events that come and go on a daily level. These might include interactions with customers or supervisors, task accomplishments and failures, or layoffs in the organization. Discrete events trigger positive and negative emotions that also vary daily, and in turn contribute to daily variance in job satisfaction. Thus, the determinants of job satisfaction include chronic features of work that are relatively stable over time as well as discrete work events that vary from day to day or even from moment to moment. Likely for this reason, there is extensive evidence that job satisfaction and work-related affect are partially stable and partially variable over time (Ilies & Judge, 2002; Judge & Ilies, 2004).

The primary contribution of work to general SWB is through job satisfaction, which represents an overall psychological response to one's job, comprises cognitive and affective components (Hulin & Judge, 2003), and reflects the extent to which work meets the values and needs that are important to the worker (Locke, 1976). The correlation between job and life satisfaction has been found to be approximately .40 (Bowling, Eschleman, & Wang, 2010; Michel, Mitchelson, Kotrba, LeBreton, & Baltes, 2009; Erdogan, Bauer, Truxillo, & Mansfield, 2012), while correlations between job satisfaction and general positive and negative affect are estimated at .38 and -.27, respectively (Bowling, Eschleman, & Wang, 2010). Thus, the factors at work that contribute to job satisfaction should in turn influence overall life satisfaction. Work can also contribute to SWB independent of job satisfaction through its direct influence on other areas of life. In particular, work can influence family life in negative and positive ways (Ford, Heinen, & Langkamer, 2007; Greenhaus & Powell, 2006), and this influence on family life should further contribute to overall SWB (Michel et al., 2009; Erdogan et al., 2012). The effects of work on one's health should also play a role in SWB. There is extensive evidence that working conditions correlate with and predict self-reported physical symptoms (Nixon, Mazzola, Bauer, Krueger, & Spector, 2011), which in turn contribute to SWB. Thus, work can contribute to SWB via job and family satisfaction as well as through one's health.

With empirical models of work and SWB in mind, we now consider established empirical findings on the relationship between SWB and a) the work itself, which refers to the features of the tasks that individuals perform; b) the work context, which refers to the social context of work and the employee-organization relationship; and c) the work-family interface, which refers to the influence of work on family life.

Established Research Findings

Research on work and SWB has yielded a large body of cumulative knowledge about the predictors of SWB from the work domain and the work-family interface. The research findings that have been synthesized in meta-analyses will be the focus of this section. These findings are primarily based on cross-sectional correlations between self-reported working conditions and experiences and self-reported measures of job satisfaction, life satisfaction, and/or indicators of affective well-being such as positive affect, negative affect, stress, emotional exhaustion, or fatigue. Concerns about causality and endogeneity in these effects warrant consideration and will be visited later in this chapter. However, when possible, we will also discuss available evidence from individual studies on specific effects that have been studied longitudinally.

The Work Itself

Some of the most robust predictors of job satisfaction, and in turn overall SWB, are characteristics of the work itself that workers perform. Much of the initial research on the work-related predictors of job satisfaction was inspired by the human relations approaches to management that emerged in the 1960s and 1970s (e.g., McGregor, 1960) as alternatives to the rigid specialization, division of labor, and chain of command characteristic of traditional bureaucratic approaches to work organization. Human relations approaches emphasized the importance of enjoyable, interesting, and enriching work for developing a satisfied and motivated workforce. Around the time of this change in thinking among management scholars, knowledge and theory were also being developed on employee workload and its impact on work role stress (Kahn, Wolfe, Quinn, Snoek, & Rosenthal, 1964).

The most influential of the human relations approaches was the job characteristics model (Hackman & Oldham, 1976), which specified five characteristics of work that improve motivation and

satisfaction. These are as follows: a) *job autonomy*, or the freedom to decide what to do and how and when to do it; b) *skill variety*, or the opportunity to perform different types of tasks and use one's different capabilities; c) *task significance*, or the chance to perform work that is personally meaningful and contributes to important outcomes; d) *task identity*, or the opportunity to create discrete products that one has ownership over; and e) *feedback*, or information about how one is doing that comes directly from the job itself rather than from someone else such as a supervisor. The opportunity to work with others is also sometimes considered within this framework. Early meta-analytic estimates of the correlations between each of these factors and job satisfaction ranged from .20 to .34 (Loher, Noe, Moeller, & Fitzgerald, 1985; Fried & Ferris, 1987). More recent estimates are similar, ranging from .23 for task identity to .37 for autonomy (Humphrey, Nahrgang, & Morgeson, 2007). With respect to affective subjective well-being, results for these dimensions are less clear. Job autonomy (r = -.18), feedback (r = -.15), and task identity (r = -.13), have been found to predict lower job stress, whereas skill variety (r = -.10, *ns*) and task significance have not (r = .04) (Humphrey et al., 2007). Anxiety has also been found to be negatively related to autonomy (r = -.08) and feedback (r = -.26), but not to the other dimensions. As such, it appears that the job characteristics are better predictors of job satisfaction than of affective well-being at work. There has also been surprisingly little research investigating the direct relationship between these job characteristics and life satisfaction, although a moderately positive relationship might be inferred via relationships with job satisfaction.

Some individual studies have investigated the effects of job characteristics and SWB longitudinally. This work has usually either a) examined reciprocal relations among the job characteristics and SWB via multi-wave panel design, or b) investigated the effects of job characteristics via intervention and quasi-experimentation. Individual studies have found that increases in some of these job characteristics were followed by increases in job satisfaction and affective well-being (Holman & Axtell, 2016; Morgeson & Campion, 2002), although such job enrichment can also increase training requirements and workload. Results from longitudinal panel designs have been more mixed (e.g., de Jonge, Dormann, Janssen, Dollard, Landeweerd, & Nijhuis, 2001; Mauno, Kinnunen, & Ruokolainen, 2007), suggesting that the effects of job characteristics on subsequent change in SWB are not as well understood.

Another prominent feature of the work itself that is worth considering is workload, which has been the subject of hundreds of individual studies. Workload generally refers to the amount and difficulty of one's work (Bowling & Kirkendall, 2012) and is treated as a subjective, continuous variable. Workload has been found to be negatively correlated with job satisfaction (r = -.18) and positively correlated with distress, depression, fatigue, and emotional exhaustion (r = .21, .17, .10, and .38, respectively), but unrelated to life satisfaction (r = -.01) (Bowling, Alarcon, Bragg, & Hartman, 2015). Because workload is sometimes associated with higher pay and status, the negative effect of workload on life satisfaction via lower job satisfaction may be offset to some degree. Still, there is a robust relationship between workload and negative affective states. As discussed later in this chapter, workload has been shown to predict subsequent increases in negative affective states in longitudinal panel studies (Ford, et al., 2014), although these effects have been found to vary substantially across studies.

Table 1

Summary of Meta-Analytic Correlations between Work-itself Variables and Subjective Well-being Measures

Correlations	Job Satisfaction	Positive Affect	Subjective Psychological Well being	Life Satisfaction	Negative Affect	Emotional Exhaustion	Stress	Depression
Job Autonomy	0.37						-0.18	
Skill variety	0.32						-.10 (n.s.)	
Task significance	0.31						0.04	
Task identity	0.23						-0.13	
Feedback	0.33						-0.15	
Workload	-0.18			-0.01		0.38		0.17

Note. All correlation coefficients presented are uncorrected and at the individual level, unless noted otherwise.

In summary, it is clear that enriching job characteristics are associated with more positive levels of job satisfaction, which likely results in more positive levels of life satisfaction. Job enrichment characteristics are less consistently related to the negative affective components of SWB, however. On the other hand, workload is associated with negative affective states and lower job satisfaction, but not with overall life satisfaction, perhaps because of the pay and status that accompanies high workloads in many jobs. Individual studies also suggest that job enrichment and workload are associated with some changes in well-being, although these longitudinal effects do not appear to be as robust.

The Work Context- Leadership and Social Support from Others at Work

Although the work itself is a strong determinant of job satisfaction and affective well-being at work, the social context within which the work is performed has received as much, if not more, empirical research attention. By social context, we are referring to the support workers received from others and the organization at large, the fairness and respect with which individuals perceive they are treated, and qualities of leadership in the organization.

Social support at work refers to instrumental (e.g., receiving help with work tasks) and emotional (e.g., having someone to talk with about personal or professional problems) assistance from others, usually supervisors or coworkers. Supportive supervisors can be important for well-being because they have control over resources and decisions that affect an employee, while supportive coworkers can be important because of the frequency with which workers interact with them in many jobs. Meta-analyses indicate that social support at work is a moderately strong predictor of job satisfaction (r = .24), and a weaker, but significant predictor of life satisfaction (r = .14) (Viswesvaran, Sanchez, & Fisher, 1999). A more recent review separating the sources of support suggests an even stronger relationship between coworker support and job satisfaction, after correcting for unreliability in the measures (r = .40) (Chiaburu & Harrison, 2008). Supportive supervision or leadership, which comprises several specific forms of leadership, has shown similar cross-sectional effects (r = .42) (Chiaburu & Harrison, 2008). When comparing types of social support, emotional or affective support from coworkers has been found to be a stronger predictor of job satisfaction (r = .34) than is instrumental support (r = .24) (Chiaburu & Harrison, 2008). Regarding affective well-being, there is meta-analytic evidence that supervisor support (r = -.28) and coworker support (r = -.23) are negatively related to emotional exhaustion or fatigue, suggesting supervisor support has a slightly stronger protective effect against negative emotions than does coworker support (Halbesleben, 2006). Individual longitudinal studies have also suggested that social support at work predicts increases in SWB, particularly when stressor levels are high (de Lange, Taris, Kompier, Houtman, & Bongers, 2004; Dormann & Zapf, 1999; ter Doest & de Jonge, 2006).

Leadership, which overlaps some with social support but includes several distinct constructs, is also an important factor in worker SWB. The most prominent leadership models that have been studied in predicting SWB at work are those involving leader behaviors, transformational/charismatic leadership phenomena, and the exchange relationship between leaders and their subordinates.

Behavioral approaches to leadership focus on the behaviors that leaders engage in, usually in reference to the supervisor. Most leader behaviors that are directly relevant for subordinate well-being fall within two general dimensions: a) *relational*, sometimes referred to as "consideration", and b) *task-oriented*, sometimes referred to as "initiating structure" (Fleishman, Mumford, Zaccaro, & Levin, 1991; Yukl, Gordon, & Taber, 2002). Relational behaviors, which involve showing concern for the subordinate's well-being, are moderately strong predictors of subordinate job satisfaction (r = .40), well-being (r = .28), and negative affective states (r = -.20 to -.21), whereas task-oriented behaviors, which involve providing clear instructions and guidance, are also positively, but not as strongly, related to job satisfaction (r = .19) and show small but significant negative relationships with negative affective states (r = -.09 to -.17) (Judge, Piccolo, & Ilies, 2004; Montano, Reeske, Franke, & Huffmeier, 2017). Such correlations in longitudinal studies have generally been smaller in size but still significant (Judge et al., 2004), although there is not a strong body of research on behavioral leadership and subsequent changes in subordinate SWB. Other leader behaviors that facilitate team processes, coordination, and cohesion may also contribute to SWB (Zaccaro, Rittman, & Marks, 2001), as may strategic behaviors by which leaders organize work tasks, but empirical results linking these behaviors to SWB have yet to be systematically structured and compiled.

Research on transformational/charismatic leadership focuses more on the inspirational processes through which leaders influence followers to meet and exceed expectations (Bass & Avolio, 1994). This work has differentiated *transformational* leadership from *transactional* leadership. Transformational leadership involves behaviors and processes that provide a purpose and vision for subordinates, stimulate followers intellectually, consider the needs of individual subordinates, and provide a role model that followers want to identify with. By contrast, transactional leadership involves providing clear expectations and rewards for meeting those expectations, and intervening to correct problems before they escalate. Research has found that both forms of leadership are strong predictors of worker job satisfaction, with correlations corrected for unreliability of .58 for transformational leadership and .64 for the dimension of transactional leadership involving the provision of contingent rewards (Judge & Piccolo, 2004). By contrast, laissez-faire leadership, which refers to the leader being absent from important leadership functions, is negatively correlated with job satisfaction (r = -.28). Transformational leadership is also positively related to psychological well-being (r = .27) and negatively related to negative affective states (r = -.16 to -.18) (Montano et al., 2017). Longitudinal research on these leadership factors and subordinate SWB has been sparse, however, and some individual studies have found little effect of transformational leadership on subsequent well-being after controlling for baseline effects (Nielsen, Randall, Yarker, &

Brenner, 2008; Nielsen & Munir, 2009; Tafvelin, Armelius, & Westerberg, 2011). Thus, although people who report having transformational leaders also report better SWB, it is not clear that transformational leadership predicts increases in SWB.

The quality of the dyadic exchange relationship between workers and their leaders or supervisors, termed *leader-member exchange*, is also an important factor in job satisfaction, and thus in SWB. Low-exchange relationships between workers and their supervisors are characterized by the formal exchange of pay for performance, whereas high-exchange relationships involve trust, social support, respect, and mutual obligation between leader and follower that goes beyond formal role requirements (Graen & Uhl-Bien, 1995). Not surprisingly, leader-member exchange quality as reported by the subordinate has been found to correlate strongly with job satisfaction (r = .42) (Dulebohn, Bommer, Liden, Brouer, & Ferris, 2012) and is also a predictor of subordinate well-being (r = .39) and negative affective states (r = -.25 to -.27) (Montano et al., 2017). Leader-member exchange from the perspective of the subordinate has also been found to predict increases in job satisfaction longitudinally (Volmer, Niessen, Spurk, Linz, & Abele, 2011). Recent meta-analytic work has shown leader-member exchange to be highly correlated with leader behavioral dimensions (Gottfredson & Aguinis, 2016), suggesting that leader behaviors may influence SWB in part through high quality leader-member exchange relationship. One notable characteristic of this research is that it has primarily focused on leader-member exchange from the perspective of the subordinate. *Leader* perceptions of leader member exchange have been found to also be correlated with subordinate job satisfaction, although not nearly as much so (Cogliser, Schriesheim, Scandura, & Gardner, 2009).

Table 2

Summary of Meta-Analytic Correlations between Social Support and Leadership Variables and Subjective Well-being Measures

Correlations	Job Satisfaction	Positive Affect	Subjective Psychological Well being	Life Satisfaction	Negative Affect	Emotional Exhaustion	Stress	Depression
Social support at work	0.24			0.14				
Coworker support	.40 (corrected)					-0.23		
Emotional support	0.34							
Instrumental support	0.24							
Supervisor support	0.42					-0.28		
Leadership								
Consideration	0.4		0.28		-.20 to -.21			
Initiating Structure	0.19				-.09 to -.17			
Transformational leadership	.58 (corrected)		0.27		-.16 to -.18			
Transactional leadership	.64 (corrected)							
Laissez-faire leadership	-0.28							
Leader-member exchange quality	0.42		0.39		-.25 to -.27			

Note. All correlation coefficients presented are uncorrected for unreliability and at the individual level, unless noted otherwise.

In summary, supportive and task-oriented leader behaviors, inspirational leadership processes, and high quality trusting and respectful relationships between leaders and subordinates are relatively strong contributors to job satisfaction and should in turn relate to life satisfaction and general affect. As with the work itself, we lack cumulative evidence about the direct relationships between leaders and SWB, including life satisfaction and general life affect, but an effect can likely be inferred via the sizeable observed relationships with job satisfaction and work-related affective states. Individual longitudinal studies also suggest that social support and LMX predict future SWB after controlling for baseline levels.

The Work Context- Fairness, Civility, and Mistreatment

Some of the most powerful emotional experiences at work involve situations in which workers are mistreated in some way. This mistreatment could be in the form of unfair policies, procedures, or pay; rude, uncivil, or aggressive interactions with customers, coworkers, or supervisors; or even abusive supervision. Because these experiences are so affectively charged, they have been studied more extensively at the event level and as predictors of affective well-being, although there is also a substantial body of research linking these factors to job satisfaction.

Fairness has received a large amount of empirical attention as a predictor of worker satisfaction and affect. This work has most commonly drawn from theory on organizational justice, which has a variety of historical and scholarly origins (Rupp, Shapiro, Folger, Skarliki, & Shao, 2017). Although debates about the structure of organizational justice remain, there has been general convergence on at least three dimensions of justice in organizations, namely *distributive* justice, *procedural* justice, and *interactional* justice.

Distributive justice refers to the fairness of pay and other valued outcomes, and is heavily influenced by principles of equity (Adams, 1965), which suggest that rewards should be distributed in a manner proportionate to one's value. Procedural justice refers to fairness of the procedures by which decisions in the organization are made. Procedural justice incorporates factors such as the control that workers have over decision-making processes, the consistency, lack of bias, and ethics in decision-making processes, and the opportunity to correct inappropriate decisions (Leventhal, 1980; Thibaut & Walker, 1975). Interactional justice refers to the disclosure of information and explanations to workers about decision-making processes as well as the treatment of employees with respect and dignity (Bies & Moag, 1986). Interactional justice has also been empirically differentiated into *informational* justice, which refers to the sharing of information, and *interpersonal* justice, which refers to treatment with respect and dignity (Colquitt, 2001).

Distributive (r = .39 to .46), procedural (r = .40 to .51), and interactional (r = .44) justice have all been found to be strong correlates of job satisfaction (Cohen-Charash & Spector, 2001; Colquitt, Conlon, Wesson, Porter, & Ng, 2001). Regarding affect, recent meta-analyses have found correlations of procedural, distributive, interpersonal, and informational justice with positive affect of .39, .34, .29, and .32, respectively, and correlations with negative affect of -.30, -.32, -.27, and -.23, respectively (Colquitt et al., 2013). Other meta-analyses found similar relationships between perceived unfairness and stress (r = .27), burnout (r = .30), and negative affective states (r = .31) (Robbins, Ford, & Tetrick, 2012). Still, individual longitudinal studies on the effects of fairness on subsequent changes in SWB have resulted in mixed findings. In one study, low SWB (depressive symptoms) predicted subsequent reductions in fairness perceptions, but fairness did not predict subsequent changes in SWB (Lang, Bliese, Lang, & Adler, 2011). However, two other studies (Elovainio et al., 2015; Ybema & van den Bos, 2010) found the opposite, with perceived fairness having stronger effects on subsequent changes in SWB.

Interpersonal mistreatment from others at work has also been studied as a predictor of SWB. This research can generally be divided into three broad and related constructs: workplace aggression, incivility, and harassment (sexual or otherwise), although there is still some debate about this structure (Hershcovis & Barling, 2010). Aggression refers to intentional efforts by individuals in organizations to harm others in the organization (Neuman & Baron, 1998). Aggression from supervisors is a stronger predictor of job satisfaction (r = -.32) than is coworker aggression (r = -.20) (Hershcovis & Barling, 2010), although both are predictive. Supervisor and coworker aggression also predict distress (r = -.28 and -.21, respectively) and depression (r = .24 and .18, respectively) (Herscovis & Barling, 2010). Workplace incivility refers to behavior that is disrespectful but unclear in its intent (Anderson & Pearson, 1999; Cortina, Magley, Williams, & Langhout, 2001). There has not been a meta-analysis of cumulative findings on incivility and SWB, but coworker antagonism, which combines incivility and aggression, shows effects similar to those for aggression (r = -.23) (Chiaburu & Harrison, 2008). Destructive leadership, which encompasses a variety of related constructs involving leader behavior that is harmful to followers such as abusive supervision, social undermining, and petty tyranny, is negatively related to follower job satisfaction (r = -.34) and is also related to positive affect (r = -.09), negative affect (r = .34), stress (r = .24), and overall well-being (r = -.35) (Schyns & Schilling, 2013). Other reviews have found that workplace harassment, which has been defined as rather similar to workplace aggression and refers to interpersonal behavior that intentionally harms another at work, is related to job satisfaction (r = -.32), life satisfaction (r = -.18), anxiety (r = .25), depression (r = .28), positive emotions (r = -.21), and negative emotions (r = .38) (Bowling & Beehr, 2006), while sexual aggression has been found to also predict lower job satisfaction (r = -.32). Research has suggested that some types of civility training can improve job satisfaction and reduce burnout (Leiter, Laschinger, Day, & Gilin-Oore, 2011), but longitudinal research on interpersonal mistreatment and SWB has been relatively uncommon (Cole, Shipp, & Taylor, 2016).

Table 3

Summary of Meta-Analytic Correlations between Fairness and Mistreatment Variables and Subjective Well-being Measures

Correlations	Job Satisfaction	Positive Affect	Subjective Psychological Well being	Life Satisfaction	Negative Affect	Emotional Exhaustion	Stress	Depression
Distributive justice	.39 to .46	0.34			-0.32			
Procedural justice	.40 to .51	0.39			-0.3			
Interactional justice	0.44							
Interpersonal justice		0.29			-0.27			
Informational justice		0.32			-0.23			
Perceived unfairness					0.31		0.27	
Supervisor aggression	-0.32							0.24
Coworker aggression	-0.2							0.18
Coworker antagonism (incivility and aggression)			-0.23					
Destructive leadership	-0.34	-0.09	-0.35		0.34		0.24	
Workplace harassment	-0.32	-0.21		-0.18	0.38			0.28
Sexual aggression	-0.32							

Note. All correlation coefficients presented are uncorrected and at the individual level, unless noted otherwise.

In summary, experiences by workers that violate norms of fairness, respect, and the avoidance of harm tend to trigger dissatisfaction and negative emotions, and thus represent a significant contributor to SWB when they occur. These experiences can include unfair pay and procedures as well as various forms of interpersonal mistreatment. Still, longitudinal research in this area has been relatively uncommon and has yielded some mixed findings on the temporal precedence of mistreatment and SWB.

The Work Context- The Organization

Some work experiences are driven by policies, procedures, and practices that originate at the organizational level. These include more formal human resource (HR) policies, practices, and procedures, as well as those that are more informal in the organization. These policies, practices, and procedures give rise to employee perceptions about the organization's climate and priorities. Furthermore, experiences that are attributed to the organization at large influence attitudes and beliefs about the organization that also predict well-being.

Human resources practices that are relevant for employee SWB include training adequacy, compensation level, grievance processes, performance appraisal systems, reward and incentive systems, participation in decision-making, employment security, and the sharing of information with employees (Combs, Liu, Hall, & Ketchen, 2006). These practices influence the extent to which workers have the knowledge, skill, ability, and motivation to perform their work at a high level (Combs et al., 2006), and have been found to correlate with indicators of SWB at the collective level (r = .25 to .33 with a combination of motivation, commitment, and job satisfaction) (Jiang, Lepak, Hu, & Baer, 2012). Another meta-analysis found a similar relationship between HR practices and job satisfaction at the individual level (r = .27) (Kooij, Jansen, Dikkers, & de Lange, 2010), although there has been little longitudinal research on these effects. Job insecurity alone has been found to predict job satisfaction (r = -.32) and mental health (r = -.19) as well (Sverke, Hellgren, & Naswall, 2002). One study also found that job insecurity predicted increases in mental health complaints over time (Hellgren & Sverke, 2003). Family-friendly HR practices have also been studied more extensively and will be discussed later in the context of the work-family interface.

Other research has focused on organizational or group climate, which refers to shared perceptions of the organization's (or group's) policies, practices, and priorities (Schneider, Ehrhart, & Macey, 2013). These perceptions can emerge as a function of HR practices, shared experiences, leader behavior, and interactions among workers (Gonzalez-Roma, Peiro, & Tordera, 2002; Rogg, Schmidt, Shull, & Schmitt, 2001; Zohar, 2000). Organizational climates usually have a referent such that organizations have a climate "for" something. Some referents are broad (e.g., social relations, empowerment) while others are more specific (e.g., safety, customer service, mistreatment, justice). Organizational or group climate variables can be operationalized at the collective level by taking the average of individual perceptions, or at the individual level by using each worker's individual ratings as a predictor or outcome. The latter of these is sometimes referred to as psychological climate because it technically is not an organizational-level variable. Accordingly, climate can be studied as a predictor and determinant of SWB at the individual or collective level, dependent on the study's level of analysis.

Research has found that climate for broad factors such as positive social relationships, involvement

in employees in organizational processes, employee development and autonomy, rewards, and freedom from organizational formality and constraints correlate strongly with job satisfaction (r = .33 to .46), but not as strongly with direct indicators of well-being (r = .07 to .17) (Carr, Schmidt, Ford, & DeShon, 2003). More specific climate dimensions also predict indicators of SWB. Climate for civility (r = .53) and climate against mistreatment/aggression (r = .43 to .52) are strong predictors of job satisfaction (Yang & Caughlin, 2017). Climate for employee safety also predicts job satisfaction (r = .34) and general well-being (r = .30) (Clarke, 2010), while climate for customer service has been found to be a strong predictor of job satisfaction at the unit (i.e., work group) level (r = .51) (Hong, Liao, Hu, & Jiang, 2013). It should be noted that unit-level correlations tend to be stronger than those at the individual level. There has been very little longitudinal research on organizational climate and SWB from an individual or group level of analysis.

Beliefs about and toward one's employer, which theoretically are in part the result of work experiences and policies, are more proximal predictors of worker SWB. Perceived organizational support, which reflects one's descriptive belief about the extent to which the organization values employee contributions and cares about their well-being (Eisenberger, Huntington, Hutchison, & Sowa, 1986), is a strong predictor of job satisfaction (r = .57) as well as stress (r = -.38) and emotional exhaustion (r = -.42) (Kurtessis et al., 2017). Affective commitment toward the organization, which refers to an emotional attachment to one's employer, is a very strong predictor or correlate of job satisfaction as well (r = .65, corrected), and a weaker but significant predictor of stress (r = -.21) (Meyer, Stanley, Herscovitch, & Topolnytsky, 2002). By contrast, organizational cynicism is a strong negative predictor of job satisfaction (r = -.50) (Chiaburu, Peng, Oh, Banks, & Lomeli, 2013). There has been very little longitudinal research on the relationship between these variables and SWB, perhaps in part because they are often both considered outcomes of the working conditions described earlier.

Table 4

Summary of Meta-Analytic Correlations between Organization-Focused Variables and Subjective Well-being Measures

Correlations	Job Satisfaction	Positive Affect	Subjective Psychological Well-being	Life Satisfaction	Negative Affect	Emotional Exhaustion	Stress	Depression
Job insecurity	-.32							
Human resource practices	.27		.25 to .33					
Positive Organizational Climate (including positive social relationships, employee involvement, development, autonomy, freedom from formality and constraints)	.33 to .46		.07 to .17					
Climate for civility	.53							
Climate against mistreatment/aggression	.43 to .52							
Climate for employee safety	.34		.30					
Climate for customer service	.51 (unit level)							
Perceived organizational support	.57					-.42	-.38	
Affective commitment toward the organization	.65 (corrected)						-.21	
Organizational cynicism	-.50							

Note. All correlation coefficients presented are uncorrected and at the individual level, unless noted otherwise.

In summary, the perceptions of and beliefs about the organization that employees develop tend to be strong predictors of job satisfaction and in turn significant predictors of SWB. The quality of the job itself and the social context of work, which were discussed earlier, help to inform these perceptions and beliefs. Thus, beliefs and feelings about the organization represent potentially more proximal factors of job satisfaction and SWB, helping to explain the influence of more distal factors. Still, there has been very little longitudinal research on relationship between perceptions of the organization and SWB.

The Work-Family Interface

The interface between work and other areas of life, especially family, contributes to worker SWB beyond what happens at work. Work and family are to some degree mutually incompatible for many workers. The hours spent at work detract from the time workers can spend at home, and stressful work experiences can spill over and influence the quality of family life. At the same time, work can provide positive affective experiences, skills, and self-beliefs that are instrumental toward a better family life. Therefore, via the work-family interface, work can influence both job satisfaction *and* family satisfaction, thus further contributing to overall SWB.

Work-family conflict, which refers to the mutual incompatibility of work and family (Greenhaus & Beutell, 1985), has been theorized and shown to be bidirectional, with work stressors and demands making family life more difficult (i.e., work interference with family or WIF) and family stressors and demands making work life more difficult (family interference with work or FIW) (Frone, Russell, & Cooper, 1992). Role stressors from work such as workload, long hours, and stressful social situations, predict higher levels of WIF, whereas family stressors and demands such as childcare responsibilities or marital discord predict higher levels of FIW (Byron, 2005). Furthermore, support from coworkers, supervisors, and the organization predicts lower levels of WIF, while that from family members predicts lower FIW (Byron, 2005).

Work-interference with family in turn predicts lower family satisfaction (r = -.18 to -.20) and job satisfaction (r = -.25 to -.26), as does family interference with work (r = -.21 to -.22 for family satisfaction and -.11 to -.14 for job satisfaction) (Amstad, Meier, Fasel, Elfering, & Semmer, 2011; Ford, Heinen, & Langkamer, 2007; Shockley & Singla, 2011). Furthermore, WIF and FIW predict life satisfaction, with the effects of WIF (r = -.30) stronger than those of FIW (r = -.20) (Michel et al., 2009). Work-family conflict also predicts the affective components of SWB, including psychological strain (r = .35 for WIF and .21 for FIW), depression (r = .23 for WIF and .22 for FIW), stress (r = .54 for WIF and .39 for FIW), and anxiety (r = .14 for WIF and .19 for FIW) (Amstad et al., 2011). Interestingly, WIF has been shown to predict life satisfaction independent of its relationships with job and family satisfaction (Michel et al., 2009), suggesting the work-family interface predicts overall SWB beyond satisfaction with specific life domains. Individual analyses have also found work-family conflict to predict life satisfaction over a 9-year period after controlling for baseline life satisfaction, with these effects mediated by job and marital satisfaction (Cho & Tay, 2016).

The positive spillover among work and family, often labeled as work-family enrichment (Greenhaus & Powell, 2006), is also bidirectional. Theory on the work-family interface suggests that skills, knowledge, self-beliefs, social capital, and material resources gained from each life domain benefit other life domains, giving rise to work-family and family-work *enrichment* (Greenhaus & Powell, 2006). Research has shown that work-to-family enrichment predicts higher job satisfaction (r = .27 to .37), family satisfaction (r = .11 to .18), and overall life satisfaction (r = .26), while family-to-work enrichment also has significant effects on job satisfaction (r = .16 to .22) and family satisfaction (r = .31 to .34) (McNall, Nicklin, & Masuda, 2010; Shockley & Singla, 2011). In the longitudinal study cited earlier (Cho & Tay, 2016), family-to-work enrichment was also found to predict life satisfaction 9 years later after controlling for baseline levels.

Given the apparent importance of the work-family interface, results have accumulated from studies on supportive work-family policies in organizations. Such policies include flexible work arrangements, dependent care assistance, and family-supportive supervision and organizational climates. It has been found that flexible work arrangements (e.g., flextime, telework availability) are only modestly related to lower work interference with family (r = -.11) and unrelated to family interference with work (r = -.03) (Allen, Johnson, Kiburz, & Shockley, 2013). Work-family policy availability is also significantly, but modestly, related to job satisfaction (r = .13) (Butts, Casper, & Yang, 2013). The extent to which the organization is perceived to support one's family life is a stronger predictor of job satisfaction (r = .36) (Butts et al., 2013). This perceived organizational support for family life reflects the informal policies and norms that signal whether people and the organization care about one's life at home.

In summary, workers' perceptions of the work-family interface predict job satisfaction and family satisfaction. The effects of work-family interface variables on job satisfaction tend to be weaker than the effects of variables within the work domain covered earlier. However, perceptions of the work-family interface appear to be stronger predictors of life satisfaction than those work domain-specific variables discussed earlier. Research also suggests that perceptions of informal organizational support from the organization are stronger predictors of job satisfaction than are the availability of formal family-friendly policies, although both do contribute to higher job satisfaction. On the whole, these findings indicate that the extent to which work fits with family life seems to be uniquely important for SWB among workers.

Unanswered Questions and Emerging

Research Findings in Work and SWB

Beyond the content covered thus far, there are some notable areas of recent growth in empirically-based knowledge about work, the work-family interface, and SWB. Furthermore, there remain some important unanswered questions that have been addressed to some degree in individual studies but for which cumulative, robust knowledge is not currently established. Here we summarize some of these areas with new and emerging questions and findings relevant to work and SWB.

Causal Inferences and Multilevel, Dynamic Perspectives on the Work-SWB Relationship

Aside from references to a few individual longitudinal studies, most of the correlations described thus far in this chapter are based on studies that report correlations between self-reported working conditions and experiences and subjective well-being, with all variables measured at the same time. This of course raises questions about the extent to which actual working conditions cause levels of subjective well-being. It could also be that a) subjective well-being causes the perceived working conditions, and/or b) a third variable such as affect at the time of the survey influences responses to all questions, thus resulting in misleading or artifactual correlations.

While it is not possible to randomize people across working conditions, one approach to address the order of causality among work and SWB is to conduct longitudinal studies that assess the extent to which work variables predict SWB over time. Cumulative knowledge on these effects is still emerging, although two meta-analyses have addressed aspects of this issue. One review (Ford et al., 2014) examined the relationships between work stressors and psychological strain (e.g., exhaustion/fatigue, anxiety, depression, distress) in which work stressors and psychological strain were measured at one point in time and psychological strain was measured again at a later point in time. Controlling for time 1 levels of psychological strain, the average standardized effect of stressors at time 1 predicting strains at a later point in time, or the "cross-lagged effect", ranged from .05 to .08, with the strongest effects for lags of 2-3 years and weaker effects for longer or shorter lags. The reciprocal or "reverse causation" effects ranged from .03 to .09, with stronger effects for longer time lags. A similar review of studies on work-family conflict and strain (Nohe, Meier, Sonntag, & Michel, 2015) found that the average lagged effect of work interference with family on psychological strain was .08, whereas the average lagged effect of family interference with work on psychological strain was .03.

The weakness with this approach to assessing causal effects is that it only assesses effects of work on SWB that a) have not yet occurred, and b) have a delayed onset. If an individual has a job that they perceive as autonomous or a supervisor that they perceive as fair, this may have an immediate influence on satisfaction and affective well-being. Lagged effects only capture the effects on well-being beyond this immediate concurrent effect. Unfortunately, theoretical and empirical approaches to work and SWB are not well established to account for the *development* of SWB as a function of work. As we know from other research, SWB has considerable stability over time, suggesting individual personality variables and dispositions explain some of SWB and could also contribute to spurious correlations with perceived work characteristics. Random intercept cross-lagged models may help to address this issue (Hamaker, Kuiper, & Grasman, 2015).

Research on stability in SWB should also take into account that work situations have stability as well, and so the stability in SWB may in part have a situational explanation. Furthermore, individuals may adapt to unfavorable work situations such that their SWB improves after initial exposure and stabilizes. Is the observed stability in SWB a function of individuals adapting to their work situations, underlying personality or dispositions, or the fact that work situations often do not change much over time? The answers to this question in the work domain are currently not clear. Recent research has begun to incorporate latent change score models to account for reciprocal effects among work and SWB that also incorporate adaptation (Ritter, Matthews, Ford, & Henderson, 2016), but this is an area that needs further empirical and theoretical development.

Relatedly, most of the research findings that have accumulated over the years have addressed correlations between *chronic* work situations and SWB. Many individual studies in recent years have investigated daily events and the extent to which these correlate with changes in affect or job satisfaction. While no published research to date has quantitatively synthesized these findings, a recent and currently unpublished meta-analysis (Pindek, Arvan, & Spector, 2017) analyzed correlations from diary studies that differentiated between- and within-person effects. Between-person correlations are those that are based on the *mean* of daily reports of stressors (e.g, demands, conflict) and the *mean* of daily reports of psychological strain (usually an indicator of affective well-being). Within-person correlations are those based on daily deviations from each person's mean on each variable being correlated. Results suggest that between-person correlations (r = .29) are stronger than within person correlations (r = .23), although not dramatically so; interestingly, this analysis found that within-person effects on affect were stronger than

those on other indicators of strain, which included work attitudes. These results suggest that within-person daily experiences have a stronger influence on daily variations in affective SWB than on daily variation in job or life satisfaction, which if true would be consistent with Affect Events Theory as discussed earlier (Weiss & Cropanzano, 1996).

Daily work experiences also likely give rise to chronic perceptions of the work situation, in turn influencing chronic levels of job satisfaction and SWB. The time course and contingencies on which this process occurs are currently unknown. For example, do repeated daily experiences of an abusive supervisor cause a lasting perception of that supervisor? Does this perception and/or any effect on SWB go away after the stressor is removed, or is there some semi-permanent effect? Answers to these questions are needed in order to determine when and why SWB may or may not change as a function of changes in work experiences.

A final issue that falls within this general domain of causal inferences is the use of self-reported measures of working conditions and experiences. The use of self-reported measures raises questions about the extent to which self-reports of the work situation are biased by SWB, thus inflating observed correlations. Alternatives to self-reported working conditions or questionnaires have limitations as well, but they do exist. For example, the Occupational Information Network (O*NET) (Peterson et al., 2001) includes publicly available ratings on a variety of important dimensions related to SWB, including job autonomy, several types of job demands, and occupational values. Other methods are available to analyze jobs that deviate from traditional survey instruments. Examples of alternative methods include the collection of task statements in which people describe what they do at work, observations that allow observers to rate jobs on relevant dimensions, interviews with workers to build deeper knowledge about the context and processes involved in SWB at work, and critical incident questionnaires in which people describe in their own words situations and events that influenced their SWB. These alternative approaches have promise to advance our knowledge of how work influences SWB.

Work-Family Boundary Characteristics and Recovery

A burgeoning area of interest among researchers studying employee well-being involves the boundaries that individuals maintain, or fail to maintain, between work and nonwork. Also of interest in this work is what individuals do with their off-work time. Technological changes that have blurred traditional work-nonwork boundaries along with the work intensification that has been driven by competition and globalization have likely inspired much of this research. Two important sets of variables in this domain are a) work-family role integration, and b) recovery and leisure experiences.

Work-family role integration is the extent to which people construe aspects of their work and family life as part of the same domain or of separate life spheres (Allen, Cho, & Meier, 2014). Work-family boundaries refer to factors such as time and place that limit a person to a particular role, whether it be one's work or family role. Boundaries can vary in their permeability and flexibility, which influence the extent to which a worker might have to switch life roles from work to family or family to work without crossing a temporal or physical boundary (Ashforth, Kreiner, & Fugate, 2000). There have been a number of individual studies on work-family role integration and boundary characteristics and these have produced some notable results. First, role integration and permeable boundaries tend to be associated with more work-family conflict (Kossek, Ruderman, Braddy, & Hannum, 2012). Furthermore, integrated roles tend to increase the relationship between work-related mental states (e.g. thoughts and emotions) and those experienced outside of work (Ilies, Wilson, & Wagner, 2009). Thus, permeable work-nonwork boundaries and highly integrated work and family roles should increase the *similarity* in satisfaction specific to these domains, for better or worse. So, for example, someone with highly integrated work and family roles and that has high (low) job satisfaction will be more likely to have high (low) family satisfaction than would someone with more segmented roles. Furthermore, research suggests there are meaningful individual differences in preference for work-family role integration, and that people often take action to manage these boundaries to their liking (Kossek & Lautsch, 2012).

Recent years have also spurred an interest in telecommuting (i.e., working from home at least some of the time), which has been found to have mixed associations with factors relevant for SWB. For instance, telecommuting has been found to be associated with less work interference with family but more family interference with work (Golden, Veiga, & Simsek, 2006). People who telecommute tend to have slightly higher job satisfaction (r = .09) and lower role stress (r = -.11) than those who do not, but these bivariate relationships are relatively weak (Gajendran & Harrison, 2007). Other work suggests that this relationship is curvilinear such that small-to-moderate amounts of telecommuting, up to 15 hours per week, are associated with higher job satisfaction, but telecommuting beyond this length of time has little benefit for SWB, perhaps because of the professional isolation that ensues among high-intensity telecommuters (Allen, Golden, & Shockley, 2015).

An additional related factor that has received considerable attention in recent years as a determinant of well-being is *recovery* from work. There is considerable variance in what people do during their time away from work, and this contributes to how satisfied people are with their work and family life as well as how they feel and think about their life overall. Important off-work recovery experiences include relaxation, psychological detachment from work, and off-job mastery experiences such as exercising or performing challenging mental tasks (Sonnentag, Binnewies, & Mojza, 2008). Although no quantitative meta-analysis has been published on these recovery experiences, a sizeable literature has developed suggesting that psychological detachment from work during off-work time (e.g., not thinking about work) is associated with lower levels of stress and fatigue and higher levels of life satisfaction, whereas relationships with positive emotions and affect are less consistent (Sonnentag & Fritz, 2015). These effects have generally held up in cross-sectional, longitudinal, and diary or experience sampling studies. A related area of study looks at leisure engagement, which captures some of these same recovery experiences. A recent meta-analysis suggests that engagement in leisure activities is related to life satisfaction (r = .22) and positive affect (r = .29), and less so to negative affect (r = -.10), with significant longitudinal effects on SWB as well (Kuykendall, Tay, & Ng, 2015). More recently, the concept of *telepressure*, or a felt obligation to respond to work-related interruptions while at home, has also emerged. Telepressure is an impediment to detachment from work and may have an additive effect on SWB (Barber & Santuzzi, 2015).

Table 5

Summary of Meta-Analytic Correlations between Work-family Variables and Subjective Well-being Measure

Correlations	Job Satisfaction	Positive Affect	Subjective Psychological Well-being	Life Satisfaction	Negative Affect	Emotional Exhaustion	Stress	Depression
Work-interference with family (WIF)	-.25 to -.26			-.30			.54	.23
Family-interference with work (FIW)	-.11 to -.14			-.20			.39	.22
Work-family enrichment	.27 to .37			.26				
Family-work enrichment	.16 to .22							
Supportive work-family policies availability	.13							
Perceived organizational support for family life	.36							

Note. All correlation coefficients presented are uncorrected and at the individual level, unless noted otherwise.

In summary, there is a growing body of literature suggesting that boundaries, work-family role integration, and recovery experiences outside of work have potential for additive effects on SWB beyond the work-domain factors discussed earlier, and may in some instances moderate the relationship between work-domain stressors and SWB by influencing the opportunity to recover from work. With the continuing pressure for workers to be available and flexible, we can expect more cumulative findings and questions on the implications of work-nonwork boundaries and recovery activities for SWB to emerge in the coming years.

A Global Perspective

As in many research areas of psychology and organizational behavior, the vast majority of the research on work and SWB has been conducted in traditionally Western settings and in relatively wealthy economies such as the U.S., Canada, Western Europe, and Australia. This raises questions as to whether the observed effects generalize across the world, particularly to workers in developing economies and more traditionally non-Western cultures. There have been a number of review papers describing theoretical frameworks and models for comparing the effects of work on SWB across nations and cultural settings (e.g., Powell, Francesco, & Ling, 2009), but individual studies and empirical evidence have been relatively sporadic, perhaps because of the practical difficulties in conducting and publishing cross-cultural research. Thus, cumulative evidence is still emerging. Nonetheless, there have been some meta-analyses that have included cross-national comparisons, and we report on some of these here.

In a few instances, empirical results from meta-analyses have suggested differential effects of

work-related factors on SWB across national settings. For example, in one analysis, the relationship between perceived unfairness and worker distress was found to be stronger in the U.S. (r = .36) than outside of the U.S. (r = .25) (Robbins et al., 2012). A narrative review of the cross-cultural work-family conflict literature found some individual studies that hypothesized a stronger relationship between work-family conflict and attitudinal work outcomes in individualist than in collectivist countries (Shockley, Douek, Smith, Yu, Dumani, & French, 2017), but it is not clear if these differences are large or reliable. Individuals from collectivist nations have also been found to report higher levels of family interference with work (Allen, French, Dumani, & Shockley, 2015). And organizational identification has been found to be a better predictor of job satisfaction in collectivist than in individualist countries (Lee, Park, & Koo, 2015).

Some relationships have been found to be similar across national or cultural settings. In one analysis, the quality of the leader-member (subordinate) exchange relationship was found to be similarly associated with job satisfaction in individualist (r = .46) and collectivist (r = .42) countries (Rockstuhl, Dulebohn, Ang, & Shore, 2012). An analysis of mean differences across studies found no mean differences in work interference with family between individualist and collectivist nations (Allen et al., 2015). Abusive supervision was also found to have similar relationships with job satisfaction, job tension, emotional exhaustion, and depression within and outside of the U.S. (Mackey, Frieder, Brees, & Martinko, 2017). Furthermore, work interference with nonwork had similar relations with emotional exhaustion and other burnout symptoms across regions of the world (Reichl, Leiter, & Spinath, 2014).

Despite this sampling of findings, questions remain about robust differences or similarities across the world in the direct relationships between work-related variables and SWB. Several individual multi-national studies have compared effects of work-related variables on SWB across nations and cultures. Furthermore, a large number of studies in the past 15 years have been conducted outside of traditionally Western or developed countries and could be assembled and compared in future meta-analyses across a number of cultural and economic variables at the national or regional level. Constructs that are indigenous to different parts of the world might shed light on new predictors of SWB as well. Thus, there is further work to be done on the work-SWB relationship from a global perspective.

Precarious Employment and Unemployment

Changes in employment arrangements, job insecurity, and unemployment rates in recent years have also generated increased interest in the implications of these arrangements for well-being. In particular, there has been considerable growth in part-time, nontraditional, temporary and/or contingent work with low levels of job security. Such work arrangements offer employers flexibility but result in jobs that are not permanent and often do not offer the benefits of more traditional permanent employment. Some have labeled this type of nontraditional or contingent work *precarious employment* and have identified it as a social determinant of health (Benach et al., 2014).

There has been some meta-analytic work relevant to precarious employment as it relates to SWB. As noted earlier in our discussion of human resource practices, job insecurity is a significant predictor of job satisfaction and mental health (Sverke et al., 2002). Beyond the effects of job insecurity, unemployed workers also have significantly poorer mental health (d = .52), life satisfaction (d = .44), and family satisfaction (d = .20) than do employed workers (McKee-Ryan, Song, Wanberg, & Kinicki, 2005). Reemployment among workers who were previously unemployed has been shown to substantially improve mental health (d = .82) and life satisfaction (d = 2.79), while job loss has the reverse effect on mental health, although the size of the effect is not as strong (d = .35) (McKee-Ryan et al., 2005). It has even been found that unemployment *rates* are negatively related to job and life satisfaction (Tay & Harter, 2013). Contingent workers (e.g., contractors, temporary workers, direct-hire workers) also tend to report lower job satisfaction than permanent workers (d = .21), although this difference is primarily found for temporary workers (d = .37), whereas the satisfaction deficit for contractors or direct hires has been found to be much smaller or nil (Wilkin, 2013). Perhaps surprisingly, little difference has been found in job satisfaction between part- and full-time workers (Thorsteinson, 2003), although this may be in part because many part-time workers choose such an arrangement.

As precarious employment arrangements continue to be increasingly prevalent, more work will be needed on the implications for subjective well-being over time. Some of this work can likely be informed by related research on the relationship between income and SWB, but precarious employment goes beyond income in its influence on security, benefits, control, and power over one's work and life situation, rendering it a potentially important variable in social gradient approaches to health and well-being.

Conclusion

In this review, we provided information about the structure of empirical models linking work to SWB, well-established research findings on the relationship between work and SWB, and findings from more recently emerging areas of scholarly and societal concern. Together these results show that work-

related variables, particularly the work people do, their interactions with others, the perceptions they form about their employers, and the work-family interface contribute significantly to SWB. The effects of work on SWB are likely primarily through job satisfaction and affective states experienced at work, but may also occur via spillover to family life. Still, more work is needed on causal relationships and dynamics among work and SWB, the relationship between SWB and precarious work over time, and SWB among workers from a more global perspective than has traditionally been taken in the literature. As the science of SWB moves forward, a consideration of work and the work-family interface will continue to inform our understanding of the situational factors that contribute to SWB among workers and their families throughout the world.
